APPLIED CHEMISTRY

VOL. I.

A DICTIONARY

OF

APPLIED CHEMISTRY

BY

SIR EDWARD THORPE, C.B., LL.D., F.R.S.

EMERITUS PROFESSOR OF GENERAL CHEMISTRY AND DIRECTOR OF THE CHEMICAL LABORATORIES
OF THE IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY, SOUTH KENSINGTON, LONDON;
LATE PRINCIPAL OF THE GOVERNMENT LABORATORY, AND A PAST PRESIDENT OF
THE CHEMICAL SOCIETY AND OF THE SOCIETY OF CHEMICAL INDUSTRY

ASSISTED BY EMINENT CONTRIBUTORS

VOL. I.

REVISED AND ENLARGED EDITION

WITH ILLUSTRATIONS

LONGMANS, GREEN, AND CO.
39 PATERNOSTER ROW, LONDON
FOURTH AVENUE & 30TH STREET, NEW YORK
BOMBAY, CALCUTTA, AND MADRAS

PREFACE

THE publication of the present edition of this work has been delayed by circumstances arising out of the Great War. Some of those who contributed to previous editions were actively engaged as combatants; others were employed in munition work or in industries closely associated with such work, and consequently were unable to find time or opportunity to revise their articles until the conclusion of hostilities. Some valued contributors were no longer with us, and it was necessary to make fresh arrangements in regard to new writers. Provision also had to be made for additional articles necessitated by the development of chemical industry since the date of the previous edition. From the fact that practically the whole chemical energies of the country were concentrated on the prosecution of the war it was impossible to make rapid progress with the revision of a work of this magnitude.

It has become a truism to say that Applied Chemistry has exercised a profound influence on the character and direction of the war. It is equally true that the war has exercised a great influence on Applied Chemistry. It has led to an enormous expansion, more or less permanent, of certain branches, both in this country and abroad. New products have been made, new processes have been devised, and established methods have been improved and extended. In spite of the economic and other evils which have followed in its train, there can be no doubt that the war will be found to have permanently affected for good the progress of manufacturing chemistry in this country, and indeed in all English-speaking countries. Whilst the disturbance and strain of the past half-dozen years have seriously affected the development of pure science and the output of chemical research, Applied Chemistry has been quickened in certain directions. The financial and industrial collapse which has overthrown our late enemies will, it may be presumed, tend still further to accelerate the expansion of our own chemical manufactures. Germany, for the present at all events, no longer holds the supreme position in certain branches in chemical industry that she enjoyed prior to 1914, and it may be doubted whether, under her altered social and economic conditions, she will ever recover it.

It is too soon to be in a position to chronicle all the results, as regards chemical manufacture, which have arisen from the intensive application of chemists during the past strenuous years. Much is of a character that in the present disturbed state of the world it would be inexpedient to make public. On certain matters, indeed, no authoritative information can be obtained. This will explain why manufacturing details of several new processes in connection with munitions have not been given.

The entire work has been carefully revised, and so much new matter included that it has been found necessary to enlarge it, and six volumes will certainly be needed, and it is possible that a seventh will be required. It is to be hoped that in its present form the book may still be considered as a reasonably adequate presentation of the state of contemporary knowledge concerning the applications of Chemical Science.

A list of the contributors, with the titles of their articles, is prefixed to the several volumes. Their names and standing are a sufficient guarantee that, as in previous editions, every effort has been made to make the Dictionary a faithful record of the present relations of chemistry to the arts and sciences.

ABBREVIATIONS

OF THE TITLES OF JOURNALS AND BOOKS.

Amer. Chem. J.	American Chemical Journal.
Amer. J. Pharm.	American Journal of Pharmacy.
Amer. J. Sci.	American Journal of Science.
Anal. Fis. Quim.	Anales de la Sociedad Española Fisica y Quimica.
Analyst	The Analyst.
Annalen	Annalen der Chemie (Justus Liebig).
Ann. Chim. anal.	Annales de Chimie analytique appliquée à l'Industrie, à l'Agriculture, à la Pharmacie et à la Biologie.
Ann. Chim.	Annales de Chimie.
Ann. Falsif.	Annales des Falsifications.
Ann. Inst. Pasteur.	Annales de l'Institut Pasteur.
Ann. Physik.	Annalen der Physik.
Ann. Physique	Annales de Physique.
Annali Chim. Appl.	Annali di Chimica Applicata.
Apoth. Zeit.	Apotheker-Zeitung.
Arch. Pharm.	Archiv der Pharmazie.
Atti R. Accad. Lincei	Atti della Reale Accademia dei Lincei.
Bentl. a. Trim.	Bentley and Trimen. Medicinal Plants.
Ber.	Berichte der Deutschen chemischen Gesellschaft.
Ber. Deut. pharm. Ges.	Berichte der Deutschen pharmazeutischen Gesellschaft.
Bied. Zentr.	Biedermann's Zentralblatt fur Agrikulturchemie und rationellen Landwirtschafts-Betrieb.
Bio-Chem. J.	The Bio-Chemical Journal.
Biochem. Zeitsch	Biochemische Zeitschrift.
Brewers J.	Brewer's Journal.
Bull. Imp. Inst.	Bulletin of the Imperial Institute.
Bull. Soc. chim.	Bulletin de la Société chimique de France.
Chem. Ind.	Chemische Industrie.
Chem. News	Chemical News.
Chem. Soc. Proc.	Journal of the Chemical Society of London. Proceedings.
Chem. Soc. Trans.	Journal of the Chemical Society of London. Transactions.
Chem. Weekblad	Chemisch Weekblad.
Chem. Zeit.	Chemiker Zeitung.
Chem. Zentr.	Chemisches Zentralblatt.
Compt. rend.	Comptes rendus hebdomadaires des Séances de l'Académie des Sciences.
Dingl. poly. J.	Dingler's polytechnisches Journal.

LIST OF CONTRIBUTORS
TO VOLUME I.

Dr. E. F. ARMSTRONG, F.I.C., F.R.S. (*Messrs. J. Crosfield & Sons, Ltd., Warrington*). [Amylans; Bread.]

Dr. G. H. BAILEY (*The British Aluminium Company, Kinlochleven, N.B.*). [Aluminium, Alums, and Aluminium Compounds.]

C. O. BANNISTER, Esq., F.I.C., A.R.S.M. (*Messrs. Edward Riley & Harbord*). [Antimony; Bismuth (Metallurgy of).]

Dr. GEORGE BARGER, M.A., F.R.S., *Professor of Chemistry in relation to Medicine in the University of Edinburgh.* [Aconitine and the Aconite Alkaloids; Adrenaline; Aloes; Areca Nut; Aristolochine; Betaines; Broom Tops.]

Dr. G. BARGER, M.A., F.R.S., and Dr. F. L. PYMAN. [Alkaloids.]

G. S. BLAKE, Esq., A.R.S.M., B.Sc., M.I.M.M. [Barium; Calcium.]

J. S. S. BRAME, Esq., F.I.C., *Professor of Chemistry, Royal Naval College, Greenwich, S.E.* [Acetylene, Commercial Applications of; Boiler Incrustations and Deposits.]

JOHN F. BRIGGS, Esq. (*British Cellulose Co., Derby*). [Acetic Anhydride.]

HAROLD BROWN, Esq., *The Imperial Institute, London.* [Balata.]

Dr. J. C. CAIN, *Editor of the Journal of the Chemical Society, London.* [Aniline; Aniline Salt; Azo-Colouring Matters; Benzene and its Homologues.]

W. H. COLEMAN, Esq. [Carbolic Acid.]

Dr. HAROLD G. COLMAN, F.I.C., *Formerly Chief Chemist to the Birmingham Corporation Gas Dept.* [Ammonia.]

JAMES CONNAH, Esq., B.A., B.Sc., F.I.C., *Deputy Principal, The Government Laboratory, London.* [Absinth; Absinthin; Absinthol; Arrack; Brandy.]

Dr. W. DITTMAR, F.R.S. [Balance.]

Dr. ARTHUR E. EVEREST, F.I.C. [Anthocyanins.]

Dr. ARTHUR J. EWINS. [Caffeine and the Alkaloids of Tea, Coffee and Cocoa.]

THOMAS FAIRLEY, Esq., F.I.C. [Aspirators.]

Professor C. S. GIBSON, O.B.E., M.A.(Oxon. and Cantab.), M.Sc.(Manc.), F.I.C. [Amyl.]

Dr. W. D. HALLIBURTON, F.R.C.P., M.R.C.S., F.R.S., *Professor of Physiology, University of London.* [Bile; Blood; Bone.]

Dr. J. T. HEWITT, M.A., F.R.S., *Emeritus Professor of Chemistry, East London College, University of London.* [Acridine Dyestuffs.]

J. W. HINCHLEY, Esq., A.R.S.M., F.I.C., *Professor of Chemical Engineering, Imperial College of Science and Technology, South Kensington.* [Autoclave.]

JOHN HOLMES, Esq., F.C.S., *The Government Laboratory, London.* [Alcoholometry.]

Dr. JULIUS HUEBNER, M.Sc., F.I.C., *Director of Dyeing and Paper-making Departments, Manchester Municipal College of Technology.* [Bleaching.]

H. W. HUTCHIN, Esq. (*The Cornish Consolidated Tin Mines, Camborne*). [Arsenic.]

HERBERT INGLE, Esq., B.Sc., F.I.C., *late Chief Chemist to the Transvaal Agricultural Department.* [Aleurone Grains; Almond; Apple; Apricot; Arginine; Arrowroot; Artichoke; Ash; Asparagus; Avocado Pear; Banana; Barley; Batatas; Bean; Beet-root; Betaine; Bilberry; Blackberries; Bran; Bread Fruit; Brussels Sprouts; Buckwheat; Cabbage.]

Dr. R. LESSING, *Consulting Chemist, London.* [Bromine.]

Dr. JULIUS LEWKOWITSCH, M.A., F.C.I. (*Revised by C. A. Mitchell, Esq., B.A., F.I.C.*) [Adipocere; Anacardium Nut; Arachis Oil; Bassia Oils; Ben Oil; Bone Fat; Borneo Tallow; Brazil Nuts; Cacao Butter.]

Dr. IDA SMEDLEY MacLEAN. [Balsams.]

JOHN J. MANLEY, Esq., M.A., *Magdalen College, Oxford.* [Balance.]

Dr. F. A. MASON, M.A.(Oxon.) (*The British Dyestuffs Corporation, Ltd.*). [Acetals; Acetylene; Aldehyde; Azines (Suppl.).]

CHARLES A. MITCHELL, Esq., B.A., F.I.C. (*Messrs. Beaufoy & Co., London*). [Acetic Acid; Acorn Oil; Aerated or Mineral Waters; Anacardium Orientale; Beechnut Oil; Behenic Acid.]

T S. Moore, Esq., M.A.(Oxon.), B.Sc.(Lond.), *Professor of Chemistry, Holloway College.* [Amines; Amino Acids.]

Dr. G. T. MORGAN, O.B.E., A.R.C.S, F.I.C., F.R.S., *Professor of Chemistry in the University of Birmingham* [Acidimetry and Alkalimetry; Analysis; Antimonials, Organic; Arsenicals, Organic.]

Professor A. G. PERKIN, F.R.S., F.I.C., *Department of Colour Chemistry in the University of Leeds.* [African Marigold; Algarrobin; Alkanet; Annatto; Archil; Asbarg; Atranorin; Barbatic Acid; Barwood; Bignonia Tecoma; Brazil Wood; Buckthorn; Butea Frondosa.]

Dr. F. MOLLWO PERKIN, F.I.C., *Consulting Chemist, London.* [Electrochemical Analysis.]

Professor W. H. PERKIN, LL.D., F.R.S., and Dr. ROBERT ROBINSON, F.I.C., F.R.S. (*of the British Dyestuffs Corporation* (*Huddersfield*), *Ltd.*), assisted by Rev. F. H. GORNALL, M.Sc. [Alizarin and Allied Colouring Matters.]

J. A. PICKARD, Esq., B.Sc., A.R.C.S., F.I.C. [Acetins; Allyl.]

Dr. F. L. PYMAN, *Professor of Technological Chemistry in the University of Manchester, and in the Manchester Municipal College of Technology.* [Bebeerine; Berberine and the Berberis Alkaloids.]

Dr. HENRY ROBINSON, M.A. [Anæsthetics.]

Sir THOMAS K. ROSE, D.Sc., F.I.C., *The Royal Mint, London.* [Assaying.]

Dr. WALTER ROSENHAIN, F.R.S., *The National Physical Laboratory, Teddington.* [Amalgam; Annealing.]

L. J. SPENCER, Esq., M.A., F.G.S., *Mineral Department, British Museum.* [Abrasives; Adamite; Aeschynite; Agalite; Agalmatolite; Agate; Alaite; Allanite; Alstonite; Alum Shale; Alunite; Alunogen; Amazon-Stone; Amber; Amblygonite; Amethyst; Ampangabeite; Anatase; Ancylite; Andalusite; Andesine; Andesite; Andorite; Anglesite; Anhydrite; Ankerite; Apatite; Aphthitalite; Aragonite; Ardennite; Argentite; Argyrodite; Asbestos; Atacamite; Autunite; Axinite; Azurite; Baddeleyite; Baeumlerite; Bakerite; Barytes; Baryto-Calcite; Basalt; Bastnasite; Bauxite; Beckelite; Bellite; Benitoite; Beryl; Berzelianite; Berzelite; Betafite; Bismite; Bismuthinite; Bismutite; Bloedite; Blomstrandine; Bloodstone; Blue Iron-Earth; Bog Iron Ore; Bole; Boracite; Borax; Bornite; Boronalrocalcite; Bostonite; Bournonite; Braunite; Brazilite; Brochantite; Broggerite; Brucite; Buhrstone; Building Stone; BuntkupferERZ; Calamine; Calaverite; Calcite.]

Dr. ARTHUR L. STERN, F.I.C. (*Messrs. Bass, Ratcliff & Gretton, Ltd., Burton-on-Trent*) [Brewing.]

GEORGE STUBBS, Esq., C.B.E., F.I.C., *The Government Laboratory, London.* [Butter.]

Dr. M A. WHITELY, O.B.E., F.I.C., A.R.C.S., *Lecturer on Organic Chemistry, Imperial College of Science and Technology, S. Kensington.* [Adenine; Alanine; Allantoin; Alloxan; Alloxantin; Arginase; Arginine; Asparagine; Aspartic Acid.]

Dr. OTTO N. WITT, *Polytechnic, Charlottenburg.* [Azines: with an Addendum by Dr. F. A. Mason.]

DICTIONARY

OF

APPLIED CHEMISTRY

AAL, A'L, ACH, AI'CH. Native names for the roots of *Morinda tinctoria* and *M. citrifolia*, employed in various parts of India, under the general trade name of Suranji, as a dyestuff, more especially for dyeing reds, purples, and chocolates.

ABACA. A species of fibre derived from *Musa textilis* (Née), obtained mainly from the Philippine Islands, and used in the manufacture of mats, cordage, &c. It is also known under other names, including 'Manilla hemp,' 'Menado hemp,' 'Cebu hemp,' 'Siam hemp,' and 'White rope.' Less valuable fibres are obtained from other species of *Musa*, such as *M. sapientum* (Linn.), the banana and plantain, which yield banana fibre and plantain fibre.

ABANONE. Trade-name for a pharmaceutical preparation of magnesium phosphotartrate.

ABIES. The generic name of the Silver Firs. *A. alba* (Mill.) [*A. pectinata* (DC.)] furnishes timber very similar to the white deal of *Picea excelsa*, the common spruce. It is the source of 'Strasburg turpentine,' containing free *abienic*, *abietric*, and *α*- and *β-abietinolic acids*, and an amorphous substance *abietoresen*, an ethereal oil of agreeable aromatic odour, a bitter principle and colouring matter (Tschirch und Weigel, Arch. Pharm. 1900, 238, 411).

A. Canadensis is the source of Canada balsam, which contains *canadic*, *canadolic*, and *α*- and *β-canadinolic acids*, an ethereal oil, *canadoresen*; and small quantities of succinic acid and a bitter substance. The acids contain no methoxyl groups and give the cholesterol reactions, including that of Tschugaeff (*l.c.* 1900, 238, 487).

ABIETENE. A hydrocarbon obtained by distilling the terebinthinate exudation of *Pinus sabiniana* (Doug.), a coniferous tree indigenous to California, and growing on the dry slopes of the foothills of the Sierra Nevada and on the hills along the coast, and known locally as the Nut pine or Digger pine. To procure the exudation, the tree during winter is notched and guttered at a convenient height from the ground, and the resin on distillation yields the liquid hydrocarbon. The crude oil was met with in San Francisco as an article of commerce under the names of 'Abietene,' 'Erasine,' 'Aurantine,' and 'Thioline,' and was used for removing grease-spots, paint-stains, &c., from clothing. It is a nearly colourless mobile liquid of powerful aromatic smell, recalling that of oil of oranges.

Abietene has been shown by Thorpe to consist almost entirely of *normal heptane*, C_7H_{16}, mixed with a small quantity of a resin to which its characteristic smell of orange oil is due (Thorpe, Chem. Soc. Trans. 35, 296; Schorlemmer and Thorpe, Phil. Trans. 174, 269; *v.* also Blasdale, J. Amer. Chem. Soc. 1901, 162).

Schorger (J. Ind. Eng. Chem. 1913, 5, 971) has shown that the volatile oil of *Pinus jeffreyi* consists of about 95 p.c. of *n*-heptane and 5 p.c. of an aldehyde, apparently citronellal.

Abietene is also the name given to the hydrocarbon which is obtained as an oil by the reduction of abietic acid (*q.v.*) (Easterfield and Bagley, Chem. Soc. Trans. 1904, 1238; Kraemer and Spilker, Ber. 1899, 2953, 3614). Its formula is $C_{18}H_{28}$, and it is probably decahydroretene, as, when carefully purified, and reduced with phosphorus and hydriodic acid, it yields a fluorescent hydrocarbon identical with the dodecahydroretene of Liebermann and Spiegel (Ber. 1889, 780).

ABIETIC ACID. An acid obtained by digesting colophony with dilute alcohol and recrystallising the product from methyl alcohol (Maly, Annalen, 129, 54; 132, 249); or by saturating an alcoholic solution of colophony with hydrogen chloride and subsequently recrystallising the product (Flückiger, J. 1867, 727; *cf.* Cohn, Chem. Zeit. 1916, 40, 791). It can also be obtained by distilling colophony under reduced pressure or with superheated steam (Easterfield and Bagley, Chem. Soc. Trans. 1904, 1238). Natural colophony is, in fact, a vitreous modification of abietic acid. It occurs in resin spirit, from which it may be obtained by extraction with ether, shaking with sodium carbonate solution and then acidifying. It is obtained in a purer condition by recrystallising from acetic acid, forms colourless triangular plates; m.p. 166°-167° (Tschirch and Wollf, Arch. Pharm. 1907, 1; 153°-154° (Mach, Monatsh. 1893, 186; 150°-152° (Ellingson, J. Amer.

Chem. Soc. 1914, 36, 325). The melting-point appears to be influenced by the manner of heating. Occurs also in Storax. $[a]_D -57·5°$. According to Easterfield and Bagley and Mach, it is a derivative of phenanthrene, and has the formula $C_{19}H_{28}O_2$, whilst Levy (Ber. 1906, 3043), Koritschoner (J. Soc. Chem. Ind 1907, 641), Fahrion (J. Soc. Chem. Ind. 1907, 264), and Vesterberg (Ber. 1907, 120) represent its composition as $C_{20}H_{30}O_2$. According to Strecker (Annalen, 150, 131), Duvernoy (Annalen, 148, 143), and Easterfield and Bagley (*l.c.*), abietic acid is identical with sylvic acid; it is not identical with pimaric acid, which yields abietic acid on distillation under reduced pressure. By distilling abietic acid under ordinary pressure, or, better, by treatment with hydriodic acid, carbon dioxide is evolved, the hydrocarbon *abietene* $C_{18}H_{28}$ being formed (E. and B. *l.c.*, Levy, *l.c.*; Kraemer and Spilker, Ber. 1899, 3614). Oxidation with nitric acid yields dinitropropane and *trans*-cyclo-hexane 1 : 2-dicarboxylic acid. Distillation with sulphur converts abietic acid into retene, $C_{18}H_{18}$ (E. and B., *l.c.*; Vesterberg, Ber. 1903, 4200). Oxidation with potassium permanganate yields an acid $C_{16}H_{16}O_3$, m.p. 123° (Mach, Monatsh. 1894, 627); and a method has been devised by Endemann (D. R. P. 183328; Chem. Zentr. 1907, i. 1607) to oxidise resinous materials, containing abietic acid, to resin acids and malonic acid.

Abietic acid is related to retene and pinene, contains a *cyclo*-hexane ring and an *iso*-propyl group, and has its carboxyl group attached to a tertiary carbon atom (Levy, Zeitsch. anorg. Chem. 1913, 81, 145).

Sodium and *potassium* abietates are prepared by direct neutralisation; the *silver* (white), *copper* (pale blue), *calcium, barium, strontium, cobalt* (lavender), *nickel* (greenish-yellow), *iron* (light brown), *zinc, chromium* (greenish-yellow), *aluminium, manganese* (pale pink), and *cadmium* salts are obtained by precipitation of solutions of salts of the respective metals by a solution of the alkaline abietate (Ellingson, *l.c.*).

It is converted by the hydrogenation method of Willstatter and Hatt into hydroabietic acid $C_{19}H_{32}O_2$, m.p. 176°–179°, $[\alpha]_D^{16} -16·85°$, identical with the acid obtained by Maly by reduction with sodium amalgam and alcohol. For the optical isomerism of the abietic acids, *see* Schulz, Chem. Zeit. 1917, 41, 666.

Detection and Estimation.—The following colour reactions may be used for detecting abietic acid:—(1) 3 vols. of conc. hydrochloric acid and 1 vol. of ferric chloride sol. give a violet red colouration; (2) sulphuric acid dissolves abietic acid to a red solution; (3) when heated with dry chloroform, acetic anhydride and sulphuric acid, a purple red colour is produced changing through violet and blue to a greenish black (Mach. *l.c.*). In order to estimate abietic acid in resins, &c., 10 grms. of the substance are refluxed with 20–25 c.c. of 10 p.c. alcoholic potash for ½ hour on a water-bath; the resulting soap is decomposed with dilute hydrochloric acid, and the separated resin filtered off, washed with cold water and dried. It is then powdered and extracted with 50 c.c. of hot petroleum ether. From this solution abietic acid is precipitated by ammonia, filtered off, dried on the water-bath, and the ammonia expelled by gentle heating. The residue represents the amount of crude abietic acid in the sample (Rebs, Chem. Zentr. 1907, i. 997).

Abietic acid (or colophony) is used in assisting the growth of lactic or butyric ferments, as it favours the production of that which is present in the greater quantity and suppresses the other. It promises to be of great use in the fermentation industry in preventing infection (Effront, Compt. rend. 136, 1556), (*v.* COLOPHONY).

ABISOL. Trade name for a 40 p.c. solution of sodium bisulphite. Used as a disinfectant and preservative.

ABRASIVES. The various hard substances, chiefly of mineral origin, used for abrasive purposes fall naturally into the following groups, in which the hardness is roughly inversely proportional to the complexity of chemical composition.

Elements.—Diamond (*q.v.*) is the hardest of all substances (hardness = 10 on Mohs's scale). Inferior material of no use for gems is known as boart (or bort), and is crushed to powder and much used by lapidaries. Diamond powder is the only material with which diamond itself can be ground and polished. Embedded in the edge of a thin disc of soft iron, diamond powder is largely used for cutting gem-stones and thin sections of rock specimens, and also for slicing larger blocks of the harder ornamental stones. A black, compact variety of diamond known as carbonado ('carbonate' or 'carbon') is embedded in the steel crowns of rock-drills.

Amongst artificial products, steel and some other hard metals are used for abrasive purposes. The so-called crushed steel, made by quenching white-hot crucible steel, is used in the stone-cutting trade. Tantalum is an extremely hard metal and may in future find some application depending on hardness.

Carbides.—Carborundum[1] (*q.v.*) or silicon carbide, CSi (H.=9½), is prepared artificially in the electric furnace from petroleum-coke and the purest quartz-sand, and is produced in large quantities at Niagara Falls. It is largely made into sharpening stones and grinding wheels; and sold under a variety of trade-names, *e.g.* crystolon, exolon, samite, &c. In lapidaries' work it has to a large extent taken the place of corundum; but although harder than corundum, it has the disadvantage of being more brittle, and it soon rubs to flour. Carbide of boron, CB_6, and silicide of boron, SiB_3, are also remarkable on account of their intense hardness (H. Moissan, Compt. rend. 1894, cxviii, 556).

Oxides.—Corundum (*q.v.*) Al_2O_3 is, next to diamond, the hardest of minerals (H. = 9). The impure variety, emery (*q.v.*), is not quite so hard. The crushed and graded material is made into corundum wheels and emery paper, and is much used in lapidaries' work. Artificial corundum, known by the trade-names of 'alundum,' 'aloxite,' 'adamite,' 'borocarbone,' &c., is now manufactured in considerable amounts at Niagara Falls, by fusing bauxite in an electric furnace. 'Corubin' is also an artificial corundum, formed as a by-product in the Goldschmidt thermite process.

Quartz (*q.v.*) SiO_2 (H. = 7), and its several varieties find extensive applications. Millstones and grindstones are made of quartz-rock, quartzite, burrstone (or buhrstone), grit, or sandstone (*q.v.*); while scythe-stones, oilstones and whetstones (*q.v.*) consist of hornstone, lydian-stone and other compact varieties of quartz. In the form of sand, quartz is used as a sand-blast, in scouring-soap, for cutting and grinding marble, making sand-paper, &c. Tripoli or infusorial earth is a powdery variety of opal (hydrated silica), and is used for polishing.

---

[1] So named by E. G. Acheson, in 1893, from carbon and corundum, because before it had been analysed, it was thought to be a compound of carbon and alumina

Silicates.—Garnet (*q.v.*) (H. = 6½–7½) is used for making 'emery' paper and cloth; and felspar (*q.v.*) (H.=6) is also used to a small degree. Silicate rocks are employed to a small extent; *e.g.* pumice for polishing, and the millstone lava (leucite-nepheline-tephrite) of Niedermendig on the Rhine, for millstones.

References.—J. V. Lewis, Abrasives (Mineral Industry, New York, 1916, 1917, xxv, 22–33); F. J. Katz, Abrasive Materials (Mineral Resources of the United States, U.S. Geol. Survey, 1915, 1916, ii, 65–80); H. Ries, Economic Geology (New York, 1916, 284-297, with bibliography).

L. J. S.

ABRASTOL or *Asaprol - Etrasol.* Trade names for the calcium salt of β-naphthol-sulphonic acid, $Ca(C_{10}H_7OSO_3)_2,3H_2O$, used in the clarification and preservation of wines. The maximum quantity needed for this purpose is 10 grms. per hectolitre. According to Noelting and Dujardin-Beaumetz and Stackler, the substance is harmless from a hygienic point of view (see Mon. Sci. 1894, 8, 257; J. Soc. Chem. Ind. 1894, 177, 534). To detect its presence, Sanglé-Ferrière proceeds as follows (Compt. rend. 1893, 117, 796): 200 c.c. of the wine is boiled for an hour in a reflux apparatus with 8 c.c. of hydrochloric acid, when the abrastol is hydrolysed to β-naphthol, which may be extracted with benzene, and the residue left after distilling the benzene sol. taken up with chloroform. A fragment of potash is dropped into the chloroform solution, which is boiled for 2 mins., when a blue colouration is produced changing to green and finally becoming yellow. 0·1 grm. per litre may thus be detected. The presence of abrastol in no way vitiates the determination of potassium sulphate (J. Soc. Chem. Ind. 1894, 177). Sinibaldi (Mon. Sci. 7, 842) has given the following method: 25 c.c. of the wine are neutralised by ammonia and shaken with 25 c.c. of amyl alcohol. After separation, the amyl alcohol is boiled to expel ammonia, and when cold is shaken with 0·25 c.c. ferric chloride sol. A grey-blue colouration denotes abrastol. Gabutti (Chem. Zentr. 1904, 2, 370) proceeds in a similar way, but instead of ferric chloride, employs phosphoric acid and formaldehyde solution, when, in presence of abrastol, a green fluorescence is produced. (For other methods, *v.* Sanna Pintus, J. Soc. Chem. Ind. 1900, 933; Briand, Compt. rend. 1894, 118, 925; Carletti, Chem. Zentr. 1909, 2, 72. For colour reactions, *v.* Barral, J. Pharm. Chim. 1903, 18, [5] 206; Salomone, Chem. Zentr. 1907, i. 306.) (For a review of the various methods of detection, *v.* Vitali, Apoth. Zeit. 1908, 23, 507; J. Soc. Chem. Ind. 1908, 830.)

ABRAUM SALTS. (Ger. *Abraumsalze*: 'salts to be removed.') The mixed salts found overlaying the rock-salt deposit at Stassfurt, in Prussia. These consist mainly of rock salt; *Carnallite*, a double chloride of potassium and magnesium; *Sylvine*, or potassium chloride; and *Kieserite*, or magnesium sulphate, *v.* POTASSIUM.

ABRIN. A brownish yellow soluble substance obtained from the seeds of *Abrus precatorius* (*Indian liquorice* or *Jequirity*). Contains a poisonous proteid, resembling, if not identical with, ricin. Lethal dose, according to Kobert, is only 0·00001 grm. per kilo body-weight: *i.e.* 1 to 100,000,000.

ABROTINE $C_{21}H_{22}ON_2$ is a crystalline diacid fluorescent alkaloid from *Artemisia abrotanum*, somewhat resembling quinine (Giacosa, Jahresber. 1883, 1356).

ABSINTH. (*Absinthe*, Fr.; *Wermuthextract*, Ger.) One of the best-known liqueurs or cordials (*q.v.*), is made chiefly at Lyons, Montpellier and Pontarlier in France, and in former years (*vide infra*) at Neufchâtel in Switzerland. It is a highly intoxicating spirituous liquor flavoured with oil of wormwood (*Artemisia absinthium*, nat. ord. *Compositæ*) and other essential oils as angelica, anise, cinnamon, cloves, fennel, hyssop, peppermint, &c. (*v.* OILS, ESSENTIAL).

There are three distinct processes in the manufacture of absinth, viz.: maceration, distillation, and colouration. The leaves and flower-tops of *Artemisia absinthium*, together with the other flavouring ingredients (which vary in kind and quality according to the requirements of the different manufacturers) are digested with spirit for periods varying from 12 hours to 10 days, according to the temperature of the infusion and the strength of the spirit used. The French manufacturers, as a rule, digest for short periods at the temperature of an ordinary water bath, and with spirit containing about 85° alcohol, whilst the Swiss maceration process was conducted at air temperature with spirit somewhat below British 'proof' strength, or about 50° alcohol.

The infusion is distilled and the distillate transferred to the colouring vessel containing small absinth leaves, balm and hyssop, dried and finely divided. This vessel is hermetically sealed and is gently heated by steam to a temperature of 60° in order to extract chlorophyll. After cooling, the green liquor is drawn off, and strained, if necessary, through a hair sieve. The colouring is sometimes separately prepared and added as required to the colourless distillate. Occasionally the latter is sweetened by the addition of about 5 p.c. by weight of crushed white sugar. Chlorophyll for imparting the green colour to absinth (and other liqueurs) is frequently obtained from nettles, parsley, and spinach, and is free from objection provided the vegetable matter is sound.

On keeping, genuine absinth assumes the yellowish tint appreciated by connoisseurs, and its qualities generally are improved by age. Many objectionable varieties of absinth are, however, on the market, made from inferior spirit, to which essences and resins are added, the former to give a fictitious flavour and the latter to produce the opalescence which occurs in genuine absinth on the addition of water, owing to the liberation of the essential oils, resinous bodies, and colouring matters derived from the plants and seeds used in its manufacture. Other colouring matters than chlorophyll are also employed, as indigo, sulphate of copper, picric acid and turmeric or other vegetable colour. Gum benzoin, guiacum and rosin are also used to produce 'milkiness' on dilution, and even chloride of antimony is said to have been employed for this purpose.

To detect adulteration it is usually sufficient to determine the essential oils, resins, and colouring matters (*vide* Hubert, Ann. Chim. anal. 6, 409, and Nivière and Hubert, Mon. Sci. 1895, 566). According to Hubert, absinth has a specific gravity of 0·8966 to 0·9982, and alcoholic strength of 47 to 72 p.c. by volume of absolute alcohol. The average results of twelve samples expressed as grams per litre were as follows: essential oils, 1·5 to 5·0; extractive, 0·36 to 1·72; acids, 0·024 to 0·288; aldehydes, 0·005 to 0·155; furfurol, 0·0002 to 0·007; ethers, 0·005 to 0·123. The strength of absinth as imported into the United kingdom varied from 'proof' to about 20 over proof, and rather more than 3000 gallons were imported annually before the war. The amount rose to 4000 gallons in 1915, since when its importation into the United Kingdom has been prohibited.

Although genuine absinth, taken in moderation, has valuable qualities as a cordial, stomachic, and febrifuge, its characteristic bitter principle, absinthiin (*q.v.*), is an active poison, having a very injurious effect upon the nervous system of those addicted to the habitual and immoderate consumption of absinth. Legal measures have therefore been taken in various European countries to control, restrict, or even prohibit its sale. In France, liqueurs may not contain more than 1 gram per litre of oil of wormwood or other oil of similar toxic nature, whilst in Belgium and Swizerland the manufacture and sale of absinth have been entirely prohibited. J. C.

ABSINTHIN or **ABSINTHIIN** $C_{15}H_{20}O_4$. The bitter principle extracted from the dried leaves of large absinth or wormwood (*Artemisia absinthium*) is an active poison. and it is to its presence in oil of wormwood that the toxic effect of absinth (*q.v.*) appears to be due.

Various formulæ have been assigned to this substance, the differences being due to the difficulty of obtaining it in a pure state (Mein, Annalen, 8, 61; Luck, Annalen, 78, 87; Kromayer, Arch. Pharm. [2] 108, 129).

Pure crystallised absinthiin was first isolated by Duquesnel (Bul. de Therapeutique, 107, 438). Senger obtained absinthiin as a pale yellow amorphous substance melting at 65° and having the empirical formula $C_{15}H_{20}O_4$. This formula was confirmed later by Bourcet, who found that the pure substance crystallises in fine white prismatic needles melting at 68°, the amorphous form and lower melting-point found by Senger being probably due to traces of a resinous impurity.

According to Senger and Bourcet, absinthiin is a glucoside, free from nitrogen, and is decomposed by the action of dilute acids, or even by boiling with water, into dextrose, a volatile oil, and a solid resinous body of the aromatic series. It is soluble in alcohol, ether, chloroform, or benzene; difficultly soluble in light petroleum, water, though more soluble in cold than in boiling water. It gives a precipitate with tannic acid and with gold chloride, which is reduced on warming; yields volatile fatty acids on oxidation with nitric acid, and oxalic and picric acids with potassium chromate and sulphuric acid. With Fröhde's reagent it gives a brown colour, changing to violet, then blue; and with sulphuric acid brown, passing through green to blue (Senger, Arch. Pharm. 230, 103; and Bourcet, Bull. Soc. chim. [3] 19, 537). J. C.

ABSINTHOL $C_{10}H_{16}O$. The essential principle of oil of wormwood derived from *Artemisia absinthium* (nat. ord. *Compositæ*), a plant indigenous to most European countries and comparatively recently introduced into the United States of America, whence increasing supplies of the cheaper qualities of wormwood oil are now obtained.

Although the oil obtained by the distillation of wormwood has been known for at least four centuries, its chemical composition was first systematically investigated in 1845, when Leblanc (Compt. rend. 21, 379) showed that its principal constituent, boiling at 203°, has the formula $C_{10}H_{16}O$. This was confirmed later by Gladstone and other investigators (Chem. Soc. Trans. 17, 1), and by Beilstein and Kupffer (Annalen, '70, 290), who gave to the product the name '*absinthol*,' and identified its dehydration product with *cymene*.

Methods for the identification of absinthol have been described by Cuniasse (J. Pharm. Chim. 1907, 25 (180–2)) and Enz (Chem. Zentr. 1911, ii. 576), but these can hardly be accepted as conclusive of the presence of wormwood, since thujone occurs in other plants. A negative reaction, however, proves the absence of wormwood.

Semmler (Ber. 25, 3350) proved absinthol to be a ketone identical with thujone or tanacetone, which occurs largely in other essential oils, as oil of tansy, sage, and *Artemisia barelieri*. It is a colourless oily liquid of pleasant odour, strongly dextrorotatory (about +68°), boils at 203°, density 0·9126 at 20°, and refractive index 1·4495.

Though isomeric with camphor, it differs from that body in combining with sodium bisulphite and in not being converted into camphoric acid by means of nitric acid, nor into camphocarboxylic acid by treatment with carbon dioxide and sodium. With melted potash it gives a resin, but no acid. When heated with P_2S_5 and $ZnCl_2$ it yields cymene (Beilstein and Kupffer, Ber. 6, 1183; Annalen, 170, 290; Wright, Chem. Soc. Trans. 27, 1 and 319; Semmler, Ber. 25, 3343 and 27, 895). J. C.

ABUTILON INDICUM (Sweet), **PETAREE** or **TUBOCUTY.** The bark of this malvaceous tree consists of long, thin, tough fibrous strips (bast fibres), and, according to Dymock (Pharm. J. [3] 8, 383) and others, is worthy of attention as a source of fibre.

ABYSSINIAN GOLD. A yellow alloy of 90·7 parts of copper and 8·3 of zinc. The ingot is plated on one side with gold, and is then rolled out into sheets, from which articles of jewellery are formed in the usual way, the amount of gold on the finished article varying from 0·03 to 1·03 p.c. Known also as *Talmi gold*. The term is sometimes applied in trade to Aluminium Bronze.

ACACIA BARK. *Acaciæ Cortex*, B. P. The dried bark of *Acacia arabica* (Willd) and of *A. decurrens* (Willd).

ACACIA CATECHU (Willd) or **KHAIR** is a tree growing in various parts of India. Its unripe pods and wood, by decoction, yield a catechu (Agricult. Ledger, 1895, No. 1, and 1896, No. 25), known by the name of Cutch or Kutch, which must not be confounded with the officinal catechu (*Catechu pallidum*). It is used in the preparation of some leather and by dyers. The timber is also used for constructional and other purposes.

ACACIA GUM *v.* Gums.

ACANTHITE. A form of silver sulphide found at the Enterprise mine, near Rico, in black crystals of orthorhombic habit (Chester, Zeitsch. Kryst. Min. 1896, 26, 526)

ACAROID RESIN or **BOTANY BAY RESIN** *v. Xanthorrhœa Balsams*, art. Balsams.

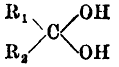
ACCIPENSERINE. A protamine belonging to the sturine group found in the testis of *Accipenser stellatus.* Composition of the sulphate: $C_{35}H_{72}O_9N_{18},4H_2SO_4$ (Kuraéeff, Zeitsch. physiol. Chem. 1901, 32, 197).

ACENAPHTHENE QUINONE. *See* Quinones.

ACERDOL. Trade-name for calcium permanganate.

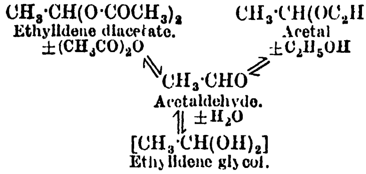
ACETAL (diethyl acetal; ethylidene diethyl ether; ethanediol (1 : 1) diethyl ether) $C_6H_{14}O_2$, or $CH_3{\cdot}CH(OC_2H_5)_2$. *See* Acetals.

ACETALS. Acetals are the ethers and esters derived from the so-called *geminal*-glycols, which are themselves for the most part incapable of existence; such glycols possess the general formulæ—

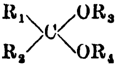


$$R_1R_2C(OH)_2$$

(where R_1 and R_2 may be either hydrogen or aliphatic or aromatic radicals); they split up at once into water and the corresponding anhydrous compound, which may be an aldehyde or a ketone; thus, in the case of ordinary acetaldehyde, we have the relationships:



Acetals may thus be given the general formula:



$$R_1R_2C(OR_3)(OR_4)$$

(where R_1 and R_2 are any alkyl or aryl radicals, and R_3 and R_4 any acidyl, alkyl or aralkyl radicals).

We may distinguish two types of acetals, according to whether the products are alkyl ethers or acid esters; the term '*acetal*' is more usually applied to the former class.

(*a*) *Dialkyl Ethers of* gem.-*Glycols* (Acetals of Aldehydes and Ketones).

They are produced by heating alcohol and an aldehyde alone, but the yield is very poor (Geuther, Annalen, 126, 62). A better yield is obtained by adding a small quantity of a catalyst such as ferric chloride, or a trace of acid to the mixture (Trillat and Cambier, Compt. rend. 118, 1277). Still better is the method of Fischer and Giebe (Ber. 30, 3053; 31, 545), consisting in passing 1 p.c. of hydrochloric acid into the mixture and heating, or allowing to stand for some time; after washing with a little dilute potassium carbonate solution the product is dried over anhydrous potassium carbonate and fractionated, the yield, however, is only about 50 p.c. in the case of diethyl acetal, as the reaction is reversible:

$$R{\cdot}CHO+2C_2H_5{\cdot}OH \rightleftharpoons R{\cdot}CH(OC_2H_5)_2+H_2O$$

Acetals may also be made by passing pure phosphine through the cooled mixture of aldehyde and alcohol (Girard, Compt. rend. 91, 629).

The most convenient method for the preparation of acetals is, perhaps, that described by King and Mason (Eng. Pat. 101428), consisting in treating a mixture of an aldehyde and an alcohol with certain metallic salts—or their saturated aqueous solutions—such as the chlorides or nitrates of aluminium, calcium, cerium, magnesium, manganese, &c., thus 50 grams acetaldehyde and 120 grams 95 p.c. alcohol are mixed and then 20 grams anhydrous calcium chloride are added. The mixture becomes warm, and is allowed to stand for some time, with occasional shaking. It has then separated into two layers, the upper of which is removed, washed with water, then with sodium carbonate solution, dried over calcium chloride, and finally over anhydrous potassium carbonate. It is then fractionated, and yields 120 grams acetal, or 90 p.c. of theory. The addition of a small quantity of an acid has the effect of causing the reaction to take place more quickly.

It is also possible to prepare certain acetals by heating another acetal with the desired alcohol:

$$R{\cdot}CH(OR_1)_2+2R_2{\cdot}OH \rightleftharpoons R{\cdot}CH(OR_2)_2+2R_1{\cdot}OH$$

Thus on heating ordinary diethyl acetal with excess of methyl alcohol it is converted almost completely into dimethyl acetal (Delépine, Compt. rend. 132, 968; Bull. Soc. chim. [3], 25, 574). The converse, however, does not hold good, since, on heating dimethyl acetal with excess of ethyl alcohol practically no reaction occurs (Geuther and Bachmann, Annalen, 218, 44). In general, the series of acetals can be descended by heating any member of the group with an alcohol containing a smaller number of carbon atoms than is present in its alcohol residue. If a little hydrochloric acid be added a balanced reaction takes place, and a certain proportion of all the possible products is obtained, the products of higher molecular weight predominating (Delépine, Compt. rend. 132, 331, 968). Another general method of wide applicability is that of Claisen (Ber. 29, 1007; 31, 1010; 40, 3903), consisting in treating the aldehyde or ketone with orthoformic ester in alcoholic solution in presence of a suitable catalyst, such as mineral acids, oxalic acid, ferric chloride, ammonium chloride, sulphate or nitrate, &c. (*cf.* also Arbusow, Ber. 40, 3301; Claisen, *ibid.* 40, 3912). Orthoformic esters can also react with alkylmagnesium salts to yield acetals (Bodroux, Compt. rend. 138, 700; Tschitschibabin, Ber. 37, 186), or with halogenated fatty esters in presence of zinc (Tschitschibabin, J. prak. Chem. [2] 72, 326; Claisen, Ber. 31, 1019):

$$(C_2H_5O)_2{\cdot}CH{\cdot}OC_2H_5+Br{\cdot}CH(CH_3){\cdot}COOR+Zn$$
$$=(C_2H_5O)_2{\cdot}CH{\cdot}CH(CH_3){\cdot}COOR+C_2H_5O{\cdot}ZnBr$$
$$(C_2H_5O)_2{\cdot}CH{\cdot}CH(CH_3){\cdot}COOR$$
$$\rightarrow (C_2H_5O)_2{\cdot}CH{\cdot}CH(CH_3){\cdot}COOH$$
$$\rightarrow (C_2H_5O)_2{\cdot}CH{\cdot}CH_2{\cdot}CH_3$$

Certain special methods for production of acetals are available for formylal and diethyl acetal, and will be noted later.

General Properties.—The true acetals, or dialkyl ethers of *gem*-glycols, are colourless liquids of pleasant ethereal odour, which can be distilled without decomposition. The lower members are somewhat soluble in water, by which they are slowly hydrolysed; in presence of dilute acids the hydrolysis is almost instantaneous; they are stable to alkalis even on boiling. With various metallic salts such as magnesium or zinc iodides, calcium chloride or magnesium bromide, double compounds are formed, *e.g.* $MgBr_2+2CH_2(COCH_3)_2$, m.p. 112°; $MgI_2+2CH_3{\cdot}CH(OC_2H_5)_2$, m.p. 86° (Timmermans, Chem. Zentr. 1907, 1, 1007). The acetals form hydrates in certain cases; thus, diethyl formylal forms a hydrate $CH_2(OC_2H_5)_2{\cdot}H_2O$, which is a liquid of b.p. 74°–75°, with an odour of rum, and dissolves in 15 parts water at 20° C.; the higher homologues also form monohydrates, boiling at lower temperatures than the acetals themselves (Trillat and Cambier, Compt. rend. 118, 1278).

The acetals are of considerable use in place of the free aldehydes or ketones for synthetic purposes, on the one hand, owing to their higher boiling-points (*e.g.* acetaldehyde, b.p. 20°; diethyl acetal, b.p. 103°), and also to the fact that alcohol and not water is split off in the condensation, which has a marked effect on the yield. Thus in preparing vinyldiacetoneamine by condensing acetaldehyde or paraldehyde with diacetoneamine acid oxalate (Fischer, Ber. 17, 1793; Heintz, Annalen, 178, 326; 191, 122; Harries, Ber. 29, 522), only a poor yield of product is obtained even on prolonged heating: but if acetal be substituted the reaction is complete in a few hours with almost quantitative yield (*cf.* King, Mason and Schryver, Eng. Pat. 101738) owing probably to the absence of the inhibiting effect of water.

In addition, the acetals can be readily halogenated and converted into amino-, hydroxy-, alkoxy-, &c., derivatives, which react like the corresponding aldehydes.

They can be separated from their aqueous solutions by the addition of concentrated calcium chloride solution. They are miscible with alcohol and ether; their vapours or solutions in alcohol, benzene, or acetone slowly harden dry gelatine films (Beckmann and Scharfenberger, Chem. Zentr. 1896, ii. 930). When heated in a sealed tube with glacial acetic acid the corresponding aldehyde is obtained (Beilstein, Annalen, 112, 239).

Mixed acetals containing two different alcohol residues have been described by Bachmann (*l.c.*), but according to Rübencamp (Annalen, 225, 271) and Fritz and Schumacher (Annalen, 279, 308), these consist of mixtures of two acetals in molecular proportions. Delepine, however (Compt. rend. 132, 331, 968), claims to have obtained mixed acetals.

Formylals $CH_2{\cdot}(OR)_2$.

Methylal $CH_2{\cdot}(OCH_3)_2$ (dimethyl formylal), b.p. 41·3–41·7°, sp. gr. 0·862, can be obtained by treating a mixture of methyl alcohol and 40 p.c. formaldehyde solution, with solid calcium chloride and a little hydrochloric acid (Fischer and Giebe, Ber. 30, 3054). It can also be obtained by treating methylene chloride with sodium methylate (Arnhold, Annalen, 240, 197), and also by treating chlormethyl alkyl ether $CH_2(OR)Cl$ (obtained by condensing formaldehyde and alcohol with excess of hydrochloric acid) with sodium methylate (Favre, Compt. rend. 119, 284; Bull. Soc. chim. [3] 11, 879; Henry, Ber. 26, Ref. 933; Compt. rend. 119, 425; de Sonay, Ber. 27, Ref. 337); or by heating polyoxymethylene and the required alcohol with 1 to 4 p.c. ferric chloride for 2–10 hours (Trillat and Cambier, Compt. rend. 118, 1277). It can be used for various condensations in place of formaldehyde, and is a good solvent for many organic compounds. (*Cf.* also Kane, Annalen, 19, 175; Malaguti, Annalen, 32, 55; Renard, Ann. chim. phys. [5] 17, 290; Brühl, Annalen, 203, 12, 25; Fileti and de Gaspari, Gazz. chim. Ital. 27, ii. 293; Trillat, Compt. rend. 137, 187; Delépine, Bull. Soc. chim. [3] 25, 364; Favre, Bull. Soc. chim. [3] 11, 1096; Brühl, Ber. 30, 159; Berthelot, Compt. rend. 126, 675; Trillat and Cambier, Compt. rend. 118, 1277; Brochet, Bull. Soc. chim. [3] 13, 687.)

The following formylals are known, but the higher members are of little importance:—

Diethyl methylal $CH_2{\cdot}(OC_2H_5)_2$, b.p. 87°; sp. gr. 0·834 (20°) (Arnhold, *l.c.*; Greene, Chem. News, 50, 75; Pratesi, Ber. 16, 1870; Favre, *l.c.*; Trillat and Cambier, Compt. rend. 118, 1278).

Dipropyl methylal $CH_2{\cdot}(OC_3H_7)_2$, b.p. 136°; sp. gr. 0·834 (20°) (Arnhold, *l.c.*; Trillat and Cambier, *l.c.*; Favre, Bull. Soc. chim. [3] 11, 881).

Di-isopropyl methylal $CH_2(OC_3H_7)_2$, b.p. 118°; sp. gr. 0·831 (20°) (Arnhold, *l.c.*; Trillat and Cambier, *l.c.*).

Di-isobutyl methylal $CH_2(OC_4H_9)_2$, b.p. 164°; sp. gr. 0·824 (20°) (Arnhold, *l.c.*; Gorbow and Kessler, Ber. 20, Ref. 778; Trillat and Cambier, *l.c.*).

Di-isoamyl methylal $CH_2(OC_5H_{11})_2$, b.p. 206°; sp. gr. 0·835 (20°) (Arnhold, *l.c.*; Trillat and Cambier, *l.c.*).

Dihexyl methylal $CH_2(OC_6H_{13})_2+H_2O$, b.p. 174°–175°; sp. gr. 0·822 (15°) (Trillat and Cambier, *l.c.*).

Dioctyl methylal $CH_2{\cdot}(OC_8H_{17})_2$, b.p. 280°; sp. gr. 0·848 (15°) (Arnhold, *l.c.*; Trillat and Cambier, *l.c.*).

Cyclohexanol formal $(C_6H_{11}O)_2{\cdot}CH_2$ is produced from cyclohexanol, 40 p.c. formaldehyde solution and hydrochloric acid (Murat and Cathala, J. Pharm. Chim. 6, 289).

Acetals $CH_3{\cdot}CH(OR)_2$.

Dimethyl acetal $CH_3{\cdot}CH(OCH_3)_2$ occurs in crude wood-spirit, b.p. 63°; sp. gr. 0·865 (22°) (Dancer, Annalen, 132, 240; Alsberg, Jahresb. f. Chem. 1864, 485; Geuther and Bachmann, Annalen, 218, 44; Schiff, Annalen, 220, 104; 223, 74).

Diethyl acetal $CH_3{\cdot}CH(OC_2H_5)_2$ (usually known simply as 'Acetal') (= ethylidene diethyl ether; ethane-diol-(1 : 1)-diethyl ether) (*cf.* Döbereiner, Gm. 4. 805; Liebig, Annalen, 5, 25; 14. 156; Stas. Ann, Chim. Phys. [3] 19, 146; Wurtz, Ann. Chim. Phys. [3] 48, 70; Geuther, Annalen, 126, 63).

To prepare acetal by Wurtz's method, 2 parts alcohol are added to a mixture of 3 parts manganese dioxide, 3 parts sulphuric acid and 2 parts water, and, after the effervescence first produced has subsided, the whole is heated at 100° until 3 parts have distilled over. The product is then fractionally distilled, and two portions, one boiling below 80° and the second boiling at 80°–95°, are collected.[1] Each fraction is treated with solution of calcium chloride and the ethereal layer which separates is distilled. The product contains aldehyde and ethyl acetate in addition to acetal; to remove these it is shaken with concentrated aqueous potash, the brown liquid separated from the aqueous layer is distilled, and the distillate shaken with calcium chloride. It is then heated with twice its volume of concentrated aqueous soda in sealed tubes at 100° for 24 hours, separated from the soda, distilled, the distillate again rectified: the fraction 100°–105°, which constitutes the greater portion, is acetal.

In addition to its formation as a by-product in the oxidation of alcohol, acetal can also be obtained from a mixture of acetaldehyde (1 vol.) and absolute alcohol (2 vols.) (1) by heating with acetic acid (½ vol.) for 12 hours at 100° (Geuther, Annalen, 126, 63); (2) by cooling in a freezing mixture, passing dry hydrogen chloride to saturation, and decomposing the resulting monochlorether with sodium ethoxide (Wurtz and Frapolli, Compt. rend. 67, 418; Annalen, 108, 223); or (3) by cooling a mixture of equal volumes to −21°, and passing a current of pure hydrogen phosphide for 24 hours (Engel and Girard, Compt. rend. 92, 692; J. 1880, 694).

The most convenient method is that of King and Mason (E. P. 101428, *vide supra*). On a technical scale considerable interest attaches to the production of diethyl acetal from acetylene by a modification of the process of Kutscherow for preparing acetaldehyde from acetylene and water in the presence of a mercury catalyst (*cf.* Kutscherow, Ber. 14, 1540; 42, 2759). Thus the Chemische Fab. Griesheim Elektron (E. P. 14246, 1913) describe the production of ethers of ethylidene glycol by the action of acetylene upon alcohols in the presence of mercury salts. They are stated to be solvents for cellulose esters. Boiteau (E. P. 15806, 1914) describes the production of ethylidene ethers by a similar method; and in E. P. 15919, 1914, a further modification is claimed, consisting in forming the catalyst *in situ*, *e.g.* by adding mercuric oxide or the mercury salt of a weak acid to the liquid, and then adding sulphuric acid to form the sulphate.

Acetal is a colourless liquid with agreeable odour: b.p. 104°, and sp. gr. 0·821 at 22·4° (Stas, Annalen, 64, 322); b.p. 103·7°–104·3° at 744·4 mm., and sp. gr. 0·8314 at 20°/4° (Brühl, Annalen, 203, 25). It is soluble in 18 vols. of water at 25°, and the solubility increases as the temperature rises. Acetal is miscible in all proportions with alcohol and ether, does not reduce ammoniacal silver solution, and is unaltered on exposure to air; platinum black, however, oxidises it first to acetaldehyde and subsequently to acetic acid. For formation and hydrolysis, *see* Lapworth and Fitzgerald (Proc. Chem. Soc. 24, 153).

Acetal has some solvent power for cellulose esters. A use for acetal is suggested by Ostromisslensky, consisting in preparing erythrene (butadiene) from it by passing over a heated catalyst, such as alumina at 360°–460° (J. Russ. Phys. Chem. Soc. 47, 1472, 1509; *cf.* also Boiteau, E. P. 15806, 1914). Pictet (Ber. 46, 2688; E. P. 17578, 1914) describes the production of a synthetic alkaloid, which he terms *coralydine*, by condensing tetrahydropapaverine and acetal in 16 p.c. hydrochloric acid on the water-bath; the product exists in two isomeric forms, α- and β-.

On heating with phosphorus pentoxide the elements of alcohol are removed from acetal, leaving vinyl ethyl ether:

$$CH_3{\cdot}CH(OC_2H_5)_2 - C_2H_5OH = CH_2{:}CH{\cdot}O{\cdot}C_2H_5$$

which forms a liquid, b.p. 35·5°; sp. gr. 0·762 (14·5°), and is split up by dilute sulphuric acid into acetaldehyde and alcohol (Wislicenus, Annalen, 192, 106; Henry, Compt. rend. 100, 1007; Nef. Annalen, 298, 327; Claisen, Ber. 31, 1021; Tschitschibabin, J. prak. Chem. [2] 74, 424). When heated with acetic anhydride to 150° one ethyl group is replaced by an acetyl group yielding 'acetaldehyde-ethyl acetate,' $CH_3{\cdot}CH(O{\cdot}C_2H_5)(O{\cdot}CO{\cdot}CH_3)$, b.p. 125°–130°; sp. gr. 0·941. On boiling with water it splits up into acetaldehyde, ethyl alcohol, and acetic acid (Claisen, Ber. 31, 1018).

Acetal does not give the iodoform reaction until shaken with a few drops of hydrochloric acid, whereby the acetal is hydrolysed to alcohol and aldehyde. Estimation in presence of paraldehyde, see Orton and McKie, Trans. Chem. Soc. 109, 184.

Derivatives.—Mono-, di-, and trichloracetal are obtained as intermediate products in the preparation of chloral by passing chlorine through 80 p.c. alcohol (Lieben, Ann. Chim. Phys. [3] 52, 313; Paternò, Compt. rend. 67, 765). According to Krey (J. 1876, 475), a better yield of these derivatives is obtained if a mixture of 2 parts absolute alcohol, 3 parts manganese dioxide, 3 parts sulphuric acid, and 2 parts water is heated until ⅔ of the liquid has distilled over and chlorine is passed through the well-cooled distillate until it shows signs of turbidity. In either case the product is washed with water, dried over calcium chloride, and submitted to fractional distillation. The fraction 80°–120° contains chiefly aldehyde and compound ethers, 120°–170° chiefly monochloracetal, 170°–185° dichloracetal (Lieben, *l.c.*), and the fraction boiling above 185° contains trichloracetal (Paternò, *l.c.*). These compounds may then be obtained in the pure state by repeated fractionation.

A better method of obtaining monochloracetal is by passing chlorine through well-cooled 94–99 p.c. alcohol until the chlorinated product has a sp. gr. 1·02–1·03 at 25°. Half the original volume of alcohol is added and the mixture heated a few hours at 50°–60°. The free acid is removed by calcium carbonate; the oil washed with water, dried and fractionated. The proportion of di- and tri- chloro-derivatives formed depends on the amount of chlorine added (Fritsch, Annalen, 279, 288).

---

[1] The b.p. is given as in the original paper, but, inasmuch as b.p. of acetal is 104°, it seems probable that 95° is a misprint for some higher temperature—say 105°.

Monochloracetal $CH_2Cl\cdot CH(OC_2H_5)_2$ (Lieben, Annalen, 146, 193; Paternò, Mazzara, Ber. 6, 1202; Klien, J. 1876, 336; Natterer, Monatsh. 3, 444; 5, 497; Wislicenus, Annalen, 192, 106; Frank, Annalen, 206, 341; Fritsch, Annalen, 279, 300) is a colourless liquid, having an aromatic ethereal odour; b.p. 155°; sp. gr. 1·0418 at 0°, 1·026 at 15° (Klien): 156°–158° (Autenrieth, Ber. 24, 159). When heated with bleaching powder it yields di- and trichloracetal, chloroform, and chlorinated acetaldehyde (Goldberg, J. pr. Chem. [2] 24, 107).

Dichloracetal $CHCl_2\cdot CH(OC_2H_5)_2$ (Jacobsen, Ber. 4, 217; Pinner, Ber. 5, 148; Annalen, 179, 34; Krey, *l.c.*; Paternò, Annalen, 149, 372; 150, 134); b.p. 183°–184°; sp. gr. 1·1383 at 14°. When treated with hydrocarbons it forms compounds of the type $CHX_2\cdot CCl_2$ (Fritsch, Annalen, 279, 219; Wiechell, Annalen, 279, 337; Buttenberg, Annalen, 279, 324).

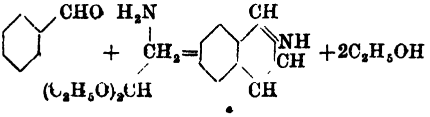
Trichloracetal $CCl_3\cdot CH(OC_2H_5)_2$ (Byasson, Bull. Soc. chim. 32, 304; Wurtz, Frapolli, J. 1872, 438); b.p. 197°; 204·8° at 758·7 mm. Paternò, Pisati J. 1872, 303), sp. gr. 1·2813. When heated with concentrated sulphuric acid it yields chloral.

Trichloracetal $C_6H_{11}Cl_3O_2$. Obtained by the action of chlorine on alcohol (Lieben, Paternò, Krey, *l.c.*); crystallises in monoclinic needles resembling caffeine; m.p. 89°.

Monobromacetal (Pinner, Ber. 5, 149; Wislicenus, Annalen, 192, 112; Fischer a. Landsteiner, Ber. 25, 2551; Freundler a. Ledru, Compt. rend. 1905, 140, 794); b.p. 81°–82° at 27–28 mm. (Freundler). According to F. a. L. a cheap method of making monobromacetal is by brominating paraldehyde at 0° with constant shaking, mixing with absolute alcohol, and after standing 12 hours pouring into an ice-cold sol. of potassium carbonate. The separated oil is dried and fractionated *in vacuó*.

Monoiodoacetal, b.p. 100° at 10 mm.; sp. gr. 1·4944 at 15° (Hesse, Ber. 1897, 30, 1438).

Aminoacetal $NH_2\cdot CH_2\cdot CH(OC_2H_5)_2$ was first prepared by Wohl by treating chloracetal with ammonia (Ber. 21, 616). It can also be prepared by reducing nitroacetal (b.p. 14°: m.p. 89°–91°, from iodoacetal and silver nitrite) with sodium and alcohol. It forms a colourless oil of b.p. 172°–174°, with a strong amine smell; it emulsifies with a little water, but dissolves on adding more water, and can be separated from the solution by the addition of solid alkali. It is of some importance as a synthetic agent, as it readily condenses with aromatic aldehydes to form derivatives of isoquinoline:



Substituted alkylaminoacetals are also known (Paal and van Gomber, Archiv. der Pharm. 246, 306; Störmer and Prall, Ber. 30, 1504).

Acetal sulphide (acetalyl sulphide) $[(C_2H_5O)_2\cdot CH\cdot CH_2)]_2S$ has been prepared by Fischer (Ber. 42, 1070) by heating chloracetal with aqueous potassium sulphide at 120°–150° C. It forms a colourless liquid, b.p. 280° C. (750 mm.). It dissolves readily in water, from which it can be precipitated by salt, and is decomposed by boiling with 1 p.c. hydrochloric acid.

Chloro-triethyl-phosphinoacetal is described by Caldwell (Trans. Chem. Soc. 109, 283). Prepared by heating monochloracetal and triethylphosphine; it forms a viscous liquid of overpowering odour. The corresponding bromo compound is also described. They are hydrolysed to the respective aldehydes.

Dipropyl acetal $CH_3\cdot CH(O\cdot C_3H_7)_2$, b.p. 147°; sp. gr. 0·825 (22°) (de Girard, Compt. rend. 91, 629).

Di-n-butyl acetal $CH_3\cdot CH\cdot(OC_4H_9)_2$, b.p. 198°–200° (King and Mason, Eng. Pat. 101428).

Di-iso-butyl acetal $CH_3\cdot CH(OC_4H_9)_2$, b.p. 170°; sp. gr. 0·816 (22°) (Claus and Trainer, Ber. 19, 3006; de Girard, Compt. rend. 91, 629).

Di-iso-amyl acetal $CH_3\cdot CH(OC_5H_{11})_2$, b.p. 211°; sp. gr. 0·835 (15°) (Alsberg, Jahresb. f. Chemie. 1864, 485; Claus and Trainer, *l.c.*).

Various other acetals have been prepared, but are for the most part unimportant; the following may be noted:—

Acrolein diethyl acetal $CH_2 : CH\cdot CH(OC_2H_5)_2$, b.p. 123·5°; sp. gr. 0·8453 (15°); sparingly soluble in water, miscible with alcohol and ether; hydrolysed by cold hydrochloric acid (Wohl, Ber. 31, 1796. For reactions, *see* Wohl, *l.c.*; Wohl and Emmerich, Ber. 33, 2761; Wohl and Schweitzer, Ber. 40, 92). Acrolein itself reacts with orthoformic ester, &c., to yield the *ethoxy derivative of propionaldehyde acetal* $CH_2\cdot(OC_2H_5)\cdot CH_2\cdot CH(OC_2H_5)_2$, b.p. 184°–186° (Claisen, Ber. 29, 2933; 31, 1014; Fischer and Giebe, Ber. 30, 3056). Similarly, crotonaldehyde yields *β-ethoxy-butyraldehyde acetal* $CH_3\cdot CH(OC_2H_5)\cdot CH_2.CH(OC_2H_5)_2$, b.p. 73°–74°/ 14 mm. (Claisen, *l.c.*).

Crotonaldehyde diethyl acetal, see Wohl and Frank (Ber. 35, 1904).

Propargylaldehyde diethyl acetal

$$CH : C\cdot CH(OC_2H_5)_2$$

forms an oil with a camphor-like odour, b.p. 140° (Claisen, Ber. 29, 2933; 31, 1015, 1022; 36, 3664, 3668; 40, 3907).

Glycerine aldehyde acetal

$$CH_2(OH)CH(OH)\cdot CH(OC_2H_5)_2$$

from acrolein acetal (Wohl, Ber. 31, 1799).

Acetals derived from ketones can be obtained by the action of the hydrochlorides of formimino-ethers or phenylacetimino-ethers (Claisen, Ber. 31, 1012; 40, 3908; Reitter and Hess, Ber. 40, 3023).

Acetone dimethyl acetal $(CH_3)_2\cdot C(OCH_3)_2$, b.p. 83.

Acetone diethyl acetal $(CH_3)_2\cdot C(OC_2H_5)_2$, b.p. 114°.

Glycol acetal, see Pinner (Ber. 5, 150), Verley, (Chem. Zentr. 1899, ii. 919).

Ethyl glyoxal acetal $C_2H_5O{\cdot}CH(OC_2H_5)_2$, b.p. 62°–68° / 10–12 mm. (Dakin and Dudley, Trans Chem. Soc. 105, 2453; *cf.* also Am. Chem. Abstr. 7, 3343; 8, 2252).

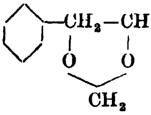
The monosaccharides form derivatives termed glucosides (*q.v.*), which are related to acetals, and it is probable that the true acetals are intermediate products in their formation:

$$HO{\cdot}CH_2{\cdot}[CH(OH)]_x{\cdot}CHO+2HOCH_3$$
$$=H_2O+HO{\cdot}CH_2[CH(OH)]_x{\cdot}CH(OCH_3)_2$$

and these acetals then split off one molecule of alcohol to form the glucosides (E. Fischer, Ber. 28, 1145), which are thus the cyclic-γ-anhydro derivatives of the half-acetals of the monosaccharides.

Aromatic acetals. The mono- and di- acetal derivatives of catechol are obtained by heating the monosodium derivative of catechol with monochloracetal (Moreau, Compt. rend. 126, 1656).

Verley describes the production of methyl acetals of aromatic glycols which are jasmine perfumes, and may be prepared synthetically or from natural extract of jasmine, which consists essentially of the methyl acetal of phenyl glycol (Eng. Pat. 4779, 1898); this substance:



is produced by heating phenyl glycol and formic aldehyde with dilute sulphuric acid. It forms an oil, b.p. 101° / 12 mm., and is identical with the natural perfume. If acetaldehyde be used in place of formaldehyde the ethyl acetal is formed, b.p. 103° / 12 mm.

Diethylbenzaldehyde acetal $C_6H_5{\cdot}CH(OC_2H_5)_2$ may be prepared by the method of Fischer and Giebe (*l.c.*) by treating the aldehyde with 5 times its weight of 1 p.c. ethyl alcoholic hydrochloric acid, and heating to 100° for 60 hours, cooling, diluting with water, and extracting with ether; or, better, by Claisen's method: 37·5 grams benzaldehyde, 57 grams orthoformic ester, and 49 grams alcohol, and 0·75 gram ammonium chloride are refluxed for 10 minutes. The product is then distilled from the accompanying formic ester (b.p. 82°), and after further purification with potassium carbonate is fractionated, the acetal distilling over between 217° and 223°. Yield 62 grams or 97 p.c. of theory. A trace of hydrochloric acid may also be used as a catalyst in place of the ammonium chloride (Claisen, *l.c.*).

(*b*) *Acidyl derivatives of* gem-*Glycols.*

The diacyl derivatives corresponding to the true acetals:

$$\genfrac{}{}{0pt}{}{R_1}{R_2}{>}C(O{\cdot}CO{\cdot}R_3)_2$$

(R_1 and R_2=alkyl or hydrogen) have hitherto been of slight importance in industry; recently, however, the diacetyl esters of ethylidene glycol have come into prominence as a means for the production of acetic anhydride. They may be prepared by condensing acid chlorides with carbonyl compounds to α-chloralkyl fatty esters, and then treating these with silver or potassium salts of the same or different acids

$$CH_3{\cdot}CH{<}\genfrac{}{}{0pt}{}{Cl}{O{\cdot}CO{\cdot}CH_3}+AgO{\cdot}CO{\cdot}CH_3$$
$$=AgCl+CH_3{\cdot}CH{<}\genfrac{}{}{0pt}{}{O{\cdot}CO{\cdot}C_2H_5}{O\,CO{\cdot}CH_3}$$

(Schiff, Ber. 9, 306; Geuther and Rübencamp, Annalen, 225, 273). Acidyl derivatives of methylene glycols can be obtained by treating methylenedihalogenides with the silver salts of fatty acids:

$$CH_2I_2+2AgO{\cdot}COCH_3=2AgI+CH_2(O{\cdot}CO{\cdot}CH_3)_2$$

(Butlerow, Annalen, 107, 111; Arnhold, Annalen, 240, 204), or by condensing polyoxymethylenes with acid chlorides or anhydrides in presence of zinc chloride

$$\genfrac{}{}{0pt}{}{R{\cdot}CO}{R{\cdot}CO}{>}O+CH_2O=\genfrac{}{}{0pt}{}{R{\cdot}CO{\cdot}O}{R{\cdot}CO{\cdot}O}{>}CH_2$$

(Descudé, Bull. Soc. chim. [3] 27, 867).

The following derivatives are known:—

Methylene diacetate $CH_2(O{\cdot}COCH_3)_2$, b.p. 170° (Butlerow, Annalen, 107, 111; Descudé, Bull. Soc. chim. [3] 27, 1215).

Ethylidene diacetate $CH_3{\cdot}CH(OCOCH_3)_2$, b.p. 169°; sp. gr. 1·073 (15°) (Geuther, Annalen, 106, 249; Schiff, Ber. 9, 306; Franchimont, Rec. trav. chim. 1, 248; Geuther and Rubencamp, Annalen, 225, 273).

Ethylidene dipropionate $CH_3CH(OCOC_2H_5)_2$, b.p. 192°; sp. gr. 1·020 (15°) (Geuther and Rubencamp, *l.c.*; *cf.* also Eng. Pat. 14246, 1913).

Ethylidene dibutyrate $CH_3{\cdot}CH(OCOC_3H_7)_2$, b.p. 215°; sp. gr. 0·985 (15°) (Geuther and Rubencamp, *l.c.*).

Ethylidene di-isovalerianate

$$CH_3{\cdot}CH(OCO{\cdot}C_4H_9)_2,$$

b.p. 225°; sp. gr. 0·947 (15°) (Geuther and Rubencamp, *l.c.*).

Of these *ethylidene diacetate* is by far the most important; it is now made technically by passing acetylene into acetic acid containing a mercury salt as catalyst

$$C_2H_2+2CH_3{\cdot}COOH=CH_3{\cdot}CH(O{\cdot}COCH_3)_2$$

The Chemisch Fab. Griesheim Elektron (Eng. Pat. 14246, 1913) claim the production of esters of ethylidene glycol and vinyl alcohol by the action of acetylene upon compounds containing carboxyl groups in the presence of mercury salts; the esters are stated to be solvents for cellulose esters; in an example, 250 grams of anhydrous acetic acid are mixed with 10 grams mercury sulphate and, at 60°–80° C., dry acetylene is passed through until action ceases. The product on distillation yields 80–90 p.c. of the theoretical amount of the ester.

Boiteau (Eng. Pat. 15919, 1914) claims a modification consisting in forming the required catalyst in the substance heated. For example, mercuric oxide, or a mercury salt of a weak acid, such as acetic acid, is dissolved in glacial acetic acid, sulphuric acid is then added, and acetylene passed in.

The Soc. Chim. des Usines du Rhône describe (Eng. Pat. 112765) a further modification in which ethylidene diacetate is prepared by the reaction of acetylene on glacial acetic acid in the presence of mercury acetate and aromatic or aliphatic sulphonic acids. In Eng. Pat. 112766 the same patentees claim also the use of mercury acetate and sulphuric esters, *e.g.* methylene sulphate.

The diacetic ester obtained by any of these processes splits up on heating into acetaldehyde (or paraldehyde) and acetic anhydride:

$$CH_3{\cdot}CH(O{\cdot}CO{\cdot}CH_3)_2 = CH_3CHO + O(CO{\cdot}CH_3)_2$$

Thus, the Bosnische Elektrizitäts A. G. (Eng. Pat. 23190, 1914) claim the production of acetic anhydride by heating ethylidene diacetate above its boiling-point, or by heating it with catalysts, such as sulphuric acid or mercuric sulphate. The Soc. Chim. des Usines du Rhône (Eng. Pat. 10906) describe the production of acetic anhydride and paraldehyde by heating ethylidene diacetate under reduced pressure in the presence of catalysts, such as acids or acid salts. For instance, 400 parts of the ester and 8 parts of sulphuric acid (66° Bé.) are placed in a suitable vessel and heated to 70°–80° C. at a pressure of 100 mm. In two hours 350 parts of a mixture of paraldehyde and acetic anhydride distil over. (The boiling-point of ethylidene diacetate at 100 mm. is about 115° C.) (Cf. also Eng. Pat. 131399, Soc. Chim. des Usines du Rhône.) The diacetate can also be made by heating acetaldehyde with acetic anhydride (Geuther, Annalen, 106, 249), but the yield is poor, and the method is without technical importance.

Benzylidene diacetate $C_6H_5CH(OCOCH_3)_2$, m.p. 45°–46°; b.p. 220° (225°–230°), can be prepared by heating 20 grams benzyl chloride with 35 grams lead peroxide and 80 c.c. boiling acetic acid (Bodroux, Bull. Soc. chim. [3] 21, 331); by refluxing 20 grams benzaldehyde with 20 grams acetic anhydride and 10 grams acetic acid for 3 hours at 150°–180° (Nef, Annalen, 298, 277), or by passing air through a mixture of benzaldehyde and acetic anhydride containing a trace of acetic acid (Freer and Novy, Am. Chem. J. 27, 160). In complete absence of acetic acid no action occurs. It is only slowly attacked by boiling with sodium carbonate solution or by treatment with soda lye, but is hydrolysed by cold concentrated sulphuric or nitric acids. (*Cf.* also Wicke, Annalen, 102, 368; Geuther, *ibid.* 106, 251; Limpricht, *ibid.* 139, 321; Beilstein and Kuhlberg, *ibid.* 146, 323; and Zeit. f. Chemie. 1867, 277; 1868, 172; Chem. Zentr. 1908, 1, 1831; 1909, 2, 1220.)

F. A. M.

ACETAMIDE C_2H_5NO, or $CH_3.CONH_2$.

(Hofmann, Ber. 15, 980; Schulze, J. pr. Chem. [2] 27, 512; Keller, J. pr. Chem. [2] 31, 364; Aschan, Ber. 31, 2344; Kündig, Annalen, 105, 277; Abel, J. Soc. Chem. Ind. 1899, 515.)

Acetamide is usually prepared by the dry distillation of ammonium acetate; a better yield (91·7 p.c.) and a purer product is obtained by distilling ammonium diacetate in the special apparatus described by François (J. Pharm. Chim. 23, 230). Between 135° and 195° acetic acid and water are evolved, and at 195°–222° some acetamide passes over. When the temperature remains constant at 222° the distillation is stopped, the residue being pure acetamide. A nearly theoretical yield is obtained by saturating a mixture of ethyl acetate and ammonia with dry ammonia gas at −10°, and after standing, fractionating *in vacuô* (Phelps, Amer. J. Sci. 24, 429).

Acetamide forms white hexagonal crystals which are odourless when pure, and melt at 81°–82° (Hofmann, Ber. 14, 2729; Mason, Chem. Soc. Trans. 1889, 107; Meyer, Ber. 22, 24; Forster, Chem. Soc. Trans. 1898, 791; Nicol, Zeitsch. anorg. Chem. 15, 397), boils at 222° (cor.) [Kündig], is readily soluble in water, and when heated with acids or alkalis is converted into acetic acid and ammonia (Coninck, Compt. rend. 121, 893; 126, 907; 127, 1028; Dunstan a. Dymond, Chem. Soc. Trans. 1894, 220; Guebet, Compt. rend. 129, 61). Chlorine, led into fused acetamide, yields acetchloramide $CH_3{\cdot}CONHCl$; and bromine, in the presence of dilute aqueous potash or soda yields acetbromamide, which on distillation with concentrated aqueous soda is converted into methylamine (Hofmann, Ber. 15, 408); Buchner and Papendieck, Ber. 25, 1160; Selivanoff, Ber. 26, 423; François, Compt. rend. 147, 680; 148, 173; Behrend a. Schreiber, Annalen, 318, 371). Acetamide acts both as a base and an acid (Pinner and Klien, Ber. 10, 1896), combining with hydrogen chloride or nitric acid, and forming compounds in which a metal takes the place of one atom of hydrogen, as $C_2H_3O{\cdot}NHAg$ (Strecker, Annalen, 103, 321; Tafel and Enock, Ber. 23, 1550; Blacher, Ber. 28, 432; Hofmann and Bagge, Ber. 41, 312; Titherley, Chem. Soc. Trans. 1897, 467). According to Forster (Chem. Soc. Trans. 1898, 783), mercury acetamide is a powerful dehydrogenising agent and owing to its tendency to exchange its mercury for hydrogen when the latter is attached to nitrogen, particularly when hydroxyl groups are in proximity, it can be employed as a convenient means of detecting primary and secondary hydrazines and primary hydroxylamines. It has also a marked tendency to form additive compounds (Morgan, Chem. Soc. Proc. 1906, 23). The hydrogen in the NH_2 group has also been replaced by alkyl groups (Titherley, Chem. Soc. Trans. 1901, 396, 411, 413). Acetamide forms molecular compounds of the type $CH_3{\cdot}CONH_2,X$, where X = an organic or inorganic acid or an inorganic salt (Titherley, *l.c.*; Topin, Ann. Chim. Phys. [7] 5, 99). When acetamide is treated with formaldehyde, paraldehyde, or trioxymethylene, condensation products of the type $R{\cdot}NH{\cdot}CH_2OH$ are obtained; these products are of value as antiseptics and as solvents for uric acid (J. Soc. Chem. Ind. 1906, 283). Mono-, di-, and trichloracetamide (Willm, Annalen, 102, 110; Geuther, J. 1864, 317; Pinner and Fuchs, Ber. 10, 1066; Malaguti, Annalen, 56, 286; Cloëz, Annalen, 60, 261; Bauer, Annalen, 229, 165; Dootson, Chem. Soc. Trans. 1899, 171; Swartz, Chem. Zentr. 1899, [i.] 588; Clermont, Compt. rend. 133, 737). Bromo-dialkyl-acetamide (J. Soc. Chem. Ind. 1904, 1238) and other halogen derivatives have also been prepared (Selivanoff, J. Russ. Phys. Chem. Soc. 24, 132; Broche, J. pr. Chem. [2], 50, 97; Conrad, Ber. 29, 1042; Zincke and Kegel, Ber. 23, 230. Willstätter, Ber. 37, 1775; Steinkopf, Ber. 41, 3571; Swartz, *l.c.*; Francesconi, Gazz. chim. ital. 33, 226; Ratz, Monatsh. 1904, 25, 687; Einhorn, Annalen, 343, 203; Finger, J. pr. Chem. 1906, [ii.] 74, 153).

The acetamido β-naphthaquinones and some of their halogen derivatives which may be used in dyeing (Kehrmann and Zimmerli, Matis, and Locker, Ber. 31, 2405; Kehrmann and Aebi, Ber.

32, 932; Kehrmann and Wolff, Ber. 33, 1538) and other acetamide derivatives have been prepared (J. Soc. Chem. Ind. 1894, 60; Lumière, Bull. Soc. chim. 1903, iii. 30, 966; Ratz, Monatsh. 26, 1487; Miolati, Gazz. chim. ital. 23, 190).

Diacetamide $C_4H_7NO_2$, or $NH(C_2H_3O)_2$ and its derivatives (*see* Gautier, Z. 1869, 127; Hofmann, Ber. 14, 2731; Hentschel, Ber. 23, 2394; Curtius, Ber. 23, 3037; Mathews, Amer. Chem. J. 20, 648; König, J. pr. Chem. 1904, [ii.] 69, 1; Troeger, J. pr. Chem. 69, 347; *Triacetamide* $C_6H_9NO_3$, or $N(C_2H_3O)_3$ and its derivatives (*see* Wichelhaus, Ber. 3, 847).

ACETANILIDE $C_6H_5{\cdot}NH{\cdot}CO{\cdot}CH_3$, also known as *Antifebrin*, is prepared by heating together glacial acetic acid and aniline for some time.

For an account of its preparation on a manufacturing scale, *see* Müller, Chem. Zeit. 1912, 36, 1055: quoted by Cain, 'Manufacture of Intermediate Products for Dyes,' Macmillan & Co., p. 51.

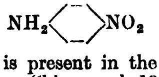
By substituting thioacetic acid for acetic acid the reaction proceeds more rapidly and at a lower temperature (Pawlewski, Ber. 1898, 661). Acetanilide may also be prepared by heating 1 part of aniline with 1¾ parts of dilute acetic acid or of crude pyroligneous acid under pressure at 150°–160° (Matheson & Co., Eng. Pat. 6220 and D. R. P. 98070; J. Soc. Chem. Ind. 1897, 559).

A simple laboratory method consists in gently boiling a mixture of equal weights of aniline and acetic acid with 2 3 p.c. of zinc chloride under a reflux condenser for 3 hours, when the whole is poured into water and the acetanilide re-crystallised from water. The use of pure aniline obviates the necessity of decolorising with animal charcoal.

The substance melts at 114·2° (Reissert, Ber. 1890, 2243), at 115°–116° (Hantzsch and Fresse, Ber. 1894, 2529), and boils without decomposition at 303·8° (corr.) (Pictet and Crépieux, Ber. 1888, 1111), at 305° (corr.) (Perkin, Chem. Soc. Trans. 1896, 1216); it is soluble in hot water, alcohol, or ether.

Acetanilide is hydrolysed at 100° by caustic potash or by hydrochloric acid, but not by sulphuric acid (Hantzsch and Fresse, Ber. 1894, 2529); it is rapidly decomposed by chromic acid, liberating carbon dioxide, and producing colouring matters (De Coninck, Compt. rend. 1899, 503). It reacts with zinc chloride at 180° with the formation of the yellow dye *flavaniline* (Braütigam, Pharm. Zeit. 44, 75).

By treating a solution of acetanilide in sulphuric acid with a mixture of nitric and sulphuric acids and hydrolysing the product, it is converted into *p*-nitroaniline



Acetanilide is present in the urine of cows (Petermann, Ann. Chim. anal. 1901, 165). It is largely used in headache powders and to adulterate drugs, such as phenacetin. It seems to act physiologically by the slow liberation of aniline, and may thus give rise to aniline poisoning. It is oxidised to some extent in the body to *p*-aminophenol. For methods of estimation *v.* Puckner, Ph. Rev. 1905, 302, and Seidell, Amer. Chem. J. 1907, 1091. The following reactions may be used for detecting its presence: (1) bromine water added to a solution of acetanilide in acetic acid gives a white crystalline precipitate of *p*-bromacetanilide, m.p. 167°; (2) evaporation of a solution to dryness with mercurous nitrate gives a green mass, changing to blood red on addition of a drop of concentrated sulphuric acid; (3) ferric chloride gives no blood-red colouration with acetanilide, thus distinguishing it from phenacetin and antipyrine.

Derivatives.—Chloracetanilides (Jones and Orton, Chem. Soc. Trans. 1909, 1056); Nitroacetanilides (Holleman and Sluiter, Rec. trav. chim. 1906, 208).

ACETIC ACID. *Acide Acétique. Essigsaure. Acidum Aceticum.* $C_2H_4O_2$ *i.e.* $CH_3{\cdot}COOH$, or $C_2H_3O{\cdot}OH$.

Acetic acid occurs in nature in the juices of many plants, especially trees, either as free acid or, generally, as the calcium or potassium salt; and, in the form of organic acetates, in the oils from many seeds. It is stated to be present in larger quantities when the plants are kept from the light. It exists in certain animal fluids; Béchamp states it to be a normal constituent of milk. Gmelin and Geiger have found it in mineral waters, doubtless from the decomposition of organic matter.

Being a very stable body both at the ordinary and at high temperatures, it is found as a product of the decomposition or destructive distillation of many organic substances. Acetic acid was first shown by Lavoisier to be formed by the oxidation of alcohol. Its true composition was ascertained by Berzelius in 1814, and in 1821 E. Davy (Schweigger's J., 1821, 1, 340) proved that it was formed, together with water, by the oxidation of alcohol, without the formation of carbonic acid as had been previously supposed. It was this observation which led Dobereiner (*ibid.* 8, 321) to explain acetic fermentation as a simple process of oxidation.

Preparation.—Acetic acid is produced by the oxidation, decomposition, and destructive distillation of many organic bodies. The greater part of that used in commerce is obtained by the destructive distillation of wood.

Hawley and Palmer (Eighth Int. Cong. Appl. Chem. 1912 [4] Orig. Comm. 6, 138) have shown that the temperature within the retort above 320° has but little influence on the yield of acetic acid obtained in the destructive distillation of wood. They obtained the following average amounts of 100 p.c. acid from samples of the body wood and slabs (*i.e.* body wood and bark together) of the hard woods commonly used for the distillation in U.S.A.: Birch, 6·50; beech, 5·55; maple, 4·95; red gum, 5·16; chestnut, 5·32; hickory, 4·61; and oak, 4·70 p.c., calculated on the dry weight of the wood.

Acetic acid may also be obtained by boiling sawdust with water under a pressure of 6 atmos. Under these conditions Bergström (Papierfabr. 1913, 11, 305) obtained from 1·17 to 1·37 p.c. of acetic acid, and 0·19 to 0·23 p.c. of formic acid from coniferous woods (spruce, pine), and more than twice as much acetic acid, and rather less formic acid from birch and other deciduous woods. Analogous results were obtained by destructive distillation of the woods, and, for this reason lime acetates made from the wood of deciduous trees contain less formic acid than those prepared from coniferous wood.

In Raisin's process (Fr. Pats. 446871 and 446878, 1911) sawdust is hydrolysed at about 150° by means of sulphurous acid and steam, and the acid vapours are condensed and neutralised with soda. Calvert (Eng. Pat. 10687, 1913) claims a method of producing acetic acid by the destructive distillation of coffee husks in a retort provided with a screw conveyor.

In 1910 the amount of acetate of lime produced in U.S.A. from hard woods was 152,779,000 lbs., and the amount of acetic acid in 1909 was 51,963,000 lbs., the bulk of which was used in the manufacture of dyes and paper (Palmer, Oil, Paint, and Drug Rep. March 9, 1914).

A method of obtaining acetic acid by the destructive distillation of coal, lignite, &c., has been patented (Behrens, Ger. Pat. 275049, 1913). Ethylenic compounds are isolated from the gases by means of sulphuric acid, mixed with carbon dioxide, and heated to about 400°. About 75 p.c. of the ethylenic compounds are thus converted into acetaldehyde, which is then oxidised to acetic acid (*vide infra*).

Manufacture of Acetic Acid from Alcohol.—Alcohol may be converted into acetic acid by powerful oxidising agents, such as chromic acid, nitric acid, &c. Advantage may be taken of the fact that spongy platinum or platinum black has the property of absorbing oxygen, and thus acting as a powerful oxidising agent. If spongy platinum be placed over a vessel of alcohol with free access of air, the platinum absorbs at the same time the oxygen and the alcohol vapour, which combine and produce acetic acid and water :—

$$\underset{\text{Alcohol.}}{CH_3CH_2OH}+O_2=\underset{\text{Acetic acid.}}{CH_3COOH}+OH_2$$

In addition to acetic acid, aldehyde (acetic aldehyde) is produced, which is intermediate in composition between alcohol and acetic acid. It is formed by the removal of two atoms of hydrogen from the alcohol and their replacement by an atom of oxygen :—

$$\underset{\text{Alcohol.}}{CH_3{\cdot}CH_2{\cdot}OH}+O=\underset{\text{Aldehyde.}}{CH_3{\cdot}CHO}+H_2O$$

In presence of excess of oxygen aldehyde forms acetic acid. Aldehyde is a very volatile liquid, and is liable to be lost before its conversion into acetic acid ; it is therefore necessary in all cases where acetic acid is produced by the oxidation of alcohol to allow free access of air.

This method produces a very pure acetic acid, but on account of the initial cost of the platinum (which, however, is not in any way injured by use) it is not extensively used on the manufacturing scale.

Numerous patents have been taken out for the oxidation of alcohol or acetaldehyde to acetic acid. In Behrens' process (Ger. Pat. 223308, 1908) alcohol is oxidised to aldehyde by the action of air in the presence of platinum as catalyst. The aldehyde is separated by fractional distillation, and, after the addition of dilute sulphuric acid to make it electrically conductive, it is electrolytically oxidised. The bulk of the acid produced may then be recovered by a single distillation in a column still.

In a later patent of Behrens (Eng. Pat 28839, 1910), the alcohol is oxidised by the catalytic action of zinc oxide at about 350°, and the aldehyde then oxidised by contact with oxygen in an absorbing tower.

According to another process patented by the Chem. Fabr. Griesheim-Elektron (Eng. Pat. 17424, 1911), acetaldehyde is oxidised by means of air in the presence of acetic acid or a chlorine derivative thereof, a catalyst, such as vanadium pentoxide, or uranium oxide, being also used to promote the reaction ; or the aldehyde may first be oxidised by excess of oxygen (Eng. Pat. 8076, 1912).

The addition of small amounts of manganese compounds promotes the oxidation, without the risk of explosion attending the use of compounds of vanadium, chromium, or cerium (Consortium Elektrochem. Ind. ; Fr. Pat. 460971, 1913).

By mixing the acetaldehyde with about 1 p.c. of ceric oxide or other catalyst, and treating it with oxygen under a pressure of about 2 atmospheres, or with air at about 5 atmospheres, about 95 p.c. of the theoretical yield of anhydrous acetic acid is obtainable (Farbenwerke vorm. Meister, Lucius and Bruning ; Eng. Pat. 10377, 1914).

The Badische Anilin u. Soda Fabr. (Ger. Pat. 294724, 1914) has claimed a process of oxidising acetaldehyde by means of air or oxygen in the presence of iron compounds and organic salts of alkalis, alkaline earths, aluminium or magnesium. The reaction is stated to take place rapidly, and without the aid of heat, whilst no per-acids are produced.

In Hibbert's process (U.S. Pat. 1230899, 1917), wood charcoal previously saturated with strong acetic acid is used as the contact material for the oxidation of acetaldehyde by means of oxygen.

Manufacture from Acetylene.—A French patent (360249, 1905) describes the preparation of acetic acid from acetylene. Acetylene is passed into a solution of a normal mercuric salt, which precipitates mercury acetylide. The liquid is then boiled, when aldehyde is formed and the mercuric salt re-formed. The aldehyde is then oxidised to acetic acid.

An electrolytic process of oxidising acetylene to acetic acid has been patented by the Farbenfabr. vorm. Bayer u. Co. (Fr. Pat. 467778, 1913), the acetylene being oxidised by the use of a solution of sulphuric acid or other acid as electrolyte, in presence of a mercury compound. In another patent by the same firm (Fr. Pat. 467515, 1914), the acetylene is passed through a solution of hydrogen peroxide, or a persulphate at about 30°–40°, in the presence of mercury or a mercury compound. The resulting liquid will contain about 25 p.c. of acetic acid.

The oxidation process may also be accelerated by the use of other catalysts in addition to mercury, with or without the simultaneous application of pressure (Fr. Pat. 471253, 1914).

Acetic acid may also be produced without preliminary isolation of acetaldehyde by oxidising acetylene in an organic acid medium, such as acetic acid, by means of oxygen, acting in the presence of the requisite quantity of water and of a catalyst, such as iron oxide or vanadium pentoxide. The best results are obtained by introducing the acetylene and oxygen alternately in small quantities into the acid medium (Chem.

Fabr. Griesheim-Elektron, Fr. Pat. 473158, 1914).

Acetic Acid by Fermentation Processes.—Several species of bacteria are capable of converting alcoholic liquids into acetic acid. The species first recognised, as forming films on sour wine and vinegar, was termed *Mycoderma* by Persoon, in 1822, although he did not associate them with the development of acidity. Even since it has been recognised that the pellicle was not the product of yeasts or mould-fungi the name has survived, and is still frequently used as a generic term for the acetic bacteria. The views of Stack, published in 1863, that the *Mycoderma aceti*, or 'mother-of-vinegar,' consisted of an aggregation of bacteria was not accepted in 1868 by Pasteur: but Cohn, in 1872, included these micro-organisms among the bacteria.

Hansen, in 1878 (*see* Compt. rend. Lab. Carlsberg, 1894 [iii.]; 1900 [v.]), isolated three species, which he termed *Bacterium aceti*, *B. Pasteurianum*, and *B. Kützingianum*, and showed that they differed from one another in form and in the nature of the pellicles which they produced when grown in alcoholic culture media.

Numerous other species of acetic bacteria have been described, such as *Bacillus xylinus* (Brown, J. Chem. Soc. 1886, 30, 432; Proc. Chem. Soc. 1887, 87); *B. oxydans*, *B. acetosus*, *B. acetigenus*, *B. curvus*, *B. xylinoides*, &c. (Henneberg, Centralbl. f. Bakt. 1909, 24, 13); and *B. rancens* (Beijerinck; Centralbl. f. Bakt. 1898, 4, 209). Although each of these differed in properties and in producing different involution forms, there is some reason for concluding that some, at least, of them are not distinct species, but varieties modified by their environment.

In 1906 Buchner and Gaunt (Annalen, 1906, 349, 140) separated an acetic enzyme by extracting the zoogloeal pellicle of 'mother-of-vinegar' with acetone. The preparations were capable of oxidising alcohol to acetic acid, and had also the power possessed by the living bacteria of oxidising propyl alcohol to propionic acid. An enzyme separated in this way from Hansen's *B. aceti* has been shown by Wieland (Ber. 1913, 46, 3327) to be capable of replacing palladium as a catalyst for the oxidation of alcohol into acetic acid.

For the production of acetic acid from alcoholic 'washes' by the action of living acetic bacteria, the liquid must contain a suitable proportion of nutrient substances (phosphates, nitrogenous substances), &c., and there must be a regulated supply of air (*see Manufacture of Vinegar, infra*).

For the manufacture of the so-called 'spirit acid,' a crude vinegar containing from 10 to 12 p.c. of acetic acid is first made by a fermentation process from an artificially prepared wash composed of potato spirit with nutrient substances. This is known as *Essigsprit* or *Spritessig*, and is a common commercial product. It is concentrated by neutralisation with lime, evaporation of the liquid to dryness, and distillation of the crude calcium acetate, as described below. Owing to its more pleasant aroma spirit acid of 80 p.c. strength fetches a higher price in the market than ordinary acetic acid.

A process of obtaining acetic acid by a fermentation process from the Japanese seaweed *Fucus evanescence*, has been described by Takahashi (J. Chem. Ind., Tokyo, 1916, 19, 30). The seaweed is mixed with water and 3 to 5 p.c. of lime, which is added in successive small quantities, and the mixture is kept at 30° for 2 weeks. The yield of acetic acid is increased by the addition of fucose.

Distillation of Acetic Acid.—The *concentrated* or *glacial* acid is usually prepared by the distillation of a dry acetate with an equivalent quantity of strong sulphuric acid, or acid potassium or sodium sulphate.

Sodium acetate is generally used. The anhydrous salt is fused on sheet-iron pans, 6 feet by 4 feet, care being taken that no sparks reach the dried salt, as it would then ignite and burn like tinder. The mass is cooled, broken into small lumps, and distilled with concentrated sulphuric acid. The first portion distilling contains the water, the later portion is collected and cooled; when crystals have formed the still liquid portion is removed, the crystals are melted and redistilled as before, producing the glacial acid.

When a solution of calcium chloride is mixed with a solution of calcium acetate, crystals of calcium aceto-chloride $CaC_2H_4O_2Cl5H_2O$ gradually separate. These crystals may be produced in comparative purity even when impure *brown* acetate of lime is used. To obtain acetic acid ordinary commercial or 'distilled' acetate of lime is mixed with the proper proportion of calcium chloride, and the solution is concentrated by evaporation until it crystallises; the mother liquor is poured from the crystals and concentrated with the production of a second crop of crystals; this is repeated until about four crops have been produced. The crystals are dissolved in water, filtered through animal charcoal, mixed with about 10 p.c. of calcium chloride, and recrystallised. The crystals are distilled with a mixture of 1 part sulphuric acid of sp. gr. 1·84 and 2 parts water, and the acetic acid concentrated in the usual way. The glacial acid may also be prepared by the distillation of di- or acid-acetate of potassium, which, when heated, decomposes into acetic acid and the normal potassium acetate. If ordinary acetic acid be heated with normal potassium acetate, the acid acetate is formed, and a weaker acid at first distils over; as the temperature rises, the diacetate begins to decompose, and the distillate increases in strength until the glacial acid passes over. When the temperature reaches 300° the distillate becomes coloured from the decomposition of the acid (Melsens, Annalen, 52, 274; Compt. rend. 19, 611).

In Chute's method of preparing acetate of lime the vapours from crude pyroligneous acid are brought into contact with a stream of water mixed with lime. The temperature of the liquid is kept at about 100° by the addition of quicklime (U.S. Pat. 939980, 1909).

Scott and Henderson (Eng. Pat. 6711, 1896) purify the crude acetates by boiling with sodium hypochlorite until nearly decolorised. The solution is then cooled and allowed to settle. The clear liquid is decanted and crystallised. The crystals are of great purity.

Another method of removing organic impurities is to boil the crude acetates with lime, an iron salt, and a bleaching agent (Zinkeisen, U.S. Pat. 1213724, 1917).

Scott (Eng. Pat. 12952, 1897) has patented a process which dispenses with lime in the manufacture of acetic acid. He distils the crude acid at 100°, and fractionally condenses the vapours. The acid collects mainly in the first portions.

Crude acetates may be decomposed with H_2SO_4 or HCl, and the acetic acid distilled *in vacuo* (Thompson, J. Soc. Chem. Ind. 1896, 357); or crude acetic acid may be treated with oxygen under pressure, filtered through charcoal and distilled over pure sodium acetate (Schmidt, Eng. Pat. 1896, 25190).

Hochstetter (J. Soc. Chem. Ind. 1902, 1469) prepares pure acetic acid by heating pure sodium acetate with dry HCl at 120°; whilst Plater and Syberg patented a process of obtaining acetic acid by the electrolysis of alkali acetates.

According to the patent process of Farbenfabr. vorm. Bayer u. Co. (Ger. Pat. 220705, 1907) the crude acetate is heated to about 130°, the pressure within the still reduced to about ½ atmosphere, and sulphuric acid introduced. The distillate is claimed to contain only traces of sulphur dioxide.

In Prager's continuous process (Fr. Pat. 449035, 1911) sulphuric acid is sprinkled progressively on the acetate in a series of compartments, the material being mechanically transferred from one compartment to the next, whilst the liberated acetic acid is condensed in the upper part of the apparatus.

Another method of distillation makes use of a hot rotating surface upon which a mixture of acetate and sulphuric acid is mechanically spread. The acetic acid is condensed, and the solid residue is removed from the hot cylinders by means of scrapers (Brauer, U.S. Pat. 1196329, 1916).

Aromatic or radical vinegar.—Before the discovery of pyroligneous acid strong acetic acid was prepared by the distillation of ordinary vinegar, or of crystallised verdigris, whence it was popularly known as *distilled verdigris.* This product, which was distilled from earthenware retorts, formed the *aromatic* or *radical vinegar* of the apothecaries, but the method is now obsolete. It owed its name to its pleasant odour, largely due to acetone, which is always produced when acetates of heavy metals are distilled, but camphor and essential oils were frequently added to increase or modify the smell. Commercial *aromatic vinegar* is now made by adding essential oils and spices to pure diluted acetic acid.

Concentration and Purification.—The acetic acid obtained by the distillation of crude acetates of lime is usually concentrated by the redistillation of united similar fractions in a column still, whilst organic impurities are oxidised by the addition of potassium permanganate or dichromate prior to the distillation.

According to a patent process of the Chem. Fabr. Griesheim-Elektron (Ger. Pat. 230171, 1909) anhydrous copper sulphate is used to dehydrate the acid during the distillation; whilst meta-phosphoric acid is used for the same purpose in another patent (Ger. Pat. 282263, 1914). Galitzenstein (A. angew. Chem. 1916, 29, 148) has described a patent process of obtaining glacial acetic acid from dilute acid by extraction with an immiscible solvent, such as dichloroethylene, and claims that 90 p.c. of the theoretical yield may thus be obtained.

In another process (Harburger Chem. Werke Schon u. Co., Ger. Pat. 292959, 1915) the dilute acid is treated with potassium acetate, and the resulting double compound of potassium acetate and acetic acid which separates from the solution is redistilled.

An electrolytic method of purification (French, U.S. Pat. 1104978, 1914) is based on the decomposition of impurities by means of an electric current, the strength of which is regulated to prevent material decomposition of acetic acid.

Formic acid and tarry matters may be removed by redistilling the crude acid with an equal weight of 70 p.c. sulphuric acid at about 130°, at which temperature formic acid is destroyed, whilst acetic acid is not appreciably attacked (A. Gorhan, U.S. Pat. 1210792, 1917).

Properties.—The strongest acid solidifies at 16·6° (Bousfield and Lowry, Chem. Soc. Proc. 1911, 27, 187) in tabular or prismatic glistening crystals. The glacial acid may be cooled to −10° without solidification, even when agitated, but on the addition of a crystal of the acid the whole solidifies and the temperature rises to 16·7°.

The specific gravity of the crystals at 15°/4° is 1·0607 (Mendeléeff, J. 1860, 7). They melt to a mobile colourless liquid of sp. gr. 1·0543 at 16°/4° (Petterson, J. pr. Chem. [2] 24, 301), 1·0495 at 20°/4° (Brühl), 1·05148 at 18°/4°, and 1·04922 at 20°/4° (Bousfield and Lowry, *l.c.*), which boils at 118·5° at 760 mm. (Perkin), 118·1° (corr.) (Thorpe and Rodger). The liquid is uninflammable, but the vapour burns with a blue flame producing water and carbon dioxide.

Boiling-point of Glacial Acetic Acid under various Pressures (*Landolt*).

Pressure	Boiling point.	Pressure.	Boiling point	Pressure.	Boiling point.
mm.	°C.	mm.	°C.	mm.	°C.
1160	132	560	109	60	48
960	126	360	96	30	31
700	119	160	73		

When passed through a red-hot tube only a small portion is decomposed, producing carbon, acetone, benzene, &c. The strong acid blackens when heated with concentrated sulphuric acid, evolving sulphurous and carbonic anhydrides.

Nitric and chromic acids have no action; for this reason acetic acid is frequently used as a solvent for organic substances such as hydrocarbons, which are to be subjected to the action of chromic acid. Chlorine under the influence of sunlight replaces a portion of the hydrogen, and produces *mono-*, *di-* and *trichloracetic acids.* Similarly, bromine produces *dibromacetic acid.*

Commercial acetic acid contains impurities which react with bromine and chlorine in the dark, whereas pure acetic acid is not attacked by these halogens in the dark. These impurities can be removed by distilling the acid over phosphoric oxide, only traces of acetic anhydride being formed in the process (Orton, Edward, and King, Chem. Soc. Proc. 1911, 27, 120).

Pure acetic acid is not decomposed by direct sunlight, which, however, effects the decomposition of acetaldehyde, with the liberation of methane and carbon monoxide. Direct rays from a mercury vapour lamp decompose both acetaldehyde and acetic acid, the latter yielding carbon monoxide and dioxide and 39 p.c. of combustible gases (Berthelot and Gaudechon, Compt. rend. 1913, 156, 68).

On the addition of water to the glacial acid heat is evolved and the density increases until 20 p.c. of water is present; from this strength to 23 p.c. of water the density remains stationary. Further dilution lowers the density, so that either dilution or concentration from this point will produce an acid of diminished density. An acid containing only 43 p.c. of acid has the same density as the glacial acid. This, together with the slight difference between the density of acetic acid and water, renders it impossible to determine, with any precision, the percentage of acid by means of the hydrometer.

No definite hydrates of acetic acid are known (De Coppet, Ann. Chim. Phys. [7] 16, 275; Colles, Chem. Soc. Trans. 1906, 1247), although the break which occurs in the curve of the solidification points at about 37 p.c. of water suggests the formation of a hydrate

$$C_2H_4O_2+2H_2O$$

The following table shows the density of aqueous acetic acid at 15° and 20° (Oudemans, Jahresber. Fortsch. Chem. 1886, 302):—

DENSITY OF AQUEOUS ACETIC ACID (OUDEMANS).

p.c.	Density		p.c.	Density		p.c.	Density	
	15°	20°		15°	20°		15°	20°
0	0·9992	0·9983	34	1·0459	1·0426	68	1·0725	1·0679
1	1·0007	0·9997	35	1·0470	1·0437	69	1·0729	1·0683
2	1·0022	1·0012	36	1·0481	1·0448	70	1·0733	1·0686
3	1·0037	1·0026	37	1·0492	1·0458	71	1·0737	1·0689
4	1·0052	1·0041	38	1·0502	1·0468	72	1·0740	1·0691

The addition of a small quantity of water lowers the melting-point of the glacial acid considerably, as shown by the table at top of p 16: Dahms (Ann. Chim. Phys. [7] 18, 141).

The tables on p. 16 of the solidification points of mixtures of acetic acid and water are of use in determining the strength of acetic acid.

Acetic acid is monobasic, but forms both acid and basic, as well as normal salts. It dissolves certain metallic oxides, as those of lead and copper, forming basic acetates.

The action of acetic acid on aluminium is a matter of technical importance, since aluminium stills are in use for distilling the acid. Alumi-

nium is dissolved by boiling 90 p.c. acetic acid with the formation of an insoluble gelatinous basic acetate $Al(O{\cdot}COCH_3)_2OH$, which probably acts as a protective coating upon the surface of aluminium plant. With the dilution of the acid the rate of the solution rapidly increases, and 90 p.c. acetic acid dissolves about 10 times as much aluminium in a given time as 99 p.c. acid, whilst dilute acid attacks the metal very rapidly. Slight variations in the strength often have a pronounced influence on the solvent action, the addition of 0·05 p.c. of water to a corrosive acid being sufficient in some cases to arrest the action (Seligman and Williams, J. Soc. Chem. Ind. 1916, 35, 88).

The most suitable metals for the construction of acetic acid plant are block tin and gun-metal containing a sufficient proportion of tin.

Acetic acid has a pungent sour taste, and when strong blisters the skin. The glacial acid has no action on litmus, but on addition of water becomes powerfully acid. It is not affected by the electric current, probably because a bad conductor, but when a little sulphuric acid is added the current decomposes it, producing, according to Renard (Ann. Chim. Phys. [5] 16, 289), carbon dioxide, carbon monoxide and oxygen. Alkali acetates when electrolysed are decomposed into hydrogen and alkali hydroxide which appear at the negative pole, and ethane and carbon dioxide at the positive pole.

Acetic acid mixes with alcohol and ether in all proportions. It dissolves resins, gelatin, fibrin, albumin, essential oils, &c. Phosphorus and sulphur are somewhat soluble in the warm acid.

Acetic acid is largely used in the preparation of the acetates of copper, aluminium, iron, lead, &c.; as pyroligneous acid in calico printing, and the curing of herrings, hams, &c.; in the preparation of varnishes and colouring matters; in the laboratory and certain industries as a solvent; for domestic use; in photography; and in medicine as a local irritant and to allay fever, and in the form of smelling salts.

Analysis.—Commercial glacial acid should contain not less than 98·9 p.c. of absolute acid. When crystallised it should not re-melt below 14·7°. If 9 volumes oil of turpentine be agitated with 1 volume of acid, no turbidity will be produced if the acid contain 97 p.c. or upwards. Acid of 99·5 p.c. produces no turbidity with any proportion of turpentine (Bardy, Chem. News, 40, 78).

A very delicate test for the presence of water is to mix the acid with an equal bulk of carbon disulphide in a dry tube, and warm with the hand for a few minutes; in presence of a trace of water the liquid becomes turbid.

The commercial acid may contain sulphuric acid, sulphates, sulphurous acid, hydrochloric acid, chlorides, nitrates, arsenic (derived from sulphuric acid), and copper, lead, zinc, iron, and tin derived from the vessels used in the manufacture.

The presence of sulphuric acid or sulphates is shown by the production of a white precipitate with barium chloride. To the filtered solution bromine or chlorine water is added, producing, if sulphurous acid be present, a further precipitate of barium sulphate. Hydrochloric acid and chlorides are detected and estimated by means of silver nitrate.

In testing for metals a considerable bulk of the acid should be evaporated; a few drops of hydrochloric acid are added, and a current of hydrogen sulphide passed through the liquid; a black or brown colouration or precipitate indicates lead or copper. Copper may also be detected in the evaporated liquid by the brown precipitate produced on the addition of potassium ferrocyanide, and estimated by electrodeposition. Iron may also be detected by the ferrocyanide test. To test for zinc, the solution, after the passage of hydrogen sulphide, is filtered, nearly neutralised with ammonia, and sodium acetate added, when zinc will be precipitated as white sulphide. For arsenic Reinsch's, Marsh's, or the electrolytic test may be used.

Small quantities of acetic acid may be recognised by neutralising the liquid with potassium hydroxide, adding arsenious oxide, evaporating to dryness, and heating the residue, when the characteristic smell of cacodyl is evolved.

To determine the free acetic acid in a solution it is usual to titrate a weighed quantity with sodium hydroxide solution standardised against acetic acid of known strength or hydrogen potassium tartrate (Stillwell and Gladding).

As indicator litmus may be used, but as it is rendered blue by the normal sodium acetate, it is preferable to use phenol-phthaleïn, to which that substance is neutral; this is also more sensitive, and, where coloured, the liquid may be considerably diluted without impairing the delicacy of the reaction.

To estimate small percentages of water in acetic acid, the solidifying-point may be determined and the percentage found by the tables before given.

Commercial glacial acetic acid usually contains formic acid in proportions of about 0·02 to 0·8 p.c. Methods of separating and estimating formic, acetic, propionic, and butyric acid in admixture are given in Zeit. anal. Chem. 1899, 38, 217. For the estimation of formic acid, Fincke (Apoth. Zeit. 1910, 727) boils the acid under a reflux condenser with sodium acetate and mercuric chloride, and separates and weighs the precipitated caramel. Another method has been based upon the fact that formic acid will expel acetic acid from acetates. The acid is neutralised with sodium hydroxide, evaporated, and the residue dried at 125°, and weighed. It is then evaporated with formic acid two or three times, and the residue again dried at 125°. The difference between the weights corresponds to the amount of acetic acid expelled. The results for formic acid are about 0·02 p.c. too high, and those for the acetic acid too low (Heermann, Chem. Zeit. 1915, 39, 124). According to the B. P. (1914) test the absence of formates is shown by the acid not darkening immediately when treated with ammonia solution and heated with silver nitrate solution.

Chapman (Analyst, 1899, 24, 114) describes a method for the estimation of *iso*valeric acid in acetic acid.

The presence of acetic anhydride may be ascertained by the red precipitate of amorphous selenium obtained on treating the acid with selenious oxide or sodium selenite, pure glacial acetic acid remaining clear in this test (Klein, J. Ind. Eng. Chem. 1910, 2, 389). Another sensitive test is based upon the fact that acetic anhydride reacts with certain aniline derivatives, notably 2 : 4-dichloro-aniline, to form insoluble anilides, which can be separated and indirectly estimated as chloroamine (Edwards and Orton, Chem. Soc. Proc. 1911, 27, 121).

Aceto-acetic acid may be detected by the violet colouration which it gives with sodium nitroprusside and ammonia, followed by insufficient acid to neutralise all the ammonia (Harding and Ruttan, Biochem. J. 1912, 6, 445).

The acetic acid in acetates may be estimated by distilling about 1 gram of the salt nearly to dryness with 10 c.c. of a 40 p.c. solution of phosphoric acid (free from nitric and other volatile acids); water is added and the distillation repeated to remove the last traces of acetic acid; the distillates are mixed and titrated as above with standard alkali. This method of distillation may also be used for highly coloured solutions of acetic acid where direct titration is not practicable; or the method of distillation with formic acid, described above, may be employed.

Most commercial acetic acid contains traces of tarry substances, though the proportion is much less in acids which have been purified by treatment with permanganate. The permissible limit for such empyreumatic substances in glacial acetic acid is prescribed by a B. P. (1914) test, according to which 2 c.c. of the acid should not decolorise within half a minute a mixture of 3 drops of a 1 p.c. solution of potassium permanganate and 10 c.c. of water.

Manufacture of Vinegar.

The term 'vinegar,' as its derivation implies, was originally applied to wine which had become sour, but is now used to describe all products made by the acetic fermentation of alcoholic liquids, the particular kind of vinegar being usually indicated by a prefix, such as 'wine vinegar,' 'malt vinegar,' 'cider vinegar,' or 'spirit vinegar.' The terms 'beer vinegar' and 'alegar,' which are to be found in the Acts of Parliament, are now obsolete.

From whatever material vinegar is derived the essentials of the process are the same. An alcoholic liquid of a suitable strength must be subjected to the oxidising action of acetic bacteria, in the presence of suitable nutrient substances, and of a regulated supply of air.

Wine vinegar. (Fr. *Vinaigre*; Ger. *Weinessig.*) In the wine district of Orleans, which has been celebrated for centuries for the production of wine vinegar of fine aroma and flavour, the original method was to add a little vinegar to sour wine, and to expose the mixture to the air in open casks. This primitive method was still in use as late as 1876, although most vinegar makers in France had long discarded it for the 'Orleans process,' in which the wine is acetified in a series of casks packed with shavings and provided with holes for the admission of air.

Full-bodied wines are selected for the manufacture, and if they contain above 10 p.c. alcohol they are suitably diluted with weaker wines. The wine, before being fermented, is usually left for some time in contact with beech shavings, on which the lees are deposited, rendering the wine brighter. A certain amount of extractive matter is, however, necessary for the development of the bacteria, and if the wine be old and the matter deposited, the fermentation is much retarded. Wine one year old is preferred.

The 'Vinaigrerie' is usually a building of southern aspect; the rooms in which the process is conducted are low-roofed, and, in order to admit air, the walls are provided with openings which can be closed when the temperature is not sufficiently high.

Sets of casks of well-seasoned oak, bound with iron hoops, each holding from 50 to 100 gallons are supported on their sides in rows about 18 inches from the floor, one set being frequently placed above another, in which case hose nearest the roof are found to work most rapidly. Each cask is bored with two holes in he front end, a larger one, the 'eye,' for the addition of wine or the removal of vinegar, and a small one for the admission of air.

When first used the casks are thoroughly scalded with boiling water to remove extractive natter, filled to a third of their capacity with boiling strong vinegar, and allowed to stand for eight days; from that time wine is added in charges of about 10 pints every eight days until he casks are not more than two-thirds full; after a further interval of 14 days a portion, varying from 10 gallons to half the total bulk, s drawn off and the periodical addition of the wine continued. The temperature of the hambers should be about 25°, and is kept up when necessary with a stove. In order to certain if the fermentation is completed at he end of the usual time, the workman plunges white spatula into the liquid; if a reddish roth adheres, more wine is added and the emperature raised; a white froth indicates he completion of the process. More than eight lays are sometimes required to complete the xidation, in which case stronger wine and a igher temperature may be used. The sluggishess may, however, be due to the casks becoming oul, which occurs usually after about six years' working. The deposit of argol, yeast sediment, &c., is thoroughly removed, and the casks leansed and recharged with hot vinegar as in he case of new casks. Good casks will often ast twenty-five years.

When working satisfactorily each cask will roduce about twice its capacity of vinegar nnually.

Before storing, the vinegar is usually passed hrough the 'rapes' where it is 'brightened' nd the acetification completed.

The drawback of the Orleans process is that is excessively slow, but, on the other hand, he slow working promotes the formation of the sters to which French wine vinegar owes its eputation.

In other parts of France and in Holland and n the Rhine the following method is used. he wine is placed in two large upright tuns bout 9 feet high and 4 feet wide, open to the ir. Each tun has a perforated false bottom bout 12 inches above the true bottom; on this placed a quantity of vine cuttings, stalks, c., so as to expose a large surface for the formaon of the fungus. One of the vats is half, and e other completely, filled. The acetification progresses more rapidly in the former; this, after twenty-four hours, is filled from the full cask, in which the action then increases. This alternate transference is continued daily until the acetification is complete. The most favourable temperature is about 24°. The vinegar is run off into casks containing chips of birch wood on which the lees settle, and in about fourteen days being thus clarified is stored in close casks for the market.

This method is described in a letter published by the Royal Society in 1670 (Phil. Trans. Roy. Soc. 1670, v. 2002).

In Claudon's process of acetification the wine is fermented in a series of superposed closed shallow vessels, so constructed that air currents can be conducted over the surface of thin layers of the wine. This is more rapid than the ordinary Orleans process.

Malt vinegar (*Malzgetreide Bieressig*). The vinegar industry in this country has developed out of the brewing industry, and the connection between the two industries is clearly shown in the Revenue Act of Charles II. (1673), in which the so-called 'vinegar beer' produced in the 'common breweries' was charged a duty of 6*d*. per barrel as against 1*s*. 3*d*. upon six-shilling beer. It is very probable that most of the vinegar first made in England was a product of the brewery which had become accidentally sour, and was then exposed to the air to complete the acetification. The manufacture of vinegar as a separate industry appears to date back not much further than the early part of the seventeenth century, and the first 'vinegar yard' in London was established about the year 1641. But long before any vinegar brewer had become established in this country 'beer vinegar' or 'alegar' was made in many a household by the simple process of adding the so-called 'vinegar plant' (*i.e* the zoogloeal form of acetic bacteria) to ale which had turned sour.

The process of making vinegar on a manufacturing scale was probably introduced into this country from France, and the methods which had been found to give the best results in the production of wine vinegar were adapted to the acetification of the English product from beer or ale. The methods of brewing used by the brewer and the vinegar maker then began to diverge, and the differences are now well marked, being based upon the different qualities desired in the alcoholic product.

Preparation of the Wort.—In preparing the fermented alcoholic liquid from malt, or malt and grain, either a mash-tun process or a conversion process is employed. The mash-tun is essentially the same as the brewer's mash-tun, with the exception that it has both rakes and sparge and is provided with a steam coil below the perforated false bottom.

The chief aim of the vinegar maker is to obtain as high a yield of alcohol as possible, and he therefore uses a malt of fairly high diastatic capacity, and makes the mash at such temperatures as will yield a wort which will attenuate well. In some works the first mash is made with water at about 65°, which gives a temperature of a little over 60° in the mash tun. After raking for an hour or two, the wort is drawn off, and a second mash made at the same temperature, and finally the 'goods' are sparged with water at about 65°-71°. In other vinegar breweries the initial mash is made with water at about 54°, and the temperature gradually raised to 65°. A second mash is made at about 65°, and the final sparging at 65°-71°. This method ensures a better yield of a more fermentable wort. It is a common practice to use raw grain, such as barley, flaked maize, or flaked rice in admixture with the malt, the diastase of the latter being sufficient to hydrolyse the whole of the starch present.

If crude rice be used a preliminary treatment, such as cooking with steam under pressure, is necessary to rupture the starch granules.

In other vinegar works the starch of the cereals used is hydrolysed by a dilute mineral acid instead of by the diastase of malt. For this purpose the grain, usually maize or rice, is mixed with dilute (about 3 p.c.) sulphuric acid in a closed iron vessel and heated for several hours by steam under pressure, until a sample of the liquid is free from unconverted starch. The contents of the converter, which now consist largely of an acid solution of dextrose, are neutralised with lime and chalk, and then drawn off, cooled, and fermented in the same way as the wort from the mash tun.

From 6 to 7 tons of grain can be treated in a converter of average size, and the whole of the starch present will be hydrolysed within 3 hours when heated with steam under a pressure of about 10 lbs.

Although most of the calcium sulphate separates from the liquid, sufficient will remain in solution to afford an indication that the vinegar was probably prepared by a conversion process.

Fermentation of the Wort.—The wort obtained by one of the above described processes is cooled in a refrigerator, and pitched with yeast as in a brewery, with the difference that a much higher temperature is permissible than in the case of beer. In fact, with some yeasts it is advisable to have a temperature as high as 21°-24° to check the growth and obtain better attenuation. If malt with good diastatic power has been used, and the wort has been prepared at a low temperature, there is usually no difficulty in attenuating a wort from a sp.gr. of 1·055 to about 1·001. In certain cases vigorous aeration of the fermenting wort is also required to effect this purpose. After fermentation, which will be complete on the third day, the *gyle* or *wash*, as it is now termed, is allowed to stand for a few days for the yeast to subside, and is then pumped into store vats until required for the further fermentation process.

Acetification of the Gyle.—The secondary or acetic fermentation of the alcoholic liquid is effected by the action of one of the species of acetic bacteria, mentioned above, which under regulated conditions of temperature and aeration oxidise the alcohol first to aldehyde and then to acetic acid, the relative proportions of the three substances present in the liquid at any given stage of the process depending largely upon the conditions of the fermentation. In addition to aldehyde and acetic acid, acetal $CH_3 \cdot CH(OC_2H_5)_2$ is also formed through the interaction of the aldehyde with the alcohol, and traces of ethyl acetate and other esters, succinic acid and other acids, are produced, their nature and quantity depending upon the nature of the substances (sugars, dextrins, &c.) in the gyle. Brown (J. Chem. Soc. 1886, 49, 172) showed that *B. xylinus* ('the vinegar plant') had the power of transforming lævulose into cellulose.

Theoretically 46 parts of alcohol should yield 60 parts of acetic acid, but in practice there is always a loss of at least 10 p.c., and in many factories very much more. This loss is due partly to volatilisation of aldehyde and esters, and partly to the fact that acetic bacteria are able to decompose the acetic acid which they have produced, and if the aeration of an acetifier is irregular the production and decomposition of acid may proceed simultaneously in different parts of the apparatus.

Should insufficient air be supplied to an acetifier, the bacteria (in this country usually Brown's *B. xylinus*) form themselves into the zoogloeal condition, which is a tough gelatinous pellicle which sooner or later chokes the acetifying medium and arrests the process. On the other hand, excess of air promotes loss by volatilisation and oxidation. The second essential is a suitable temperature for the action of the bacteria. On the Continent the acetifiers work best at a temperature of about 85° to 90° F., whereas in England the optimum temperature is 108° to 110° F., which may be partly due to acclimatisation of the bacteria. Sunlight checks the acetification process, and hence the early vinegar makers took pains to exclude all daylight from their apparatus, but under the present conditions of working this is unnecessary, for the amount of light which can find its way through the aeration holes of the large acetifiers now in use is practically negligible.

The methods of acetification first used in this country were essentially the same as those used in the earlier methods of making wine vinegar (*vide supra*), the casks being placed on their sides in a room at about 24°, or placed in rows in a 'vinegar field.' The bung holes of the casks were left open; at each end near the top holes were left for the circulation of the air. Each day a portion of the liquid was removed from a full cask and replaced by an equal quantity of liquid in a more advanced stage of fermentation, until, after about three months, the process was complete. This method of acetification, which was known as 'fielding,' has been obsolete for many years.

Quick vinegar process (*Schnellessigbereitung*). The introduction of the so-called 'quick' process of making vinegar is attributed to Schützenbach, although in its main essentials it is only a development of the method of acetification used in certain wine-vinegar factories in France in 1670 (*vide supra*). The main features introduced by Schützenbach were the use of a larger vessel, and of mechanical means for the repeated distribution of the gyle over the acetifying medium.

The acetifiers introduced into British vinegar works about sixty years ago, at the time when 'stoves,' as the acetifying rooms were called, replaced the vinegar fields, were large vats taking a charge of about 3000 gallons. About two-thirds of the way up was a perforated false bottom upon which beech shavings or twigs were loosely packed, and upon these the bacteria developed while air currents were admitted through a number of holes bored in the side of the vat just below the false bottom, and escaped through small holes in the top of the vat.

The gyle was distributed in a fine shower over the shavings, by means of a revolving sparge, and trickling downwards encountered the currents of air, which enabled the bacteria to acetify a small amount of the alcohol. The liquid from the bottom of the vat was then pumped up again, to be once more distributed over the shavings, and so on continually for two or three weeks until nearly the whole of the alcohol had been transformed into acetic acid. The drawback of shavings as a medium was that they soon became clogged with mother-of-vinegar in places, so that the air was no longer evenly distributed throughout the medium, but made channels in various places.

For this reason, in many factories shavings were replaced by basket work in superposed layers, and these worked much more regularly, and could be more easily cleaned. In other works porous lumps of charcoal, which had been washed, first with acid and then with water, were used as the acetifying medium, and promoted the acetification by the absorption of oxygen.

In Wagenmann's 'graduator,' which was devised about 1830, a perforated shelf was fixed about 5 inches from the top of the vat, and through each of the 400 holes cotton or hemp wick was suspended to guide the liquid downwards on to the shavings.

In this apparatus was foreshadowed the idea utilised in Luck's acetifier, in which the shavings were replaced by bunches of cords stretched between the distributing tray and the false bottom. This type of acetifier works regularly and is easily cleaned.

Another type of acetifier, patented by Leaker, is made up of a series of rectangular compartments containing shelves of absorbent woven material which act as the acetifying medium, whilst a fan is employed to draw the evaporated products into a condensing coil.

In Singer's acetifier several rectangular compartments are superposed, and each of them contains a series of wooden tubes packed with shavings or charcoal, and the wash is acetified as it trickles successively through these tubes from the top to the bottom of the apparatus.

Bersch's apparatus is also rectangular in form, and is packed with a series of frames filled with slats of wood with a space of about ¼ inch between each slat. These frames are superposed, with the slats running in alternate directions, and the wash is acetified as it trickles down through the successive layers of frames. It is claimed that this acetifier gives a theoretical yield of acetic acid, owing to its perfect system of aeration, but in the writer's experience, this is not the case under English methods of acetification, the best yield obtained being 0·96 p.c. of acetic acid from 0·97 p.c. of alcohol in 24 hours (J. Inst. Brewing, 1917, 23, 362).

Other modifications of the acetifier make use of a siphon within a tank for distributing the wash over a perforated tray, whilst the air required in the siphon tank is drawn from the space at the top of the acetifier, so that the aeration of the apparatus remains under control.

The working of acetifiers is liable to be disturbed by the development of vinegar eels (*Leptodera oxophila*), although these cause less trouble in this country than on the Continent, where acetification is effected at a lower temperature. Another enemy of the acetification process is the 'vinegar mite,' which, if allowed to develop, will eventually stop the process.

The use of pure cultivations of specific acetic bacteria has been shown to increase the speed of acetification and improve the flavour of the vinegar, but so far no attempt has been made to make use of them in this country, where insufficient importance is attached to the flavour of vinegar (Henneberg, Zeit. für Spiritusind. 1898, 180, and Cent. Bakt. 1905, 14, 681; Rothenbach, Woch. für Brau. 25, 445, and Deuts. Essiggind 1905, 9, 217, and Woch. fur Brau. 1906, 23, 260; Mayer, Zeit. fur Spiritusind. 21, 334; Büchner and Gaunt, Annalen, 1906, 349, 140).

The Group System.—Acetic bacteria are sensitive to the action both of alcohol and of acetic acid, being killed by alcohol of 10 p.c. strength, and weakened by alcohol of much lower strength. Their greatest vital activity is attained when the wash reaches an acidity of between 2 and 3 p.c. of acetic acid, and their acetifying power becomes less as the proportion of acid rises. It is possible, however, to acclimatise them to resist the action of more alcohol and acetic acid than under normal conditions, and on this fact is based the *group system* of acetification.

Since a 12 p.c. vinegar could not be obtained directly from one acetifier, the acetification of such concentrated products as *Essigsprit* (*vide supra*) is effected in three groups of acetifiers. The first group is charged with a wash which will yield a vinegar of about 6 p.c. strength, and this is fortified with an alcoholic wash (usually grain or potato spirit) in sufficient quantity to yield a vinegar containing 9 to 10 p.c. of acetic acid in the second group of acetifiers; and the vinegar from these is again fortified before being transferred to the third group of acetifiers for the completion of the acetification.

Filtration and Storage of Vinegar.—As soon as the vinegar has reached its maximum acidity it is at once pumped into store vats, for it is essential that it should not be left in the acetifiers, where the bacteria would oxidise the acetic acid (*vide supra*).

In some works the vinegar is clarified by the addition of potassium ferrocyanide. It has been shown by Harden that there is a possibility of hydrocyanic acid being liberated in the presence of excess of the precipitant (L. G. B. Report on Vinegar, 1908, p. 27).

After remaining in the store vats for as long a time as possible, preferably not less than three months, the crude vinegar is filtered. The filters used in most vinegar works are known as *rapes*, owing to the fact that raisin stalks were at one time—and to a limited extent are still—used as part of the filtering medium. Filter beds composed of layers of sand, shingle, and beech chips are used for the rapes in other factories, whilst in others again the rapes have been entirely superseded by filters containing paper pulp as the filtering medium.

After being filtered the 'bright' vinegar is again stored to develop an aroma through the combination of acetic acid with traces of residual alcohol, and is then diluted to the strength required by the trade.

These different strengths, technically known as 'trade numbers,' are termed Nos. 16, 18, 20, 22, and 24. It is sometimes asserted that these numbers denote the number of grains of sodium carbonate neutralised by 1 oz. of the vinegar, but both the tradition of the industry and contemporary evidence show that they indicated the price in pence per gallon at which the vinegar was sold (Penny Magazine, 1842, p. 430; Tomlinson's Cyclopædia of Useful Arts, 1854, p. 7; J. Soc. Chem. Ind. 1918, 148 R).

The trade numbers would thus originally be analogous to the term 'six ale,' meaning 'six-shilling ale.'

Before being sent out to the trade vinegar is frequently coloured to a dark shade by the addition of caramel.

Distilled Vinegar.—In the early method of preparing *aromatic* or *radical vinegar* (*vide supra*), vinegar was distilled in a retort at the ordinary pressure, but in the modern process the distillation is effected at a lower temperature under reduced pressure, and can thus be carried very much further without risk of burning the solid residue, and flavouring the distillate.

The small stills commonly used for this purpose are made of gunmetal lined with tin, and are heated by a steam jacket. The outlet pipe from the still is connected with a tin coil immersed in a vessel of running water, and delivers into a receiver in which is a pipe connected with a vacuum pump. The still takes a charge of about 100 gallons, which is distilled under a reduced pressure of about 20 inches until only a semi-solid mass resembling treacle remains in the still.

The distillate is sold under the names of *distilled malt vinegar, white vinegar* and (incorrectly) *white wine vinegar.*

In addition to wine and malt, vinegar is prepared from many other substances. *Cider vinegar* is of a yellowish colour, sp.gr. 1·013 to 1·015. It contains 3½ to 6 p.c. acetic acid, and on evaporation leaves a mucilaginous residue, smelling and tasting of baked apples, and containing malic but not tartaric acid. The residue varies from 1·5 to 1·8 p.c. Genuine cider vinegar is distinguished from spurious cider vinegar by the residue, which consists of glycerol, albuminous matters, gums, malic and other organic acids and mineral matters. They have no rotation and little cupric reducing power after the usual clarification with basic lead acetate solution. Acetylmethyl carbinol is a characteristic constituent of cider vinegar. The ash of a pure cider vinegar amounts to not less than 0·25 p c., consisting mainly of potassium oxide, with small quantities of alumina, lime, magnesia, sulphate, and phosphate, variable amounts of carbonate, and complete absence of soda. Spurious cider vinegars leave a molasses-like residue and an ash with a large percentage of lime or soda (Doolittle and Hess. *See* also Smith, J. Amer. Chem. Soc. 1898, 20, 3; Leach and Lythgoe, *l.c.* 1904, 26, 375; Van Slyke, New York Agric. Exp. Stn. Bull. 1904, 258, 439; Ladd, N. Dakota Exp. Stn. Bull. 32, 278). Cider vinegar made by the 'quick' process contains on the average 5·7 p.c. of acetic acid, and 0·4 p.c. of alcohol. The total solids, ash and glycerol are substantially the same as in the cider from which the vinegar was prepared (Tolman and Goodnow, J. Ind Eng. Chem. 1913, 5, 928). *Perry* and *crab-apple vinegar* are used in Wales and Monmouthshire, and possess characteristic properties.

Glucose or *sugar vinegar* is prepared by the conversion of amylaceous substances into sugar, by the action of dilute acids, followed by fermentation and acetification. It contains dextrose, dextrin, and very often gypsum, with hardly any proteins. The ash is composed mainly of potassium salts, is rich in sulphates, and in the case of cane-sugar vinegars, readily fusible (Allen's Comm. Org. Anal. 1909, 498). It is stated to be used for adulterating wine vinegar. It can be distinguished from other vinegars by the addition of 3 or 4 volumes strong alcohol, which produces a slimy precipitate of dextrin. Barium chloride usually gives a copious precipitate, due to the sulphuric acid used in the manufacture of the glucose.

Vinegar is now made from skim milk by addition of sugar, neutralisation with chalk, pitching first with yeast and then with *Mycoderma aceti* (Barbier, Fr. Pat. 334071, 1903).

Date vinegar is made by the consecutive alcoholic and acetic fermentations. Compared with malt vinegar, it is low in phosphoric aci and nitrogen.

Wood 'vinegar,' as its name indicates, i nothing more than dilute acetic acid coloure with caramel, and sometimes flavoured wit brewed vinegar or with acetic ester. It cor tains about 0·2 to 0·6 p.c. of total solids, 0·02 t 0·04 p.c. of ash, and traces of phosphoric aci and nitrogen.

Properties.—Malt vinegar is a brown liquid of a characteristic odour due to the presence, in addition to the acetic acid, of acetic and other esters. Acetic ester is sometimes added in small quantity to increase this aroma.

The addition of 1 part sulphuric acid to 1000 parts vinegar was permitted by an Excise Act of George III. of 1818, but this Act has long been repealed. Such addition is quite unnecessary, and is probably never made at the present time.

Malt vinegar usually contains alcohol, dextrin, sugar, and extractive matter, acetates, chlorides, and sulphates, and on evaporation and ignition leaves a residue containing much phosphate.

Analysis of typical vinegars sold as 'malt vinegar' are given in the table at top of p. 22.

Of these samples Nos. I. and II. show the normal figures for barley malt vinegar. No. III. was said to contain products of cereals other than barley, whilst No. IV. was made from a mixture of rice and green malt, the former being responsible for the low phosphoric acid, and the latter for the high nitrogen. No. V. contains abnormally low solid matter, and No. VI. was made by the conversion process.

Wine vinegar varies in colour from pale yellow to red; that made from white wine is most esteemed; it usually has an alcoholic odour. Its sp.gr. is 1·014 to 1·015; it contains from 6 to 12 p.c. acetic acid. A litre (1·76 pint) of Orleans vinegar usually saturates 6 or 7 grams (92 to 108 grains) of pure dry sodium

No.	Sp gr. at 15 5°.	Acetic acid.	Total solids.	Ash.	P_2O_5.	Nitrogen.	P_2O_5 on original solids.	Nitrogen on original solids.
		p c.	p c.	p.c.	p c.	p c.	p c.	p c.

carbonate. On evaporation the total extract varies from 1·7 to 2·4 p.c., of which 0·25 p.c. is usually potassium tartrate, a salt peculiar to wine vinegar. The residue, with the exception of the tartar, should dissolve in alcohol.

The proof vinegars of various countries differ considerably; the minimum of acetic acid allowed by the various Pharmacopœias is—France, 8 to 9 p.c.; Germany and Austria, 6 p.c.; Belgium, 5 6 p.c.; Russia, 5 p.c.; United States, 4·6 p.c. Vinegar is no longer official in the British Pharmacopœia. The bulk of the vinegar sold in this country is of a strength just over 4 p.c. A standard was fixed by the Society of Public Analysts in 1876 of a minimum of 3 p.c., and this being accepted by the trade, became in practice the legal standard. In 1912 the Local Government Board recommended the adoption of a 4 p.c. standard, but no statutory force has been given to this recommendation.

Analysis of Vinegar.

Acidity.—This is usually estimated by titration with standard alkali, with phenolphthalein as indicator. In the case of dark samples caramel may be precipitated by means of fuller's earth and an aliquot part of the filtrate titrated. 'Spotting' tests with litmus as indicator give results about 1 p.c. lower in terms of *N*/2 alkali solution than direct titration with phenolphthalein as indicator (Brode and Lange, Arb. Kaiserl. Gesundheitsamte, 1909, 30, 1).

Total solids.—A measured quantity is evaporated and the residue dried to constant weight at 100°. Constant shaking during the evaporation is necessary to expel the acetic acid, and a final titration of the acidity of the residue is advisable.

Alkalinity of the ash.—This may afford an indication of the probable origin of the vinegar, a glucose product, for instance, showing a low proportion of potassium oxide owing to the mineral acid used for the hydrolysis having combined with part of the bases. Variations in the results given by different types of vinegar are seen in the following results:—

	Vinegar from grain and malt.	Grain and sugar	Rice.	Sugar.
Alkalinity at K_2O per 100 parts of vinegar	0·091–0·118	0·03	0·013	trace

(Allen, Analyst, 1894, 19, 15).

Free mineral acids.—These are seldom, if ever, added to vinegar at the present time. They may be detected by means of 0·1 p.c. methyl violet solution, which is not affected by acetic acid, but is changed to blue or green by mineral acids (Hilger, Arch. Pharm. 1876, 193). A method of detecting and estimating free sulphuric and other acids was based by Hehner on the fact that vinegars containing acetates or tartrates cannot contain free mineral acid, and since on igniting these salts they are decomposed into carbonates, an examination of the ash of the vinegar will afford an indication of the presence of free acid (Analyst, 1877, 1, 105). A later method devised by Richardson and Bowen (J. Soc. Chem. Ind. 1906, 25, 836) enables an estimate to be made of the amount of sulphuric acid originally added to a vinegar.

Combined sulphuric acid. — Commercial samples usually contain from about 0 03 to 0·17 p.c. of sulphuric acid in the form of sulphates, quantities in excess of the lower figure usually being due to the vinegars having been made by the conversion process.

Added acetic acid.—No direct test for added acetic acid has been devised, and an inference is usually drawn from the deviation of the figures from those normally given by a vinegar brewed from barley malt. Fincke's test for formic acid, which is usually present in acetic acid (*vide supra*), is untrustworthy, since formic acid is also a normal constituent of grain and wine vinegars.

Phosphoric acid.—The ash from 10 c.c. of the vinegar is dissolved in dilute nitric acid, and treated with a large excess of molybdic reagent. The yellow precipitate is washed twice by decantation with cold water, dissolved in ammonia solution, and the solution evaporated. The weight of the residue multiplied by 28·5 gives the amount of phosphoric acid P_2O_5.

Nitrogen is conveniently estimated by Kjeldahl's method in 10 to 25 c.c. of the vinegar. For comparing the results both of phosphoric acid and nitrogen in vinegars of different strength Hehner's method of expressing them in terms of 'original solids' is a convenient though empirical, method (Analyst, 1891, 16, 92; *ibid.* 1893, 18, 245).

Optical Standard for Malt Vinegar.—The U.S.A. Dept. Agric. (Circular No. 19, 1906) stated that vinegar made from barley malt or cereal was dextrorotatory, but Chapman (Analyst, 1912, 37, 123) showed that the proteins and their hydrolytic products may cause a vinegar to show a lævo-rotation.

Caramel.—Added caramel may frequently be precipitated by the addition of fuller's earth, but the test is not always satisfactory, since the amount removed varies with the character of the earth (Dubois, J. Amer. Chem. Soc. 1907, 29, 75). A method of precipitation with tannin is recommended by Lichthardt (J. Ind. Eng. Chem. 1910, 2, 389), but has the drawback that proteins and iron are also precipitated by tannin. Amthor has based a method of detecting caramel on its precipitation by paraldehyde (Zeitsch. anal. Chem. 24, 30).

Metallic Impurities.—The chief metallic impurities to be looked for in vinegar are iron, copper, lead, and tin. The presence of iron may be detected by adding potassium ferrocyanide directly to the vinegar. For the detection of traces of the other metals the methods (suitably modified) described under AERATED WATERS may be used, whilst arsenic may be detected and estimated by the official method of the Conjoint Committee of the Soc. Chem. Ind. and Soc. Public Analysts (Analyst, 1902, 27, 48).

Formic acid in distilled vinegar or spirit vinegar may be estimated by the method recommended by Ost and Klein (Chem. Zeit. 1908, 32, 815). The acid is neutralised with alkali and titrated with permanganate. Other substances which reduce permanganate must be absent, which renders the method inapplicable to ordinary malt and grain vinegars.

Oxalic acid may be estimated by concentrating the vinegar and then boiling with calcium acetate solution.

Potassium hydrogen tartrate is estimated by titration against $N/2$ alkali, and tartaric acid by conversion to potassium hydrogen tartrate and subsequent titration (Zeitsch. anal. Chem. 1908, 47, 57).

(For the estimation of methyl alcohol in vinegar, *see* Ann. Chim. anal. 1901, 6, 127 and 171.)

Cayenne pepper, ginger, and other flavouring matters may be discovered by neutralising and tasting the vinegar.

Chevallier has found fuchsine in French wine vinegars. C. A. M.

METALLIC ACETATES.

Aluminium acetates.

The triacetate or normal acetate $Al_2(C_2H_3O_2)_6$ is not known. A solution corresponding to this compound, but which appears to be a mixture of the diacetate and acetic acid, is the only acetate of commercial importance. It is known as 'red liquor' or 'mordant rouge,' and is largely used in dyeing and calico-printing, especially for the production of red colours, madder reds and pinks (whence its name of red liquor); for the production of dense lakes, and for waterproofing woollen fabrics. It is prepared by several methods

A solution of alum is added to acetate of lime liquor. The lime is precipitated as sulphate, its place being taken by the aluminium, with the formation of aluminium acetate; ammonium or potassium sulphate (according to whether ammonium or potassium alum has been used) is produced at the same time. The mixture is agitated and allowed to settle, and a small quantity of the clear fluid removed and tested by the addition of alum; if a precipitate forms sufficient alum has not been used and more must be added. The solution is filtered, concentrated to a specific gravity of 1·087 to 1·10, and allowed to deposit any calcium sulphate still present. Calcium sulphate, being slightly soluble in water, is contained in the liquid in small quantity, and diminishes the brilliancy of the colours produced. By the substitution of lead acetate for the calcium acetate a better product is obtained. For this purpose 100 lbs. alum are dissolved in 50 gallons water, and treated with 100 lbs. finely-powdered lead acetate with constant stirring; or, using the same quantities, 10 lbs. crystallised sodium carbonate are added before the acetate of lead; or, to 100 lbs. alum in 50 gallons water 6 lbs. of carbonate are added in small portions, followed by 50 lbs. of lead acetate. The addition of the carbonate is made with a view to the production of a basic aluminium sulphate in addition to the acetate, and as the sulphate assists the mordanting, less acetate is required. The solutions are allowed to settle and decanted. They contain the aluminium acetate mixed with basic aluminium sulphate and alkaline sulphate.

An aluminium sulpho-acetate appears to act satisfactorily. It is prepared by mixing (1) 453 lbs. ammonium alum (or 383 lbs. aluminium sulphate), 379 lbs. lead acetate, 1132 lbs. water; or (2) 453 lbs. alum (or 333 lbs. aluminium sulphate) and 158 lbs. acetate of lime. The mixture is agitated, settled, and the clear liquid decanted.

By the use of aluminium sulphate, red liquor of the same density contains much more of the active alumina than that prepared with alum. Thus in a sample of the former 1 gallon contained 4 oz. 416 grs. alumina, whilst the average amount found in three samples prepared from alum was 3 oz. 245 grs. The addition of a little ammonia or other alkali to the red liquor prepared from aluminium sulphate is advantageous for certain colours. Red liquor usually contains from 3 to 5 p.c. alumina (Al_2O_3) and 6 to 10 p.c. acetic acid; its density varies from 1·085 to 1·120.

The importance of the formation of the gelatinous basic aluminium acetate $Al(O{\cdot}COCH_3)OH$ in protecting aluminium plant from the action of acetic acid has been mentioned above.

Ammonium acetate $C_2H_3O_2NH_4$.

The crystalline salt is usually prepared by saturating glacial acetic acid with dry ammonia gas. In solution it may be prepared more cheaply by neutralising acetic acid solution with ammonia. On evaporation, a solution of the salt loses ammonia, and leaves the acid acetate or diacetate.

Ordinary solid ammonium acetate always has an odour of acetic acid; it is very soluble in water and alcohol.

Pure ammonium acetate should be entirely volatilised on heating. The commercial salt usually contains the same impurities as sodium acetate.

The official ammonium acetate solution of the B.P. is prepared by neutralising 33 p.c. acetic acid with ammonium carbonate and diluting the liquid to a sp.gr. of 1·016. When treated with an equal volume of a saturated solution of hydrogen sulphide it should not darken in colour (limit of heavy metals).

Calcium acetate. *Diacetate of lime. Pyrolignite of lime.* $Ca(C_2H_3O_2)_2$.

This important salt is prepared by neutralising acetic acid, or pyroligneous acid, with lime or chalk.

In the preparation from pyroligneous acid, the crude acid may be used, in which case the acetate of lime is known as *brown acetate*; or the distilled liquor may be employed, producing *grey acetate*. The acid is placed in large wooden or iron pans, and powdered chalk or lime added in slight excess; the liquor remains at rest at a warm temperature until clear, and is then siphoned off into the evaporating pans. It is generally evaporated by means of coils of pipe through which steam passes; in this case the vessels are usually wooden, and lined with lead, but sometimes iron pans are used, the evaporation being conducted over a fire. The tarry impurities which rise to the surface as the liquid evaporates are removed with a skimmer. As the acetate forms, it is withdrawn and drained in wicker baskets suspended over the pans.

The proper drying of the salt is necessary to the formation of a good product. In large works a drying house is used, which is usually a wind furnace 7 or 8 feet long, 4½ feet broad. It is first heated from 75° to 115°, and the fire slackened; the salt is then spread over the bottom to the depth of about 2 inches, and when somewhat dry an equal quantity is spread above it, the salt is repeatedly turned, and the heat continued for about 24 hours. When the product appears to be dry, the heat is increased to about 125°, and the last traces of moisture driven off. Care must be taken that the heat is not too high, or the salt becomes decomposed. As in the case of sodium acetate, no sparks must touch the mass, or it may burn away like tinder.

The product, when prepared from the *brown* liquor, is dark-coloured and contains charcoal and decomposed tarry matters; it may be dissolved in 3 parts hot water, filtered through animal charcoal, and again evaporated and crystallised, yielding a nearly colourless product.

Pure calcium acetate crystallises in silky needles or prisms containing two molecules of water. At the ordinary temperature the crystals effloresce, and at 100° become anhydrous, forming a white powder of saline taste, very soluble in water.

Calcium acetate is used in the preparation of other acetates, and of acetic acid, and in calico-printing. The pure salt is completely soluble in water and proof spirit. The commercial article usually contains 62 to 67 p.c. of real acetate, and 1 to 8 p.c. of matters insoluble in water. The impurities are hydroxide, carbonate, and sulphate of calcium and tarry matters; formate and other salts of calcium with fatty acids also occur.

Many methods of assay for this substance are in use, varying considerably in accuracy.

The most trustworthy method is to distil with pure phosphoric acid and titrate the distillate as already described under acetic acid (*see* Stillwell, J. Soc. Chem. Ind. 1904, 305; Grosvenor, *ibid.* 530; Gladding, J. Ind. Eng. Chem. 1909, 250). The acetic acid may also be expelled by evaporation with formic acid (Heermann, Chem. Zeit. 1915, 39, 124).

Calcium aceto-chloride $CaC_2H_3O_2Cl,5H_2O$ has already been described as used in Condy's process for the preparation of pure acetic acid.

Copper acetates.

The normal *copper acetate* is prepared by dissolving cupric oxide or verdigris in acetic acid; or by the action of copper sulphate on the acetates of lead, calcium, or barium.

It crystallises in prisms; soluble in 13 parts cold or 5 parts hot water, and in 14 parts alcohol. In commerce it usually occurs in bunches of deep-green coloured opaque crystals known as 'grappes.'

Copper acetate is used in the manufacture of pigments; as an oxidising agent in the indigo vat; and, formerly, for the preparation of acetic acid.

Basic copper acetate. *Verdigris. Vert-de-gris Vert de Montpellier. Grunspan.*

This substance consists of a mixture of mono-, di-, and tri-basic acetates of copper, which are present in different proportions in different varieties of verdigris.

At Grenoble and Montpellier the following process is used: The 'marcs' or residues from the wine factories, consisting of the skins and stems of grapes, are loosely placed in earthen vessels, about 16 inches high, 14 inches in diameter at the widest part, and 12 inches at the mouth, covered and allowed to ferment, until on inserting a piece of copper (previously moistened with verdigris and dried), it becomes uniformly coated green in 24 hours. The fermentation should not proceed too far, or decomposition may ensue.

The copper used is in sheets $\frac{1}{24}$ inch thick, 4 to 6 inches long, and 3 to 4 broad, each weighing about 4 oz.; they are freed from scales, if necessary, rubbed with a solution of verdigris and dried; unless this precaution be adopted, the first coating produced by the marcs will be black instead of green. They are heated over a charcoal fire until as hot as the hand can bear, and placed in an earthenware vessel in layers with the marcs. 30 to 40 lbs. of copper are used for each vessel. In from ten to twenty days, according to the temperature, the covers are removed, when, if the process has progressed favourably, the marcs will be whitish and the copper covered with fine, glossy, green crystals. The plates are then removed and placed on end one against another. After two or three days they are moistened by immersion in water or damaged wine, and again placed on end for about a week. This alternate moistening and exposure to the air is continued for about six or eight weeks. The plates thus become covered with increasing coatings of the verdigris, which is detached and the plates are again used until entirely eaten away. The verdigris is kneaded with a little water into leather bags, pressed into rectangular cakes and dried.

This substance is known as *blue verdigris*, and consists principally of the basic acetate

$$(C_2H_3O_2)_2Cu_2O.$$

It should be dry, of a fine bluish colour, and soluble in dilute acids and ammonia.

Green verdigris contains as a principal constituent the sesquibasic acetate, $CuO{\cdot}2Cu(C_2H_3O_2)_2$, and is prepared by placing the copper plates alternately with cloths moistened every two or three days with pyroligneous acid or acetic acid until the plates show green crystals. The plates are arranged so as to allow free access of air and occasionally moistened, for five or six weeks. Large quantities of verdigris are manufactured in England by this process from pyroligneous acid. The imports of verdigris are very small.

In Abresh's process (Fr. Pat. 391603, 1908) minerals containing the oxide or carbonate of copper are decomposed with 15 p.c. acetic acid solution, the excess of acid neutralised or distilled, alkali added to precipitate iron aluminium, calcium, &c., the liquid filtered and concentrated, and the copper acetate separated by crystallisation.

The various forms of verdigris are used as oil and water colours. With white lead it is used in Russia and Holland as an oil paint, which by double decomposition produces a peculiar green. The paint is considered a good preservative. Verdigris is used in dyeing and calico-printing, and for the preparation of Schweinfurth green and other copper paints.

Verdigris is frequently adulterated with chalk, sand, clay, pumice, and sulphates of copper, barium, and calcium. When brass sheets have been used in the preparation instead of copper, zinc will also be present.

When warmed with dilute hydrochloric acid the sand, clay, baryta, &c., will remain undissolved, and may be weighed. The total residue in a good sample will usually amount to 3 p.c., but should not exceed 6 p.c.

Aceto-arsenite of copper. *Schweinfurth green* (*v.* ARSENIC).

Ferric acetate $Fe_2(C_2H_3O_2)_6$. This salt is prepared by the addition of calcium or lead acetate to ferric sulphate or iron alum, avoiding excess of the acetate. It is used as a mordant, its action corresponding with that of aluminium acetate. An alcoholic solution is used in medicine, but is no longer an official drug in the B.P.

For many purposes a mixture of ferrous and ferric acetates is preferred. It is prepared by repeatedly pouring pyroligneous acid on iron turnings until saturated with iron. The liquid is known as 'pyrolignite of iron,' 'bouillon noir,' 'liqueur de ferraille.'

Ferrous acetate $Fe(C_2H_3O_2)_2$. *Pyrolignite of iron; iron liquor or black liquor.* Is prepared on the large scale by the action of crude pyroligneous acid of sp.gr. 1·035 to 1·040 on iron turnings, nails, &c., at a temperature of 65°. The solution is frequently agitated and the tarry matters skimmed from the surface as they rise.

It is found that the purified acid produces a less satisfactory liquor, a fact due, according to Moyret (J. Soc. Dyers, i. 117), to the presence of a small quantity of pyrocatechol in the crude acid, which forms a compound with the ferrosoferric oxide in the solution, and causes its intense colour and keeping properties.

The liquid is intensely black, of sp.gr. 1·085 to 1·090, and is evaporated until its density rises to 1·120, or sometimes to 1·140. It is then ready for use, and is known as 'printer's iron liquor.' The liquor of density 1·120 contains about 10 p.c. iron.

The density of the liquor used by dyers is frequently raised by the addition of copperas (ferrous sulphate); thus, the addition to 1 gallon of black liquor, sp.gr. 1·085, of ½ lb. copperas, would raise its density to 1·111. Tannin also is sometimes added.

Black liquor is also prepared by the action of ferrous sulphate on acetate of lime; the liquor produced has an average density of 1·11, and always contains calcium sulphate. By the action of lead acetate on ferrous carbonate, carbonate of lead and ferrous acetate are produced.

Black liquor absorbs oxygen from the air, forming ferric acetate, which is always present in the liquid. To diminish this action clean metallic iron is frequently added.

It is largely used in calico-printing and in dyeing, in the preparation of blue, violet, black, brown, and other colours, and for producing a black colour on hats, furs, leather, wood, &c.

Lead acetate. *Normal or di-acetate of lead. Sugar of lead. Sel de Saturne. Bleizucker.* $Pb(C_2H_3O_2)_2$.

For the preparation of *white acetate* of lead, leaden vessels are used, or copper pans, on the bottom of each of which a piece of metallic lead is soldered to produce a galvanic action and prevent the copper from being acted upon. In the vessel acetic acid of 45 p.c. or less is placed, and to 100 parts of 45 p.c., or a proportionate quantity of a weaker acid, 86·5 parts of litharge are added in small quantities, with constant stirring, until the liquid is nearly neutral; it is then heated to boiling and impurities skimmed from the surface, transferred to another vessel, evaporated to a density of 1·5, and removed to the crystallising pans, which are usually of wood, lined with lead or copper, 4 feet by 2 feet, and 6 or 8 inches high. The coarsely crystalline mass thus obtained is drained on wooden racks, and broken into lumps for the market.

A coarser variety, known as *brown acetate*, is prepared by substituting distilled pyroligneous acid for the purer acid. The muddy liquid produced is left to settle in a large tun, and the supernatant liquid transferred to a large iron pan and heated to boiling. It is again allowed to settle, transferred to another pan, evaporated until crystallisation commences, when about 3 volumes of water added, causing the remaining impurities to rise to the surface. The liquid is skimmed and diluted if the liquid is not sufficiently clear, and again evaporated until a small portion crystallises when removed and cooled. It is then ladled into pans and allowed to crystallise.

As a rule, about 3 parts acetate are produced from 2 parts litharge.

By another method granulated lead, white lead residues, &c., are placed in vessels standing obliquely one above another; the upper vessel is filled with strong acetic acid, which after the expiration of half an hour is allowed to run into the second vessel. Every half-hour it is removed to a lower one. After the acid has been removed, the lead absorbs oxygen rapidly, and becomes heated. On leaving the last vessel, the acid is again passed through the series, dissolving the acetate which has been formed, and is evaporated and crystallised.

Schmidt (Eng. Pat. 7192, 1897) describes a process for preparing the neutral and basic acetates of metals such as lead and copper by the action of dilute acetic acid and oxygen upon the metal contained in closed iron cylinders.

Pure lead acetate is a white crystalline salt of sweetish taste and weak acid reaction, containing 3 molecules of water. 100 parts of water dissolve 54·38 parts at 25°, 87·77 parts at 35°, and 154·25 parts at 45°. At 280° it melts, and when heated more strongly it forms a basic salt and suddenly solidifies.

Lead acetate is largely used in dyeing and calico-printing; for the preparation of alum mordants, &c.; in the manufacture of chrome yellow and other pigments, and in medicine.

Lead forms two well-defined basic acetates—the dibasic acetate $Pb(C_2H_3O_2)_2PbO,2H_2O$ (Wittstein, Annalen, 52, 253), formed by dissolving litharge in the normal acetate in calculated proportions; and the tribasic acetate $Pb(C_2H_3O_2)_2,2PbO$·aq, prepared by boiling the normal acetate with excess of litharge for some time. Lead acetate and solutions of subacetate of lead are official drugs of the B.P. The solutions are termed *Goulard water* and *Liquor plumbi subacetatis*.

In 1911 the annual production of *white acetate* in Germany was estimated at 2600 metric tons, about half of which was exported, mainly to Great Britain (Badermann, Zeitsch. angew. Chem. 1911, 24, 1211).

Lead sub-acetate $CH_3·CO_2Pb$ may be obtained by the action of acetic anhydride on lead suboxide at 195°. It is a bluish grey substance, soluble in alcohol (Denham, Chem. Soc. Trans. 1919, 109).

Magnesium acetate. A basic acetate of magnesium, prepared by warming the normal acetate with magnesia, is stated to be a powerful antiseptic, disinfectant, and deodoriser (W. Kubel, Ber. 15, 684–686). A syrupy solution of the salt containing suspended magnesium hydroxide is found in commerce under the name of 'Sinodor.'

Potassium acetate $C_2H_3O_2K$ occurs in the sap of many plants, and of trees.

Its mode of preparation is similar to that of sodium acetate. It is a deliquescent crystalline solid, soluble in 0·53 part ice-cold water, and in hot water forms a solution which, boiling at 169°, contains 88 p.c. of the salt.

When chlorine gas is passed through a solution of potassium acetate, carbon dioxide is evolved and a powerful, unstable, bleaching fluid is produced.

Potassium acetate may contain the same impurities as the sodium salt. The di- and triacetates are prepared like those of sodium.

Sodium acetate $C_2H_3O_2Na$ is formed (1) by the action of dilute acetic acid on sodium carbonate, the solution being evaporated and crystallised; (2) by neutralisation of pyroligneous acid with soda, and evaporation and fusion of the salt to remove tarry matters; (3) by the addition of Glauber's salt to solution of acetate of lime or of lead. The solution is decanted and filtered from the precipitated calcium or lead sulphate, evaporated and crystallised, and the crystals dissolved and recrystallised. Methods (2) and (3) are used on the manufacturing scale.

Sodium acetate forms monoclinic crystals, containing 3 molecules of water; has a strong saline taste; is soluble in 2·8 parts cold water and in 0·5 boiling water. The crystals melt completely at 75° and lose their water of crystallisation at 100°. By solution of this salt in ordinary strong acetic acid and rapid evaporation the diacetate of soda is formed; when glacial acid is used the triacetate is produced.

Sodium acetate is used for the preparation of acetic acid and in medicine, but is not official in the B.P.; for the preservation of meat and other foods instead of salt. The saturated solution is occasionally used for filling carriage foot-warmers.

The commercial acetate is liable to contain sulphates, chlorides and carbonates, and metallic salts. Tarry matters are frequently present from the pyroligneous acid used in its manufacture. Acetate of lime, and sulphate and carbonate of potassium are occasionally added as adulterants.

For the estimation of acetic acid in commercial acetates the method of Stillwell and Gladding in a modified form is used (*v. supra*).

Titanium acetate. A double acetate of titanium has been patented by Kunheim (Ger. Pat. 248251, 1911). It is prepared by adding excess of an alkali solution to a strong solution of a salt of trivalent titanium, and crystallising the double salt in a vessel from which air is excluded.

Anhydrous metallic acetates may be obtained by the action of acetic anhydride on nitrates containing water of crystallisation. The reaction is accelerated catalytically by acids and also apparently by water, as anhydrous nitrates do not react so readily (Spath, Monatsh. 1912, 33, 235).

ALKYL ACETATES. *Acetic esters.*

Acetic acid forms numerous acetates with organic radicals. Some of these occur in the oils from various seeds.

Amyl acetates $C_5H_{11}(C_2H_3O_2)$.

The following isomeric amyl acetates are known:—

1. Normal amyl acetate, boiling at 147·6° (Gartenmeister); at 148·4° (737 mm.) (Lieben and Rossi).
2. *Iso*amyl acetate.
3. Methyl propyl carbinyl acetate, boiling at 133°–135° (Wurtz); at 134°–137° (Schorlemmer).
4. Methyl *iso*propyl carbinyl acetate, boiling at 125° (Wurtz).
5. Diethyl carbinyl acetate, boiling at 132° (741 mm.) (Wagner and Saytzeff).
6. Tertiary amyl acetate, boiling at 124° (750 mm.) (Flavitzky).

Of these, only the second is of technical interest.

***iso*Amyl acetate**, generally known as *amyl acetate* $(CH_3)_2CH·CH_2CH_2O·C_2H_3O$, is a colourless liquid with an odour resembling that of jargonelle pears. Sp.gr. 0·8762 15°/4° (Mendeléeff), 0·8562 22°/4° (Bruhl), b.p. 138·5°–139° at 758·6 (Schiff).

It may be prepared by distilling a mixture of 1 part amyl alcohol, 1 part strong sulphuric acid, and 2 parts dried potassium acetate; or by warming a mixture of 1 part amyl alcohol, 1 part acetic acid and 0·5 part strong sulphuric acid on the water-bath and pouring the solution when cold into excess of water. The upper layer of purified amyl acetate is separated, shaken with a strong solution of sodium carbonate, again separated, dried over calcium chloride, and redistilled.

It may be prepared commercially from fusel oil, hydrochloric acid, and calcium acetate (Wilson, Eng. Pat.), and by the interaction of chloropentane with sodium acetate, in the presence of strong acetic acid. To prevent the formation of amylene the sodium acetate should be in a porous, bulky condition (Kaufler, Eng. Pat. 2779, 1913). The commercial amyl acetate contains some of the other isomerides.

It is insoluble in water, but dissolves in all proportions in ether, amyl alcohol, and ordinary alcohol. The latter solution is largely used under the name of *Jargonelle pear essence* for flavouring confectionery.

Camphor, tannin, resins, &c., dissolve readily in amyl acetate. A solution of gun-cotton therein is used as a varnish, for lacquering metals, &c., and in the form of a stiff jelly, mixed with opaque substances such as china clay, as a substitute for celluloid.

It is also used in the manufacture of photographic films and in some smokeless powders.

It has been recommended for use for the production of a standard flame in photometry (J. Soc. Chem. Ind. 1885, 262).

The Hefner standard lamp burns amyl acetate as an illuminant.

Ethyl acetate. *Acetic ether* $C_2H_5(C_2H_3O_2)$ is a fragrant limpid liquid of sp.gr. 0·92454 0°/4°. b.p. 77·15° (Wade and Merriman); sp.gr. 0·92446 0°/4°, b.p. 77·17° at 760 mm. (Young and Forty).

For the preparation of acetic ether 3·6 pts. by weight of commercial absolute alcohol are mixed with 9 pts. sulphuric acid with constant stirring. After standing twenty-four hours the mixture is poured on 6 pts. of fused sodium acetate (in small lumps), allowed to stand for twelve hours and distilled. The product is rectified over calcium chloride and potassium carbonate and redistilled.

Clark recommends the following process: 283 c.c. (10 oz.) of rectified alcohol (sp gr. 0·838) are placed in a flask, and 283 c.c. of sulphuric acid (B.P.) are added with constant stirring. The liquid should be cooled externally as far as possible, allowed to stand till the temperature has sunk to 15°, and 351 grams (12⅜ oz.) of dried sodium acetate added gradually, with constant stirring and cooling. The liquid is distilled until 400 c.c. (14 oz.) have passed over; this is digested for three days with 2 oz. freshly dried potassium carbonate and filtered. The filtrate is distilled on the water-bath until all but 1 oz. has passed over. On the large scale dried sodium acetate may be substituted for the potassium carbonate with advantage (*v.* further W. I. Clark, Pharm. J. [3] 1883, 777).

Ethyl acetate may be prepared by the action of an aluminium alkyl oxide on acetaldehyde in the presence of aluminium chloride, which has preferably been added during the preparation of the alkyl oxide from aluminium and alcohol; or the melted alcoholate may be dissolved in anhydrous camphor, alum, &c., to increase the catalytic action (Consortium f. Elektrochem. Ind., Ger. Pat. 286812, 1914; Eng. Pat. 4887, 1915).

In the process of Farbwerke vorm. Meister, Lucius and Bruning (Eng. Pat. 1288, 1915) acetaldehyde is treated with a filtered solution of aluminium ethoxide in an organic solvent, such as xylene or solvent naphtha at 0°-15°, a yield of about 86 p.c. of the theoretical amount of ethyl acetate being claimed (*cf.* Senderens and Aboulenc, Compt. rend. 1911, 152, 1671; Kuitenacker and Habermann, J. pr. Chem. 1911 [ii.] 83, 541).

Ethyl acetate is soluble in 8 parts of water at 0°, and somewhat *less* soluble in water at 15°. On the other hand, 1 part water dissolves 26 parts of the acetate at 0° and 24 parts at 15°.

Commercial acetic ether usually contains less than 75 p.c. of ethyl acetate, the rest being acetic acid, alcohol, water, ether, &c. It occurs, together with other organic acetates, in vinegar and wines.

Methyl acetate $CH_3(C_2H_3O_2)$ is a colourless fragrant liquid of sp.gr. 0·9398 15°/15°, boiling at 57·5° (760 mm.) (Perkin). It occurs in wood-spirit, and in crude wood-vinegar.

Methyl acetate is best prepared by distilling a mixture of 1 part methyl alcohol, 1 part potassium acetate, and 2 parts sulphuric acid. The product is dried over calcium chloride and quicklime and redistilled. It is soluble in water, alcohol, and ether.

A solvent for resins, fats, cellulose, nitrate, &c., which consists largely of methyl acetate, may be prepared by distilling pyroligneous acid until a tenth of its volume has passed over, then adding a mineral acid, and continuing the distillation until a third of the residue has distilled. The united distillates are then rectified (Heilbronner and Criquebeuf, Fr. Pat. 464646, 1913).

ACETIC ANHYDRIDE $(CH_3CO)_2O$ is formed smoothly and quantitatively by heating acetyl chloride with a metallic acetate. It is not, however, necessary to make a separate preparation of the acetyl chloride and almost any reaction which yields acetyl chloride will yield acetic anhydride if an excess of metallic acetate be employed. The method originally employed by Gerhardt (Ann. Chim. Phys. 1853, [3] 37 285) consisted in treating an excess of anhydrous potassium or sodium acetate with a chloride or oxychloride of phosphorus. Later, Geuther (Annalen, 1862, 123, 114) showed that the reaction occurs according to the equation

$$4CH_3COONa+POCl_3 = 2(CH_3CO)_2O+3NaCl+NaPO_3$$

This method is a satisfactory one, but since acetic anhydride has become an article of commercial interest, it has been found desirable to substitute a cheaper reagent for the phosphorus compound. In nearly all the commercially practicable processes an anhydrous chloride or oxychloride of sulphur is employed.

Sulphur chlorides. The use of the chlorides of sulphur instead of those of phosphorus has been known for a very long time (Heintz, Jahr. 1856, 560), but these liquids are unpleasant to handle, and their action is not easy to control. The action of sulphur monochloride on the alkali salts of organic acids has been studied by Denham and Woodhouse (Chem. Soc. Trans. 1909, 1235, and 1913, 1861), who used an indifferent solvent to dilute the reagent and control its local action. By treating dry sodium acetate with sulphur monochloride S_2Cl_2, in presence of a neutral solvent, Denham obtained an intermediate compound $(CH_3COO)_2S_2$, which breaks up on heating, according to the equation $2(CH_3COO)_2S_2 = 2(CH_3CO)_2O + SO_2 + 3S$. Denham's reaction, however, does not provide for the maximum technical utilisation of the reagents, since the sulphur dioxide, as an inorganic anhydride, should be capable of taking part in the reaction and should not be allowed to escape unused.

Kessler (Fr. Pat. 315938, 1901), in making use of the action of sulphur chloride on anhydrous sodium acetate, claims that by distilling off the acetic anhydride at a low temperature under reduced pressure, the production of sulphur dioxide is avoided. Whether this is the case or not, it is nevertheless certain that the distillation of the acetic anhydride under reduced pressure constitutes a definite technical advantage when steam-heated vessels are used, and this procedure has remained standard practice in all subsequent methods.

H. Dreyfus (Eng. Pat. 100450, 1916) has clearly set forth the principles which govern the technical manufacture of acetic anhydride by the action of sulphur chloride on dry sodium acetate, in order to avoid the production of sulphur dioxide and of chloroacetic acids by substitution. (*a*) The reagents are used in the proportion of 6 atoms of chlorine to 8 of sodium; (*b*) the reaction is allowed to take place in presence of a diluting agent, in order to avoid any local excess of sulphur chloride and overheating, for which purpose acetic anhydride is most conveniently employed; (*c*) the sulphur chloride is run slowly into the well-cooled mixture of sodium acetate and acetic anhydride and the temperature is not allowed to rise above 15° C. until all the sulphur chloride has been added. For example: a mixture of 720 kilos of dry pulverised sodium acetate and 600 kilos of acetic anhydride is cooled below 0° C., and 306 kilos of sulphur dichloride is gradually introduced, the temperature being maintained at about 0° and the mixture continually stirred. Stirring is continued for some time after all the sulphur dichloride has been added and the anhydride is subsequently distilled off, preferably *in vacuo*. The equations representing this reaction for sulphur monochloride and dichloride respectively may be written:

$$8CH_3COONa + 3S_2Cl_2 = 4(CH_3CO)_2O + 6NaCl + Na_2SO_4 + 5S$$

$$8CH_3COONa + 3SCl_2 = 4(CH_3CO)_2O + 6NaCl + Na_2SO_4 + 2S$$

Thus there is a loss of sulphur which is obviously minimised by employing a sulphur chloride as rich as possible in chlorine. This waste of sulphur may be avoided altogether according to the process of the Akt. Ges. für Anilinfab. (Ger. Pat. 273101; J. Soc. Chem. Ind. 1914, 667) by passing chlorine gas into a mixture of sodium acetate and sulphur chloride at a temperature not exceeding 20° C., thus:

$$8CH_3COONa + SCl_2 + 2Cl_2 = 4(CH_3CO)_2O + 6NaCl + Na_2SO_4$$

The above is a variant of Goldschmidt's process (Eng. Pat. 25433, 1908), in which the whole of the sulphur chloride is generated *in situ* by the action of 6 atoms of chlorine on 1 atom of sulphur at a low temperature in presence of 8-9 mols. of sodium acetate. The sulphur may be replaced by a metallic compound containing sulphur, *e.g.* ferrous sulphide (1st addition to Fr. Pat. 408035), and, according to a later addition to the same patent (Dec. 29, 1910), the intense cooling is not necessary and the reaction may be conducted at temperatures up to 40°-50° C. A similar process is patented by de Jahn (Eng. Pat. 5039, 1910), in which several oxidisable compounds of sulphur may be used, but it is obvious that these must be anhydrous.

Oxychlorides of Sulphur.—Thionyl chloride reacts with dry sodium acetate giving acetic anhydride and sulphur dioxide (G. Wyss, Bull. Soc. Ind. Mul. 1902, 198). Denham and Woodhouse (Chem. Soc. Trans. 1913, 103, 1861) have also studied this reaction, which, however, is not of industrial interest. Sulphuryl chloride, on the other hand, either as such or in the nascent state, is of considerable importance, since it is easily prepared and can be utilised to full advantage according to the equation

$$4CH_3COONa + SO_2Cl_2 = 2(CH_3CO)_2O + 2NaCl + Na_2SO_4$$

The Farbenfab. vorm. F. Bayer und Co. (Eng. Pat. 21560, 1900) treat dry sodium acetate with a mixture of gaseous chlorine and sulphur dioxide at about 20° C. in a closed vessel; to avoid chlorination it is important that the sulphur dioxide be always present in slight excess. According to Farbw. vorm. Meister, Lucius and Bruning (Ger. Pat. 210805, 1907), sulphur dioxide forms a solid addition product with sodium acetate, which is readily decomposed by chlorine with the production of acetyl chloride or acetic anhydride, according to the proportions of sodium acetate used; the reaction may be controlled by mixing the solid addition compound with an anhydrous inorganic salt or with sand. The Badische Co. prepare liquid sulphuryl chloride by mixing the two liquefied gases in a special vessel in presence of a catalyst such as camphor or glacial acetic acid (Eng. Pat. 24255, 1902). Glacial acetic acid and acetic anhydride, being excellent solvents for sulphur dioxide gas, are capable of acting as catalysers for its combination with chlorine gas, and the reaction proceeds quite smoothly without the formation of chloroacetic acids provided the temperature be kept within moderate limits and local excess of chlorine be avoided. Thus in the process of the Akt. Ges. für Anilin fabr., according to Ger. Pat 226218, 1909, sulphuryl chloride is prepared by passing a mixture of sulphur dioxide and chlorine in equivalent proportions into acetic anhydride and separating the product by fractional distillation; the yield is nearly quantitative. It is, however, by no means necessary to isolate the sulphuryl chloride as such, and the same company, according to Eng. Pat. 23924, 1910, employ acetic anhydride both as an absorbing agent for the gases and as a diluting agent for the subsequent reaction with sodium acetate. For instance, 256 parts of sulphur dioxide and 284 parts of chlorine by weight are absorbed in 100 of acetic anhydride and this solution is mixed, while cooling, with 312 parts of sodium acetate; the mixture is stirred and when the reaction is complete, the anhydride is distilled off.

The above summary of methods based on the use of chloro and oxychloro compounds of sulphur covers the majority of the industrial processes successfully practised at the present time. They may all be classed together in one group, in that they may be conceived to yield acetyl chloride as an intermediate product, and their mechanism depends on the intervention of the chlorine ion. To another group belong processes based on the decomposition of sodium acetate with a strong mineral anhydride, such as sulphuric anhydride. Before passing to this second group certain methods of the first group must be mentioned, depending on the use of sulphuric anhydride in conjunction with chlorine as a possible intermediary.

Chlorosulphonic acid SO_3HCl can react with sodium acetate to produce acetyl chloride or acetic anhydride, but only under disadvantageous conditions owing to the presence of the hydracid which liberates acetic acid. The Badische Co. (Eng. Pat. 24255, 1902) proposed to avoid this difficulty by the use of sodium chlorosulphonate, obtained by the action of chlorosulphonic acid on sodium chloride: 150 parts of sodium chlorosulphonate are heated with 170 parts of sodium acetate at 70° C., and the anhydride produced is distilled off. The equation may be written

$$NaSO_3Cl+2CH_3COONa$$
$$=(CH_3CO)_2O+NaCl+Na_2SO_4$$

If half the quantity of sodium acetate be used, acetyl chloride is produced. A similar process in a simplified form has been devised by H. Dreyfus (Eng. Pat. 17920, 1915), who uses a compound formed by the direct absorption of sulphuric anhydride by sodium chloride. In these reactions, the sodium chloride most probably does not serve merely as a vehicle for the absorption of the sulphuric anhydride, but may be assumed to play a part in the reaction through the intermediate formation of pyrosulphuryl chloride $ClSO_2{\cdot}O{\cdot}SO_2Cl$, thus:

$$3NaSO_3Cl=S_2O_5Cl_2+Na_2SO_4+NaCl$$
$$S_2O_5Cl_2+6CH_3COONa$$
$$=3(CH_3CO)_2O+2Na_2SO_4+2NaCl$$

Pyrosulphuryl chloride is formed together with carbonyl chloride by the action of sulphuric anhydride on carbon tetrachloride. Both products are capable of reacting with sodium acetate to produce acetic anhydride, and Beatty (Eng. Pat. 18823, 1912) has proposed to utilise this reaction, but the process hardly appears suitable for commercial application.

Methods of the second group depending on the direct action of inorganic anhydrides without the intervention of chlorine have been far less widely developed, because secondary reactions which destroy the acetic anhydride very readily occur. A method for the direct application of sulphuric anhydride was patented by the Fabriek van Chem. Prod. of Schiedam, Holland (Eng. Pats. 12130 and 12042, 1913), and further described by Van Peski (Chem. Soc. Abst. 1914, i. 653), in which use is made of an addition compound of glacial acetic acid with sulphuric anhydride and its reaction with sodium acetate. The method is attended by certain technical drawbacks, the operations have to be carried out at a very low temperature, and it is impossible to prepare acetic anhydride of high strength owing to the use of acetic acid as a vehicle. According to a process patented by H. Dreyfus (Eng. Pat. 17920, 1915) sulphuric anhydride is absorbed by sodium sulphate to form a solid addition compound which appears to be different from ordinary sodium pyrosulphate: 800 kilos of sulphuric anhydride are added with constant stirring to 1000 kilos of powdered anhydrous sodium sulphate, and the product, when thoroughly cooled, is added to 1640 kilos of sodium acetate suspended in 1600 kilos of acetic anhydride, the mixture being constantly stirred and cooled with water. The reaction is completed by heating at 60°-70° C.

The above account sufficiently summarises the principal processes which are of industrial importance. There are several others of potential interest and some only of academic importance. An excellent review of the subject is contained in a paper by Hewitt and Lumsden (J. Soc. Chem. Ind. 1916, 210). Among the proposed dehydrating agents of minor importance may be mentioned: Silicon tetrafluoride, which may be regenerated by heating the residue with sand and sulphuric acid (Sommer, Fr. Pat. 354742, 1905); Nitric anhydride (Muller, Fr. Pat. 468963, 1914); *p*-Toluenesulphochloride, a by-product of the manufacture of saccharin (von Heyden, Ger. Pat. 123052, 1901).

Recent research has been directed to the synthetic preparation of acetic anhydride from acetylene and acetaldehyde, for instance, according to Fr. Pats. 420346 and 442738, by the action of chlorine or chlorous anhydride. An interesting method is based on the hydration of acetylene to aldehyde in presence of a mercuric salt at the expense of the dehydration of acetic acid (Boiteau, Fr. Pats. 474828 and 475853), with production of ethylidene diacetate, which yields acetic anhydride and acetaldehyde on distillation (Eng. Pats. 23190, 1914; 110906, 1917; and 112765, 1917).

The chemical engineering of the manufacture of acetic anhydride presents no unusual problems. Ample cooling power must be provided to take up the considerable amount of heat produced during the mixing of the reagents. Powerful and effective stirring gear is necessary both in the mixing and the distilling plants to deal with the masses of semi-solid and finally solid materials which result from the reaction. Access of moist air is the principal source of loss, since 1 part of water will destroy 5·7 parts of anhydride.

Crude acetic anhydride is purified and freed from mineral acids and sulphur compounds by redistillation under reduced pressure in presence of sodium acetate and a metallic oxide, *e.g.* copper oxide, which yields an insoluble sulphide. Commercially pure acetic anhydride contains 80-95 p.c. of anhydride, the remainder being acetic acid. A richer product for laboratory purposes may be prepared by fractional distillation.

Physical Constants.—The properties of pure acetic anhydride have been studied by Orton and Jones (Chem. Soc. Trans. 1912, 101, 1720). The pure compound boils at 139·5° C. at 760 mm. pressure, and has sp.gr. 1·0876 at 15°/4° C., and 1·0820 at 20°/4° C. The commercial anhydride containing a little acetic acid boils at about 138° C. The specific heat is 0·434, and the latent heat of vaporisation at 137° is 66·1 Cals. per kilo (Berthelot). The heat of hydration per grm.-mol to form 2 mols. of acetic acid (liquid) is 13·1 Cals. The refractive index for the ray D at 20° C. is 1·39038, and for the ray Hγ is 1·39927 (Landolt).

Chemical Properties.—Acetic anhydride is not immediately hydrolysed on shaking with cold water, and at low temperatures anhydride and water or aqueous acetic acid may remain in contact with each other for a considerable time. At 20° C. and over the hydrolysis proceeds rapidly, and the temperature rises very considerably. The hydration is accelerated by a trace of sulphuric acid. According to Orton and Jones (*l.c.*), 100 grams of pure acetic anhydride dissolve about 2·7 grams of water at 15° C., but the solvent power is considerably increased by the presence of small quantities of acetic acid. Lumière and Barbier (Bl. 1906, 35, 625) have studied the stability of solutions of acetic anhydride in water and alcohol at 15° and 0° C.; 100 parts of cold water dissolve 12 of acetic anhydride on shaking.

When mixed with concentrated sulphuric acid at 0° C. acetic anhydride forms an addition compound, acetylsulphuric acid, which is a viscous syrupy liquid; if the temperature is allowed to rise this changes to the isomeric sulphoacetic acid $HSO_3CH_2{\cdot}COOH$, and brown condensation products are also formed (Stillich, Ber. 1905, 1241). With concentrated nitric acid at a low temperature, acetic anhydride gives a compound $C_4H_9NO_7$, which is described as diacetylorthonitric acid (Pictet and Genequand, Ber. 1902, 2526), and with nitric anhydride it gives acetyl nitrate $C_2H_3O_2NO_2$ (Pictet and Khotinsky, Compt. rend. 1907, 144, 210). These substances react generally with organic hydroxyl compounds as nitrating agents, more rarely as acetylating agents. Acetic anhydride dissolves boric anhydride slowly, boric acid rapidly, on heating, giving a mixed boric acetic anhydride $B(OOC{\cdot}CH_3)_3$, m.p. 121° C. (Pictet and Geleznoff, Ber. 1903, 2219). This substance may be used for the preparation of neutral boric esters by warming with alcohols and phenols. With absolute formic acid at a temperature not exceeding 50° C., acetic anhydride combines to give formyl acetic anhydride which distils with decomposition at 105°–120° C. This compound generally yields formic esters with alcohols and formyl derivatives with amines (Béhal, Bl. 1900, 24, 745; Eng. Pat. 12157, 1899).

Acetic anhydride is employed for the manufacture of cellulose acetate, acetylsalicylic acid (aspirin), and diacetylmorphine (heroin), also in the dyestuffs and pharmaceutical industries; it is largely employed in the laboratory for the quantitative estimation of hydroxyl groups and for the preparation of acetyl derivatives of bases. With aldehyde groups it reacts, forming the diacetates of ortholdehydes

$$R{\cdot}CHO \rightarrow R{\cdot}C(OH)_2 \rightarrow R{\cdot}C(OOC{\cdot}CH_3)_2$$

which are not very stable.

Analysis.—Commercial acetic anhydride should be substantially free from sulphur and phosphorus compounds, chlorides and chloroacetic acids. Copper from the distillation plant and higher homologues, such as propionic and butyric acids, may be objectionable for pharmaceutical or analytical purposes; these may be removed by careful fractionation. The valuation of purified acetic anhydride is performed by simple titration of the total acidity as acetic acid and calculation of the excess of acidity in terms of acetic anhydride. About 5 grams of the sample is accurately weighed in a small weighing tube which is then dropped into 100 c.c. of N/1-sodium hydroxide. When the anhydride has completely disappeared, the excess of alkali is titrated back with N/10-acid in presence of phenolphthalein. If p is the weight of sample taken, and q its acidity as acetic acid, the weight of anhydride present is $5{\cdot}6641\ (q-p)$. The success of this method depends entirely on the accuracy of the measuring vessels and the standardisation of the solutions. An error of 0·1 c.c. of N/1-soda involves an error of 0·7 p.c. in the anhydride result, and the greatest care must be exercised in the calibration of the burettes; it is necessary also to apply a correction for the change in volume of the normal solution at temperatures different from that at which it was standardised. The method of Menschutkin and Vasilieff is based on the formation of acetanilide from aniline at a moderate temperature; it does not give satisfactory results in its original form. For a *résumé* of the various methods and an improved modification of the aniline method, *see* Radcliffe and Medofski, J. Soc. Chem. Ind. 1917, 628. There is no simple and accurate method for the estimation of higher homologues in presence of large proportions of acetic acid; besides the standard analytical text-books, the following references may be consulted: Muspratt, J. Soc. Chem. Ind. 1900, 204; Langheld and Zeileis, Ber. 1913, 1171; Crowell, J. Amer. Chem. Soc. 1918, 413.

J. F. B.

ACETINS. The acetins are the acetyl derivatives of glycerol, or glycerol acetates. Five of these are theoretically possible, two mono-, two di-, and one tri- derivative, according to the number and position of the hydroxyl groups attacked by the acetic acid. Only three of these compounds have been prepared so far, one in each class, and the positions which the acetyl groups take up in the mono- and di- derivatives does not appear to be experimentally proved, though they are probably terminal. Commercial acetin is a mixture of all three compounds with other products.

The following method for the preparation of mono-, di-, and tri-acetin has been described by A. C. Geitel (J. pr. Chem. 1897, [ii.] 55, 41):—

200 grams of dry glycerol are heated with 500 grams of glacial acetic acid for 8 hours, and the acetic acid and water distilled off under reduced pressure. A further quantity of 150 grams acid is then added, and the heating continued for 16 hours. *Triacetin* is isolated from the product by diluting with water and extracting with ether, and is a colourless liquid, dissolving in water to the extent of about 7 p.c. at 15°. It has a sp.gr. 1·1605 at 15° and distils without decomposition at 172°–172·50/40 mm. *Diacetin* is obtained from

the remaining solution by fractionating (after concentration) under a pressure of 40 mm., when it comes over between 175°–176°. It is a soluble colourless liquid with sp.gr. 1·1769 at 15°. In order to isolate the monoacetin formed in the reaction the aqueous solution after removal of the triacetin is extracted for 8 hours with ether at 34°–35° in an extracting apparatus for liquids; the later extracts are collected separately, diluted with an equal volume of water, and, after being extracted with hot benzene, are concentrated. The monacetin thus formed is a thick syrup of sp.gr. 1·2212 at 15°. By prolonging the ether extraction still further *monacetyldiglycerol* $C_3H_5(OH)_2{\cdot}O{\cdot}C_3H_5(OAc){\cdot}OH$ may be obtained; it is a colourless liquid of sp.gr. 1·2323 at 15°. *Diacetyldiglycide* may also be separated from the monacetin by fractionation, and *triacetyldiglycerol* is also formed.

Commercial Acetin ('*Acetine*') is prepared by heating in an oil-bath a mixture of 60 parts of glycerol and 82 parts of glacial acetic acid for 12–15 hours at 120°, and gradually raising the temperature to 160° to expel the excess of acetic acid. The product is a thick liquid smelling of acetic acid and varying in colour from light yellow to dark brown, according to the purity of the glycerol used.

The value of the product depends upon the extent to which combination has taken place, and this is determined by observing the specific gravity and estimating the free and combined acetic acid. The density varies between 1·1608 and 1·1896, being lowest when the free acetic acid is present in largest amount. The free and combined acetic acid are determined as follows: 50 grams of 'acetin' are diluted with water to 500 c.c. The free acid in 50 c.c. of this solution is determined by titration with normal caustic soda, using phenolphthaleïn as indicator. 15 c.c. of normal caustic soda are added to 10 c.c. of the acetin solution, and the combined acetic acid liberated by hydrolysis by boiling for five minutes. The excess of caustic soda remaining is a measure of the total acid present; and the amount of combined acid is found by subtracting from the amount of caustic soda used up in the hydrolysis the quantity accounted for by the free acid. The following table (Kopp and Grandmougin, Bull. Soc. Ind. Mulhouse, 1894, 112) shows the results of typical analyses:—

No	Density	Acid free	Acid combined	Remarks
		p.c.	p.c.	
1	1·1774	9·2	46·0	A medium quality sample
2	1·1896	6·98	55·7	A good sample
3	1·1608	23·0	43·5	Poor sample.

Acetin is used as a solvent for basic colouring matters, such as Induline and Perkin's violet. They are dissolved by being heated together for about two hours, cooling, and filtering through a silk filter. Acetin is to be preferred to ethyl and methyl tartaric acids as a solvent, as acetic acid is less injurious to the fibres than tartaric acid.

Halogen derivatives of the Acetins.

αγ-dibromo-β-acetylglycerol $(CH_2Br)_2CH{\cdot}OAc$ is obtained by the prolonged action of hydrogen bromide on triacetin, or by heating the mixture to 100° in sealed tubes; it boils at 130°–135° (40 mm.) and has sp.gr. 1·5880 at 15°. It has an agreeable aromatic odour, is slightly soluble in water, and readily soluble in alcohol and ether. It yields *iso*propyl alcohol on reduction.

α-bromo-βγ-diacetylglycerol $CH_2Br{\cdot}CH(OAc){\cdot}CH_2{\cdot}OAc$ is produced by the prolonged action of hydrogen bromide dissolved in acetic acid on triacetin at 0° in the dark. It boils at 150°–155° (40 mm.), and has sp.gr. 1·2905 at 15°. It yields *iso*propylene glycol on reduction.

αγ-dichloro-β-acetylglycerol $(CH_2Cl)_2CH{\cdot}OAc$, prepared similarly to the bromine compound, boils at 115°–120° (40 mm.), and has sp.gr. 1·1618 at 15°.

α-chloro-βγ-diacetylglycerol $CH_2Cl{\cdot}CH(OAc)CH_2{\cdot}OAc$ boils at 145°–150° (40 mm.), and has sp.gr. 1·1307 at 15°.

αβ-dichloromonoacetin $CH_2Cl{\cdot}CHCl{\cdot}CH_2{\cdot}OAc$ is prepared by the action of acetic anhydride on chlorinated allyl alcohol, and has sp.gr. 1·1677 at 15°, but in all other respects is identical with the αγ-dichloro- compound.

α-iododiacetin $CH_2I{\cdot}CH(OAc){\cdot}CH_2{\cdot}OAc$ is obtained by the action of sodium iodide on the corresponding chloro- compound. It is an unstable oil having a sp.gr. 1.4584 at 15°.

J. A. P

ACETNAPHTHALIDE DISULPHONIC ACID

v. NAPHTHALENE.

ACETOACETIC ACID $CH_3{\cdot}CO{\cdot}CH_2{\cdot}CO_2H$ is a thick acid liquid miscible with water in all proportions. It is prepared from its ethyl ester by leaving 4¼ parts of ester in contact with 2·1 parts of potash and 80 parts of water for 24 hours and acidifying with sulphuric acid. It is extracted from the solution with ether.

It is very unstable and readily decomposes below 100° into acetone and carbon dioxide. It yields a violet colouration with ferric chloride and forms ill-characterised amorphous salts, $Ba\bar{A}_2,2H_2O$ and $Cu\bar{A}_2,2H_2O$, when treated with the corresponding carbonate.

Acetoacetic acid appears in the urine of diabetic patients, and indicates defective oxidation. Its detection and estimation have been the subject of much controversy and investigation. Arnold (Chem. Zentr. 1899, ii. 146) makes use of a colour reaction with acetophenone, which will show 1 part in 10,000, but is affected to some extent by the presence of acetone. Riegler (Chem. Soc. Abstr. 1903, ii. 112) employs the colour produced by the addition of sulphuric and iodic acids, which he states to be unaffected by the presence of sugars, leucine, tyrosine, or acetone. Bondi (Chem. Zentr. 1906, i. 707) recommends the use of a solution of iodine and the detection of acetoacetic acid by the characteristic smell of the iodacetone produced; but Lindemann (*ibid.* 717) says that this smell is not characteristic of acetoacetic acid. Mayer adds the urine to a very dilute solution of ferric chloride in brine, when, in the presence of acetoacetic acid, a claret-red ring is formed. When the red colour is only just visible, the liquid may be assumed to contain 0·01 p.c. of the acid. A blank test performed after boiling the acid for five minutes should give no colour (Chem. Zentr. 1906, i. 406).

Messinger's process as modified by Huppert (Analyse des Harns, 1898) estimates the total amount of acetone and acetoacetic acid present with fair accuracy, and the acetone may be estimated separately with considerable exactitude by the method of Folin (J. Biol. Chem. 1907, 3, 177), in which it is aspirated out of the liquid into iodine and potash, and the resulting iodoform weighed.

Methyl acetoacetate $CH_3\cdot CO\cdot CH_2\cdot CO_2Me$ is prepared by heating together methyl acetate and sodium under a reflux condenser and subsequently distilling in a stream of carbon dioxide. It is a colourless liquid, easily miscible with water, which boils at 169°–170° and has a sp.gr. 1·0917 at 4°; 1·0809 at 15°; and 1·0724 at 25°. It is decomposed on boiling with water into carbon dioxide, acetone, and methyl alcohol. With ferric chloride it yields a deep red colouration.

Ethyl acetoacetate (acetoacetic ester) $CH_3\cdot CO\cdot CH_2\cdot CO_2Et$ and $CH_3\cdot C(OH):CH\cdot CO_2Et$, was discovered by Geuther in 1863, and independently by Frankland and Duppa in 1865. It is a colourless, slightly syrupy liquid, with a pleasant odour. It boils at 180·6°–181·2°/754 mm. (Brühl); 180°–180·3°/754·5 mm. (Schiff); 71°/12·5 mm. and 100·2°/80 mm. (Kahlbaum). It has a specific gravity 1·0465 0°/4° (Schiff); 1·0282 20°/4° (Schaum). The density gradually changes on keeping (*v. infra*).

Ethyl acetoacetate is prepared by the action of sodium on ethyl acetate. The following details of the method are given by Conrad (Annalen, 186, 214): 100 grams of sodium are added to 1000 grams of pure ethyl acetate, and after the reaction has moderated considerably, the whole is heated on a water-bath under a reflux condenser for 2–2½ hours until all the sodium has disappeared. To the warm mass 550 grams of 50 p.c. acetic acid are added, and after cooling 500 c.c. of water. The whole is well shaken, and the upper layer separated, washed with a little water, and fractionated. The fractions 100°–130°, 130°–165°, 165°–175°, 175°–185°, 185°–200° are collected separately and refractionated twice. The yield is 175 grams of product boiling at 175°–185°, and from the fraction boiling below 100°, 350–400 grams of ethyl acetate may be recovered after removing the alcohol by salting out. Details of a method of preparation on the large scale are given by Cobenzl in Chem. Zeit. 1914, 38, 665.

Ethyl acetoacetate is neutral to litmus, but forms salts with sodium, copper, and other metals by replacement of hydrogen. Only one atom of hydrogen can be replaced by sodium, but if the sodium in the resulting compound is replaced by an alkyl radicle a second hydrogen atom may then be replaced. Ferric chloride produces a violet colouration. With sodium bisulphite a crystalline addition product $C_6H_{10}O_3$, $NaHSO_3$ is formed. On heating for a long time, or leading the vapour through a hot tube, acetone, alcohol, dehydracetic acid, and methane are formed. Sodium amalgam reduces it to *β-hydroxy butyric* acid $CH_3\cdot CH(OH)\cdot CH_2\cdot CO_2H$. It condenses with hydroxylamine, but does not form an oxime, as internal condensation takes place, resulting in the production of *methyl isooxazolone* $CH_3\cdot C\cdot CH_2\cdot CO$ which is converted by
$\ddot{N}$——$\dot{O}$
alkalis into salts of β-oximinobutyric acid.

Applications in Synthesis.—By means of ethyl acetoacetate fatty acids, ketones, and many ring compounds may be prepared.

Fatty acids may be obtained by dissolving sodium (1 atom) in absolute alcohol, adding ethyl acetoacetate (1 mol.) followed by an alkyl halogen compound (1 mol.). The resulting alkyl derivative is treated with strong alkalis, when the molecule is hydrolysed with formation of acetic acid and the desired alkyl acetic acid.

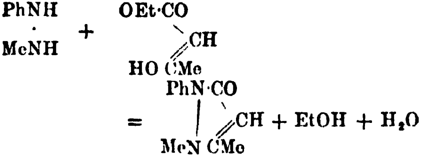
$$CH_3\cdot CO\cdot CH_2\cdot CO_2H \rightarrow CH_3\cdot C(ONa):CH\cdot CO_2Et \rightarrow CH_3\cdot CO\cdot CHR\cdot CO_2Et \rightarrow CH_3\cdot CO_2H + RCH_2\cdot CO_2H$$

If the hydrolysis is brought about by *dilute acids* instead of concentrated alkalis, the molecule is differently divided, producing ketones.

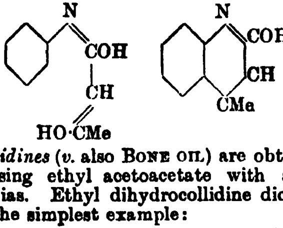
$$CH_3\cdot CO\cdot CHR\cdot CO_2Et \rightarrow CH_3CO\cdot CH_2R + EtOH + CO_2.$$

Dialkyl acetic acids and ketones may be produced by introducing a second alkyl radicle into the molecule by a similar process after the first has entered, but the two cannot be introduced together in one operation.

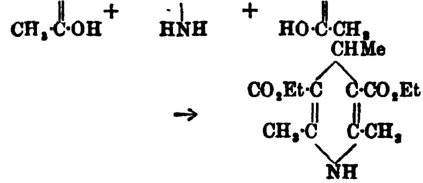
Pyrazolones, of which the most important industrially is *antipyrine*, are produced by the condensation of ethyl acetoacetate with hydrazines. Antipyrin (1-*phenyl* 2:3-*dimethyl*-5-*pyrazolone*) is prepared from symmetrical methyl phenylhydrazine and ethyl acetoacetate (*v.* also PYRAZOLE and ANTIPYRINE).



Quinolines may be prepared by first making the anilide of ethyl acetoacetate by heating with aniline at 110°, and afterwards heating this product with concentrated hydrochloric acid. $CH_3\cdot CO\cdot CH_2\cdot CO\cdot NHPh$ changes into $CH_3\cdot C(OH):CH\cdot C(OH):NPh$, and readily condenses to 1 *hydroxy*-4-*methylquinoline*



Pyridines (*v.* also BONE OIL) are obtained by condensing ethyl acetoacetate with aldehyde ammonias. Ethyl dihydrocollidine dicarboxylate is the simplest example:



Pyrones.—Dehydracetic acid, α-methyl βacetylpyrone, is produced on heating ethyl acetoacetate for a considerable time.

Constitution.—The constitution of ethyl acetoacetate and its sodium derivatives was for many years a subject of discussion by Frankland and Duppa, Geuther, Claisen, Laar, Wislicenus, Brühl, Perkin, and others. The general opinion is that ethyl acetoacetate consists of a mixture of the two forms, ketonic $CH_3{\cdot}CO{\cdot}CH_2{\cdot}CO_2Et$, and enolic $CH_3{\cdot}C(OH):CH{\cdot}CO_2Et$. The freshly prepared substance is practically a pure ketone, but on keeping it changes partially into the enolic form, and when equilibrium is reached about 10 p.c. of the latter is present at ordinary temperatures. The rate of change has been studied by observing the change of viscosity. *See* Dunstan and Mussel, Chem. Soc. Trans. 1911, 99, 566. The sodium compound is a derivative of the enolic form.

Alkyl derivatives of ethyl acetoacetate.

1 *Mono-substituted alkyl derivatives.*

Ethyl methylacetoacetate $CH_3{\cdot}CO{\cdot}CHMe{\cdot}CO_2Et$ boils at 186·8°, and has sp.gr. 1·009 at 6°. Prepared from methyl iodide and sodium acetoacetate (Geuther, J. 1865, 303)

Ethyl ethylacetoacetate $CH_3{\cdot}CO{\cdot}CHEt{\cdot}CO_2Et$ boils at 195°–196°, and has sp.gr. 0·9834 at 16°. It is readily decomposed by baryta or alcoholic potash into alcohol, carbon dioxide and methyl propyl ketone; and by dry sodium ethoxide into acetic and butyric esters (Miller, Annalen, 200, 281; Wedel, Annalen, 210, 100, Frankland and Duppa, Annalen, 138, 215; Wislicenus, Annalen, 186, 187)

Ethyl propylacetoacetate $CH_3{\cdot}CO{\cdot}CHPr^{a}{\cdot}CO_2Et$ boils at 208°–209°, and has sp.gr. 0·981 a 0°/4°. It is prepared by adding to a solution of 27 grams of sodium in 270 grams absolute alcohol, 152·7 grams ethyl acetoacetate, followed gradually by 206 grams propyl iodide.

Ethyl isopropylacetoacetate $CH_3{\cdot}CO{\cdot}CHPr\beta{\cdot}CO_2Et$ boils at 201°/758·4 mm., and has sp.gr 0·9805 at 0°.

Ethyl isobutylacetoacetate $CH_3{\cdot}CO{\cdot}CH(CH_2{\cdot}CHMe_2){\cdot}CO_2Et$ boils at 217°–218°, and has sp.gr. 0·951 at 17·5° (Rohn, Annalen, 190, 306; Minter, Ber. 1874, 501).

Ethyl isoamylacetoacetate $CH_3{\cdot}CO{\cdot}CH(CH_2{\cdot}CH_2{\cdot}CHMe_2)CO_2Et$ boils at 227°–228° (Peters, Ber. 1887, 3322).

Ethyl amylacetoacetate $CH_3{\cdot}CO{\cdot}CH(C_5H_{11})CO_2Et$ boils at 242°–244° (Ponzio and Prandi, Gazz. chem. ital. 28, ii. 280).

Ethyl heptylacetoacetate boils at 271°–273°, and has sp.gr. 0·9324 at 17·7°.

Ethyl octylacetoacetate boils at 280°–282°, and has sp.gr. 0·9354 at 18°·5/17·5°.

2. *Di-substituted alkyl derivatives.*

Ethyl dimethylacetoacetate $CH_3{\cdot}CO{\cdot}CMe_2{\cdot}CO_2Et$ boils at 184°, and has sp.gr. 0·9913 at 16°.

Ethyl methylethylacetoacetate $CH_3{\cdot}CO{\cdot}CMeEt{\cdot}CO_2Et$ boils at 198°, and has sp.gr. 0·947 at 22°/17°·5.

Ethyl methylpropylacetoacetate $CH_3{\cdot}CO{\cdot}CMePrCO_2Et$ boils at 214°, and has sp.gr. 0·9575 at 17°/4°.

Ethyl diethylacetoacetate $CH_3{\cdot}CO{\cdot}CEt_2{\cdot}CO_2Et$ boils at 218°, and has sp.gr. 0·9738 at 20°.

Ethyl dipropylacetoacetate $CH_3{\cdot}CO{\cdot}CPr_2{\cdot}CO_2Et$ boils at 236°, and has sp.gr. 0·9585 at 0°/4°.

Ethyl diisobutylacetoacetate boils at 250°–253°, and has sp.gr. 0·947 at 10°.

Ethyl diheptylacetoacetate boils at 332°, and has sp.gr. 0·891 at 17·5°/17·5°.

Ethyl dioctylacetoacetate boils at 264° /90 mm., 340°–342° /760 mm.

ACETOFORM. Trade name for a combination of hexamethylenetetramine and aluminium aceto citrate.

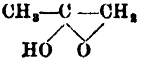
ACETOL (*methyl-ketol, acetyl carbinol,* or *propanolon*) CH_3COCH_2OH is the simplest ketone alcohol. It is obtained by saponification of the acetyl carbinol acetate or formate produced on condensing chloro-acetone with potassium acetate or formate (Henry, Ber. 1872, 5, 966; W. H. Perkin, Trans. Chem. Soc. 1891, 59, 786; Nef, Annalen, 1904, 335, 248). For the purpose of saponification in this case boiling with methyl alcohol containing 1–2 p.c. hydrochloric acid is employed. It is also formed in the biochemical oxidation of propylene glycol by means of the sorbose bacterium or by *mycoderma aceti*, in the pyrochemical decomposition of glycerol (Nef, *l.c.*), and by heating α-bromopropionic aldehyde with a methyl alcoholic solution of potassium or sodium formate for 10–15 hours (Nef, *ibid.* 265). In this latter preparation the metal halide is filtered off and the acetol fractionated twice under diminished pressure, when it is obtained perfectly pure.

Acetol boils at 54° (18 mm.), and with slight decomposition at 147° under atmospheric pressure. It possesses a faint, characteristic smell, and is miscible with water. It readily forms more complex condensation products, especially in the presence of traces of halogen compounds; but this may be avoided by diluting it with its own volume of methyl alcohol. When passed through a tube heated to 450° it decomposes into acetaldehyde and *meta*formaldehyde, together with a small quantity of their decomposition products, namely, crotonaldehyde, carbon monoxide, hydrogen, &c.

On oxidation with mercuric oxide, silver oxide, or chromic acid in the presence of sulphuric acid it yields formic and acetic acids; but with copper oxide in alkaline solution it yields lactic acid:

$$CH_3COCH_2OH \rightarrow CH_3CO\,CHO \xrightarrow{+H_2O} CH_3{\cdot}CHOH{\cdot}COOH$$

On reduction with sodium amalgam in aqueous solution, acetone, *iso*propyl alcohol, and propylene glycol are produced; a reaction which suggests that in aqueous solution acetol has changed into the tautomeric form:



The behaviour of acetol and its esters to the Grignard reagent shows that they exist in the carbonyl form, for with magnesium ethyl iodide, amylene glycol $\begin{matrix}CH_3\\C_2H_5\end{matrix}\!>\!C\!<\!\begin{matrix}OH\\CH_2OH\end{matrix}$ is obtained, which could not be the case with the ethylene oxide type of structure. In contact with solid caustic alkali, acetol is converted into dark red tarry matters, with simultaneous development of great heat.

Acetol-oxime is obtained by the oxidation of 2-methyl-2-hydroxyaminopropane di-ol-1·3 $(HONH)(CH_3)C(CH_2OH)_2$, with mercuric oxid-

(Pilotz and Ruff, Ber. 1897, 30, 1656, 3161). It crystallises in prisms, melts at 71° C., and is easily soluble in water.

Acetol semicarbazone

$$CH_3{\cdot}C(:N{\cdot}NH{\cdot}CONH_2){\cdot}CH_2OH$$

serves as the best means of identifying acetol. It melts at 195°–200° C., is very stable, and is only very slightly soluble in ether, benzene, and chloroform. The *phenylhydrazone* melts at 106° C.; the *osazone* at 153°–154° C.

The name 'Acetol' is also given to a product obtained as an ester of salicylic acid by condensing sodium salicylate with monochloracetone $OH{\cdot}C_6H_4{\cdot}COO{\cdot}CH_2{\cdot}CO{\cdot}CH_3$. Forms needles from solution in alcohol, m.p. 71°; sparingly soluble in warm water (Fritsch, E. P. 3961, 1893; J. Soc. Chem. Ind. 1894, 274).

ACETOMETER. A hydrometer graduated to indicate the strength of commercial acetic acid according to its density.

ACETOMORPHINE. Syn. for diacetylmorphine. Used to check spasmodic coughing, and in lowering reflex irritability, *v.* OPIUM and OPIUM ALKALOIDS.

ACETONE C_3H_6O or $CH_3{\cdot}CO{\cdot}CH_3$. *Dimethyl ketone.* A product of the destructive distillation of acetates; obtained by Liebig from lead acetate (Annalen, 1, 225) and further examined by Dumas (Ann. Chim. Phys. [2] 49, 208), who first determined its composition. Acetone is also produced in the dry distillation of wood (Völckel, Annalen, 80, 310; J. Soc. Chem. Ind. 16, 667, 722; 27, 798); of citric acid (Robiquet, B. J. 18, 502); of sugar, starch, and gums with lime (Frémy, Annalen, 15, 279; J. Soc. Chem. Ind. 21, 541, 1006). Large quantities of acetone are now produced by the destructive distillation of the giant kelp of the Pacific Coast; the quantity of cut kelp averaged above 24,000 tons a month in 1917. By oxidation of proteid substances with iron salts (Blumenthal and Neuberg, Chem. Zentr. 1901, i. 788; Ingler, Beitr. Chem. Phys. Path. 1902, i. 583), and by heating citric acid with potassium permanganate (Péan de St. Gilles, J. 1858, 585; Sabbatani, Atti Acad. Sci. Torino, 1900, 35, 678); and by the oxidation of *iso*valeric acid (Crossley and Le Sueur, Chem. Soc. Trans. 1899, 165). Acetone is also produced by the Fernbach process, in which starch from maize or other grain is fermented by a special ferment which resolves the carbohydrate into a mixture of butyl alcohol and acetone.

Preparation.—1. Acetone can be obtained by distilling a mixture of 1 part of caustic lime and 2 parts of crystallised lead acetate (Zeise, Annalen, 33, 32); but is usually prepared by the dry distillation of barium acetate at a moderate heat. Calcium acetate can also be employed, but the temperature required is greater, and the product is contaminated with impurities, such as *dumasin*, an isomeride of mesityl oxide; but according to Becker (J. Soc. Chem. Ind. 26, 279) a lower temperature is required if the calcium salts are made quite neutral and the formation of free lime is prevented by the introduction of a stream of dry carbon dioxide. Bamberger (Ber. 1910, 43, 3517) considers that the formation of acetone consists first in the formation of lime and acetic anhydride, and that the latter is decomposed into acetone and carbon dioxide. It has been shown (Freudenheim, J. Physical Chem. 1918, 22, 184) that when acetone is heated with lime at temperatures ranging up to 630°, a species of 'cracking' occurs, which results in the formation of methane, ethylene, hydrogen, carbon monoxide, and carbon dioxide. As the temperature is raised to the upper limit mentioned, the amount of methane increases rapidly, whilst that of hydrogen is diminished. The explanation put forward is that acetone undergeos (*a*) a high temperature dissociation; and (*b*) conversion into keten, which thereafter decomposes:

$$\begin{aligned} CH_3{\cdot}CO{\cdot}CH_3 &\rightarrow CH_4+CO+C+H_2 \\ CH_3{\cdot}CO{\cdot}CH_3 &\rightarrow CH_4+CH_2:CO \\ 2CH_2:CO &\rightarrow 2CO+C_2H_4 \end{aligned}$$

Magnesium or strontium acetates can also be used. Industrially, acetone can be prepared by passing the vapour of acetic acid into air-tight vessels heated to 500°, containing some porous substances saturated with lime or baryta (J. Soc. Chem. Ind. 18, 128, 824; Bauschlicker, D. R. P. 81914); also by passing a continuous current of pyroligneous acid over a heated acetate capable of forming acetone (J. Soc. Chem. Ind. 25, 634; 26, 1002; 27, 277). An improved method is also described by Wenghoffer (D. R. P. 144328; compare also J. Soc. Chem. Ind. 14, 987; 20, 1130; 22, 297).

According to Squibb (J. Soc. Chem. Ind. 1896, 231; J. Amer. Chem. Soc.), pure acetone for use in the preparation of smokeless powders can be obtained by subjecting acetates mixed with an excess of calcium hydroxide to destructive distillation and to the action of superheated steam.

2. From wood spirit acetone can be separated by distilling over calcium chloride. The product obtained by these methods can readily be purified by converting the acetone into its crystalline compound with acid sodium (or potassium) sulphite, crystallising this, and subsequently distilling with aqueous sodium carbonate; the distillate is then treated with concentrated calcium chloride solution and the ethereal layer rectified over solid chloride. According to Conroy (J. Soc. Chem. Ind. 19, 206), it should be purified by distillation over sulphuric acid (Dott, J. Soc. Chem. Ind. 27, 272), whilst Arnoult (*ibid.* 27, 679) recommends treatment with oxidising agents.

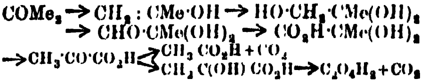
According to Shipsey and Werner (Chem. Soc. Trans. 1913, 103, 1255), sodium iodide forms a crystalline compound with acetone $NaI,3C_3H_6O$, which easily gives off all the acetone on gentle warming. The formation of this compound can be used for the preparation of pure acetone from the commercial material. It may be readily prepared by dissolving anhydrous sodium iodide to the point of saturation in the hot acetone, and allowing the solution to cool to the ordinary temperature; if the liquid is cooled to about −8° by means of ice and salt, the yield of crystals is largely increased.

Acetone has been prepared synthetically from zinc methyl and acetyl chloride (Freund, Annalen, 118, 11). It occurs in the urine, blood, and brain of calcium diabetic patients.

Properties.—Acetone is a limpid, mobile liquid, having an agreeable odour and a peppermint-like taste. It is very inflammable and burns with a white smokeless flame, b.p. 56·3° (Regnault); sp.gr. 0·8144 at 0°, 0·79945 at 13·9° (Kopp, Annalen, 64, 214); b.p. 56·1°–56·2° (corr.), and sp.gr. 0·8137 at 0°/4° (Shipsey and Werner); 56·22° (corr.) and sp.gr. 0·81[illegible]58 0°/4° (Thorpe and Rodger); sp.gr. 0·81378 at 0°/4°, 0·79705 at 15°/4°, 0·77986 at 30°/4° (Saposchnikoff, J. Russ. Phys. Chem. Soc. 28, 229); m.p. −94·9° (Ladenburg and Krugel, Ber. 32, 1821; Formenti, L'Orosi, 1900, 23, 223). Acetone is miscible in all proportions with water, alcohol, ether, and many ethereal salts; it can be separated from its aqueous solution by the addition of calcium chloride, and dissolves many fats and resins. It is also an excellent solvent for acetylene and tannins (Trimble and Peacock, Pharm. J. 53, 317). Acetone is used in perfumery and pharmacy; in the manufacture of smokeless powders; of cordite and of celluloid articles (Marshal, J. Soc. Chem. Ind. 23, 24, 645), also in the preparation of iodoform (Teeple, J. Amer. Chem. Soc. 26, 170; Abbott, J. Phys. Chem. 7, 83); of chloroform (Squibb, J. Amer. Chem. Soc. 1896, 231; Orndorff and Jessel, Amer. Chem. J. 10, 363; Dolt, *l.c.* 271); and in the presence of sodium sulphite it can be used as a good substitute for alkali in photographic developers (Lumière and Segewetz, Bull. Soc. chim. 15, [3] 1164; Mon. Sci. 1903, 257, 568; Eichengrun, Zeitsch. angew. Chem. 1902, 1114). When its vapour is passed through a red-hot copper tube, a very small proportion of tarry products containing naphthalene is obtained together with a large volume of gas having the composition: carbon monoxide, 39·23 p.c.; methane, 37·58 p.c.; hydrogen, 17·54 p.c.; and ethylene, 5·65 p.c. (Barbier and Roux, Compt. rend. 102, 1559). Dehydrating agents readily act on acetone and convert it into condensation products; thus, caustic lime converts acetone into mesityl oxide $C_6H_{10}O$ and phorone $C_9H_{14}O$ when the action is allowed to continue for a week (Fittig, Annalen, 110, 32), and, together with smaller proportions of other products, these two compounds are also formed when it is saturated with hydrogen chloride and allowed to stand for 8 to 14 days (Baeyer, Annalen, 140, 297): with zinc chloride terpene condensation products are formed (Raikow, Ber. 30, 905). Distillation with concentrated sulphuric acid converts acetone into mesitylene, mesityl oxide, phorone and *iso*durene and other substances (Orndorff and Young, Amer. Chem. J. 15, 249). A similar result is obtained when it is heated with boron fluoride. The action of nitric acid and nitric oxide on acetone has been studied by Newbury and Orndoff (Amer. Chem. J. 12, 517), Behrend and Schmitz (Annalen, 277, 310), Behrend and Tryller (Annalen, 283, 209), Apetz and Hell (Ber. 27, 933), Traube (Annalen, 300, 81), McIntosh (Amer. Chem. Soc. 27, 1013); of hydrogen peroxide by Baeyer and Villiger (Ber. 32, 3625; 33, 174, 858), Pastureau (Compt. rend. 140, 1591), Wolffenstein (Ber. 28, 2265); of thionyl chloride by Loth and Michaels (Ber. 27, 2540); and of hypophosphorous acid by Marie (Compt. rend. 133, 219).

Sodium in the presence of water reduces acetone to *iso*propyl alcohol and pinacone (Fittig, Annalen, 110, 25; 114, 54; Städeler, Annalen, 111, 277; Friedel, Annalen, 124, 329), but when the materials are quite dry and air is excluded, sodium acetonate is formed (Freer, Amer. Chem. J. 12, 355; 13, 308; 15, 582; Taylor, Chem. Soc. Trans. 1906, 1258; Bacon and Freer, Philippine J. Sci. 1907, 2, 67). Red-hot magnesium acts on acetone, yielding hydrogen and allylene, whilst magnesium amalgam forms magnesium acetonate which is rapidly decomposed by water, yielding pinacone hydrate (Keiser, Amer. Chem. J. 18, 328; Conturier and Meunier, Compt. rend. 140, 721). Anhydrous acetone, in presence of metallic calcium, is slowly converted at the ordinary temperature into mesityl oxide (Raikow, Chem. Zeit. 1913, 37, 1455). Chlorine, bromine, and iodine in the presence of alkalis convert acetone into chloroform, bromoform, and iodoform respectively.

Reactions.—When quite pure acetone should remain perfectly colourless on exposure to light, and should not be attacked by potassium permanganate in the cold; in the presence of alkali, however, and on warming, carbonic and oxalic acids are formed (Cochenhausen, J. pr. Chem. 166, 451; Conroy, J. Soc. Chem. Ind. 19, 206; Fournier, Bull. Soc. chim. 1908, 3, 259). According to Witzemann (J. Amer. Chem. Soc. 1917, 39, 2657), the oxidation process involves preliminary enolisation of the acetone, followed by the formation of pyruvic acid.



$$\mathrm{COMe_2 \rightarrow CH_2:CMe{\cdot}OH \rightarrow HO{\cdot}CH_2{\cdot}CMe(OH)_2 \rightarrow CHO{\cdot}CMe(OH)_2 \rightarrow CO_2H{\cdot}CMe(OH)_2 \rightarrow CH_3{\cdot}CO{\cdot}CO_2H} \begin{cases} \mathrm{CH_3\,CO_2H + CO_2} \\ \mathrm{CH_2\,C(OH)\,CO_2H \rightarrow C_2O_4H_2 + CO_2} \end{cases}$$

Acetone, when treated with aqueous potash and iodine, yields iodoform (Lieben). Gunning (Zeitsch. anal. Chem. 24, 147) has modified this reaction to render it available when alcohol is present by employing ammonia and a solution of iodine in ammonium iodide. Another test proposed by Reynolds (*ibid.* 24, 147) is based on the fact that mercuric oxide is soluble in acetone in the presence of potassium hydroxide; the suspected liquid is mixed with a solution of mercuric chloride rendered strongly alkaline with alcoholic potash, and after shaking the mixture is filtered and the filtrate tested for mercury by means of ammonium sulphide or stannous chloride. Denigès (Compt. rend. 126, 1868; 127, 963; Bull. Soc. chim. 13, [3] 543; 19, [3] 754) recommends the use of the additive compound formed by acetone with mercury sulphate, for detecting acetone in methyl and ethyl alcohol (Oppenheimer, Ber. 32, 986). Penzoldt (Zeitsch. anal. Chem. 24, 147) adds to the suspected liquid orthonitrobenzaldehyde, which in presence of caustic alkali combines with acetone to form indigo. Another delicate test is to add sodium hydroxide, hydroxylamine and pyridine, then ether and bromine until the solution is yellow, hydrogen peroxide is now added when, if acetone is present, the solution becomes blue (Stock); dimethyl *p*-phenylenediamine produces a red colouration which changes to violet on addition of alkali or acid (Malerba, Zeitsch. anal. Chem. 37, 690). Similar colour reactions are obtained by adding a few drops of sodium nitroprusside to a mixture of acetone and a primary aliphatic amine (Rimini, Chem. Zentr. 1893, 2, 132). Of all these tests Lieben's is perhaps the most sensitive. To detect acetone in urine a strong solution of sodium nitroprusside is added, then the mixture made alkaline with potash, when a red colouration is produced which changes to violet on addition of acetic acid (Legal, J. Pharm. Chim. 1888, 17, 206; Denigès, Bull. Soc. chim. [3] 15, 1058). According to Egeling (Chem. Zentr. 1894, ii. 457), it is best to use ammonia, when a brilliant violet colour is at once produced: this reaction is not given by aldehyde. For other methods of detecting and estimating acetone, compare Arachequesne, Compt. rend. 110, 642; Collischonn, Zeitsch. anal. Chem. 29, 562; Squibb, J. Amer. Chem. Soc. 18, 1068; Kebler, *ibid.* 19, 316; Schwicker, Chem. Zeit. 15, 914; Strache, Monatsh. 13, 299; Klar, J. Soc. Chem. Ind. 15, 299; Hintz, Zeitsch. anal. Chem. 27, 182; Sternberg, Chem Zentr. 1901, i. 270; Keppeler, Zeitsch. angew. Chem. 18, 464; Vaubel and Schleuer, *ibid.* 18, 214; Jolles, Ber. 39, 1306; Auld, J. Soc. Chem. Ind. 25, 100; Heikel, Chem. Zeit. 32, 75.

(For estimating acetone in wood spirit, *see* Arachequesne, *l.c.*; Vignon, Compt. rend. 110, 534; 112, 873; and in urine, *see* Huppert, Zeitsch. anal. Chem. 29, 632; Salkowski, J. Pharm. Chim. 1891, 194; Geelmuyden, Zeitsch. anal. Chem. 35, 503; Willen, Chem. Zentr. 1897, i. 134; Martz, ii. 232; Argenson, Bull. Soc chim. 15, [3] 1055; Studer, Chem. Zentr. 1898, i. 1152; Mallat, J. Pharm. 1897, 6296; Sabbatani, Chem. Zentr. 1899, ii. 22; Riegler, Zeitsch. anal. Chem. 40, 94; Vournasos, Bull. Soc. chim. 31, [3] 137; Graaff, Pharm. Weekblad, 1907, 44, 555; Folin, J. Biol. Chem. 1907, 3, 177; Monimart, J. Pharm. Chem. 1892, 26, 302; Heikel, *l.c.*; Hart, J. Biol. Chem. 1908, 4, 477.)

Derivatives.—Acetone combines directly with a large number of substances yielding well-characterised additive compounds. 1. *Compounds with alkaline sulphites*:—Acetone forms definite crystalline compounds when shaken with concentrated solutions of the acid sulphites (bisulphites) of the alkali metals (Precht, Phot. Centr. 1902, 8, 301; Kerp, Kaiserl. Gesundh. 1904, 21, 40; Rothwood, Monatsh. 26, 1545). The *potassium* salt $C_3H_6O,KHSO_3$, and the *sodium* salt $C_3H_6O,NaHSO_3$, crystallise in nacreous scales (Limpricht, Annalen 93, 238); the *ammonium* salt C_3H_6O,NH_4HSO_3 crystallises in laminæ (Städeler, Annalen, 111, 307). The *barium* salt has formula $2C_3H_6O,Ba(SO_3H)_2,H_2O$ (Fagard, J. Pharm. Chim. 1895, 2, 145). These salts yield acetone when heated with aqueous potash. *Calcium chloride* combines with acetone to form $CaCl_2,2C_3H_6O$ and $CaCl_2,C_3H_6O$ (Bagster, Chem. Soc. Trans. 1917, 111, 494).—2. *Compounds with chloroform* (Willgerodt, Ber. 14, 2451; 15, 2308; Cameron and Holly, Chem. Zentr. 1898, ii. 277; Jocitsch, *ibid.* 1899, i. 606; Willgerodt and Dürr, J. pr. Chem. 148, 283). —3. *Compounds with hydrogen cyanide* (Urech, Annalen, 164, 255):—Acetone yields acetone-cyanhydrol C_4H_7NO, b.p. 120°, when added to anhydrous hydrogen cyanide; and diacetone-cyanhydrol $C_7H_{13}NO_2$, a crystalline substance, when treated with a 25 p.c. solution (aqueous) of hydrogen cyanide (Tiemann and Friedländer, Ber. 14, 1965); with 3·3 p.c. hydrogen cyanide acetone-cyanhydrin is obtained in the dark, but in the light a mixture of products is formed (Silber, Ber. 38, 1671).—4. *Compounds with ammonia*:—Ammonia unites with acetone in the cold with the elimination of the elements of water; the reaction, however, proceeds more quickly if the temperature is raised to 100°, or if dry ammonia gas is passed into boiling acetone. Several bases, diacetonamine $C_6H_{13}NO$, triacetonamine $C_9H_{17}NO$, triacetonediamine $C_9H_{20}N_2O$, and dehydrotriacetonamine $C_9H_{15}N$; the last two in very small quantity only, have been obtained by these methods, the relative proportions in which they are formed varying with the temperature and time employed. These bases and their derivatives have been examined by Heintz (Annalen, 174, 133; 175, 252; 178, 305, 326; 181, 70; 183, 276; 189, 214; 191; 122; 198, 42, 87; 201, 90; 203, 336) and by Sokolow and Latschinow (Ber. 7, 1384), Ruhemann and Carnegie (Chem. Soc. Trans. 1888, 424), Rügheimer (Ber. 21, 3325; 25, 1562), Harries (Annalen, 296, 328), Franchimont and Friedmann (Rec. Trav. Chim. 1907, 223), Gabriel and Colman (Ber. 35, 3805), Kohn and Lindauer (Monatsh. 23, 754), Kohn (Annalen, 351, 13[illegible]; Monatsh. 24, 765, 773; 25, 135, 817, 850; 28, 429, 508, 529, 537, 1040); they yield well-crystallised salts, and can be separated from one another by means of their oxalates. Methylamine also gives corresponding compounds with acetone, but dimethylamine yields dimethyldiacetonamine as the sole product (Göttschmann, Annalen, 197, 27).

Thioacetones have been studied by Baumann and Fromm (Ber. 22, 1035, 2592). Acetone forms compounds with mercuric sulphate (Denigès, *l.c*; Oppenheimer, *l.c.*), with mercuric oxide (Auld and Hantzsch, Ber. 38, 2677; Lasserre, J. Pharm. Chim. 1890, 22, 246), with mercuric cyanide (Marsh and Struthers, Chem. Soc. Trans. 1905, 1878), with mercuric iodide (Gernez, Compt. rend. 137, 255; Marsh and Struthers, Chem. Soc. Proc. 1908, 266), and with mercuric nitrate (Hofmann, Ber. 31, 2212). Metallic derivatives of the type $CH_3{\cdot}CO{\cdot}CH_2K$ are obtained by the electrolysis of acetone solutions of potassium or sodium iodides or of potassium thiocyanate (Levi and Voghera, Gazz. chim. ital. 35, i. 277).

Acetone yields substitution derivatives when acted upon with chlorine or bromine (Bischoff, Ber. 5, 863, 963; 8, 1329). The following derivatives have been obtained:—Monochloracetone (Henry, Ber. 5, 190; Mulder, Ber. 5, 1009; Barbaglia, Ber. 7, 467; Linnemann, Annalen, 134, 171; Koenigs and Wagstaffe, Ber. 26, 554; Wislicenus, Kircheisen and Sattler, *ibid.* 26, 908; Fritsch, *ibid.* 26, 597; Tcherniac, Ber. 25, 2629; Kling, Bull. Soc. chim. [3] 33, 322); unsymmetrical dichloracetone (Fittig, Annalen, 110, 40; Borsche and Fittig, Annalen, 133, 112· Erlenbach, Annalen, 269, 46; Tcherniac, *l.c.*; Fritsch, *l.c.*; McIntosh, Chem. Soc. Trans. 1905, 790); symmetrical dichloracetone (Barbaglia, *l.c.*; Fritsch, *l.c.*); trichloracetone (Bischoff, *l.c.*; Kraemer, Ber. 7, 252; Perrier and Prost, Compt. rend. 140, 146; Hantzsch, Ber. 21, 242); tetrachloracetone (Bischoff, Levy, Witte and Curchod, Annalen, 252, 330, 254, 83; Levy and Jedlicka, Ber. 21, 318); and pentachloracetone (Cloëz, Bull. Soc. chim. [2] 39, 638; Fritsch, Annalen, 279, 310 and *l.c.*; Levy and Jedlicka, *l.c.*). Pentachloroacetone treated with phosphorus pentachloride yields as-heptachloropropane C_3Cl_{10}, a crystalline substance, m.p. 32°; also obtained by the direct addition of chloroform to tetrachloroethylene under the influence of aluminium chloride (Böeseken and Prins, Proc. K. Akad. Wetensch. Amsterdam, 1911, 13, 685). The corresponding bromo-derivatives, with the exception of tribromacetone, are obtained by the direct action of bromine upon acetone (Mulder, J. 1864, 330; McIntosh, *l.c.*; Lapworth, Chem. Soc. Trans. 1904, 33), also by other methods (Hjelt and Siven, Ber. 21, 3288; Norton and Westenhoff, Amer. Chem. J. 10, 213; Hartzsch, *l.c.*). Other halogen derivatives (J. Soc. Chem. Ind. 16, 933; Hantzsch, *l.c.* and Ber. 22, 1238) and the compounds of acetone with the halogen acids (Archibald and McIntosh, Chem. Soc. Trans. 1904, 924) have been described.

Acetone forms a large number of condensation products and derivatives with other organic compounds: Cyanacetones (Hantzsch, Ber. 23, 1472; Tche niac, Ber. 25, 2607, 2621; Kowppa, Ber. 33, 3530). Acetone dioxalic ester obtained by the action of sodium ethylate on a mixture of acetone and oxalic ester is converted when treated with sodium ethoxide to a dienolic substance forming lemon-yellow needles, m.p. 98°, and dyeing wool in alcoholic solution It is the first nitrogen free dye-stuff of the fatty series yet obtained (Willstatter and Pummerer, Ber. 37, 3733). Pseudo*cyclo*citralidene acetone and its homologues have an odour of violets, and are suitable for use in perfumes (J. Soc Chem. Ind. 24, 200).

For acetone dicarboxylic acid and its derivatives, *see* Ormerod, Chem. Soc. Proc. 1906, 205, Denigès, Compt. rend. 128, 680; Lippmann, Ber. 41, 3981; for acetonyl acetone and its derivatives, *see* Knorr, Ber. 22, 168, 2100; Claisen and Ehrhardt, Ber. 22, 1009; Zincke and Kegel, Ber. 23, 230; Claisen, Ber. 25, 3164; the azo- (Bulow and Schlotterbeck, Ber. 35, 2187) and diazo- derivatives of acetonyl acetone, have dyeing properties (Faurel, Compt. rend. 128, 318).

Acetone, with diazobenzene chloride in the presence of alkali, yields a compound $C_{15}H_{14}ON_2$ m.p. 134°–135°, which has dyeing properties (Bamberger and Wulz, Ber. 24, 2793). For other condensation products compare Boessneck, Ber. 21, 1906; Pechmann and Wehsarg, *ibid.* 2989, 2994; Franke and Kohn, Monatsh. 19, 354; 20, 876; Spier, Ber. 28, 2531; Perkin and Thorpe, Chem. Soc. Trans. 1896, 1482; Weidel, Monatsh. 17, 401; Micko, *ibid.* 442; Stobbe Ber. 28, 1122; Cornelson and Kostanecki, Ber. 29, 240; Claisen, *ibid.* 2931; Röhmer, Ber. 31, 281; Pfitzinger, J. pr. Chem. 164, 283; Freer, Amer. Chem. J. 17, 1; Barbier and Bouveault, Compt. rend. 118, 198; Haller and March. Compt. rend. 139, 99; Straus, Ber. 37, 3293 Harries and Ferrari, Ber. 36, 656; Ulpiani and Bernardini, Atti R. Accad. Lincei, 1904, 13, 331; Pechmann and Sidgwick, Ber. 37, 3816; Duntwitz, Monatsh. 27, 773; Knoevenagel, Ber. 39, 3451, 3457; Purdie, Chem. Soc. Trans. 1906, 1200; Richard, Compt. rend. 145, 129. Diacetones and their derivatives have been studied by Combes (Compt. rend. 108. 1252; Behal and Auger, Compt. rend. 109, 970; Claisen and Stylos, Ber. 21, 141); derivatives of triacetone by Weinschenk (Ber. 34, 2185).

ACETONECHLOROFORM, *ααα-trichlor-β-hydroxy-β-methylpropane* (*Chloretone*) $(CH_3)_2 \cdot C(OH) \cdot CCl_3$, prepared by slowly adding powdered potassium hydroxide (3 parts) to a cooled mixture of acetone (5 parts) and chloroform (1 part) (Willgerodt, J. pr. Chem. [2] 37, 361) is a white crystalline compound, b.p. 167°, melting near but above 97°; it has a camphor-like odour, is soluble in hot, sparingly soluble in cold water, and crystallises well from ether, alcohol, acetic acid, acetone, or chloroform; it forms no definite hydrate, but the system acetone-chloroform/water presents a quadruple point for the solid, two solutions and the vapour at 75·2° (Cameron and Holly, J. Phys. Chem. 1898, 2, 322). The *acetate* $(CH_3)_2 \cdot C(OAc) \cdot CCl_3$ boils at 191°. The *benzoate* $(CH_3)_2 \cdot C(OBz).CCl_3$ boils at 282° (Willgerodt and Dürr, J. pr. Chem. [2] 39, 283). Acetonechloroform is reduced by zinc-dust and alcohol, forming dichloro*iso*butylene, *iso*crotylchloride, and *iso*butylene (Jocitsch, J. Russ. Phys Chem. Soc. 1898, 30, 920); and is decomposed by water at 180°, yielding hydrogen chloride and hydroxy*iso*butyric acid (Willgerodt, Ber. 1882, 15, 2305). By the action of benzene in presence of aluminium chloride the chlorine atoms of acetonechloroform are replaced wholly or in part by phenyl residues, and the compounds *diphenylchloromethyl dimethyl carbinol* $CPh_2Cl \cdot CMe_2 \cdot OH$ b.p. 230°; *phenyldichloromethyl dimethyl carbinol* $CPhCl_2 \cdot CMe_2 \cdot OH$ b.p. 217°; and *triphenylmethyl dimethyl carbinol* $CPh_3 \cdot CMe_2 \cdot OH$ b.p. 260°, have been prepared, and similar compounds are obtained using toluene or *p*-xylene (Willgerodt, J. pr. Chem. [2] 37, 361).

Acetonechloroform is a powerful germicide, a satisfactory surgical dressing, and hypnotic for internal use (Aldrich and Houghton, Amer. J. Physiol. 1900, 3, 26); it is used as a specific for sea-sickness (Merck. Ann. Report, 1907, 1), forming the chief ingredient of "Zotos," and a 1 2 p.c. solution is used under the name of *anesin* for producing local anaesthesia (Cohn, Pharm Zentr. H. 40, 33).

ACETONEDICARBOXYLIC ACID *v.* KETONES.

ACETONE OIL is the oily residue remaining after the separation of acetone from the products of the dry distillation of calcium acetate. It can also be prepared by the dry distillation of the lime salts obtained by neutralising fleece washings with milk of lime. About 15 litres of the oil are obtained from a cubic metre of fleece washings of 11°B. It is a slightly-coloured liquid of sp.gr. 0·835, having a penetrating smell and acrid burning taste. It consists mainly of methyl ethyl ketone (A. and P, Buisine, Compt. rend. 126, 351; 128, 561). According to Duchemin (Bull. Soc. chim. [3] 21, 798) acetone oil is of very variable composition, depending upon the nature of the pyrolignate from which it is prepared. A French Commission reported that it was effective as a denaturant of alcohol and it was adopted for this purpose by the Swiss Government in 1895.

For details of mode of manufacture from wool washings, *v.* Buisine (J. Soc. Chim. Ind. 18, 292; 21, 164); P. Baechlin, (Rev. Chim. Ind. 9, 112; 15, 240).

ACETONIC ACID, *v.* HYDROXYBUTYRIC ACID.

ACETOPHENONE. *Phenyl methyl ketone. Hypnone* $C_6H_5{\cdot}CO{\cdot}CH_3$, is obtained by acting with benzoyl chloride on zinc methyl; by distilling a mixture of the calcium salts of benzoic and acetic acids; or by boiling together benzene and acetyl chloride with aluminium chloride. It can be isolated from the fraction of heavy oil of coal tar boiling at 160°–190° by addition of sulphuric acid, distilling the solution in steam and converting the distillate into the *p*-bromophenylhydrazone derivative of acetophenone (Weissgerber, Ber. 36, 754). It is best obtained synthetically by adding small quantities of sublimed ferric chloride (7 parts) to a mixture of benzene (5 parts) and acetyl chloride (7 parts) diluted with carbon disulphide. The mixture is then warmed on the water-bath, dried and fractionated (Nencki and Stoeber, Ber. 30, 1768).

Acetophenone crystallises in large plates, m.p. 20·5°; b.p. 202°. It possesses a persistent odour of oil of bitter almonds and cherry laurel water; is insoluble in water, but dissolves easily in alcohol, ether, chloroform, or benzene. It is readily oxidised by potassium permanganate to phenylglyoxylic acid (Glücksmann, Monatsh. 11, 246). By the action of ammonia on an alcoholic solution of acetophenone, the acetophenone ammonia is formed $CMePh(N : CMePh)_2$, m.p. 115° (Thomae, Arch. Pharm. 244. 643) (*v.* KETONES).

Acetophenone forms a large number of derivatives and condensation products with aldehydes, halogens, acids, mercury salts, &c. By the action of hydrogen in presence of finely divided nickel it may be converted into phenyl methyl carbinol.

Acetophenone was discovered by Dujardin-Beaumetz and Bardet to possess powerful soporific properties (Compt. rend. 101, 960; Karmensky, Liss. Med. Chi. Acad. St. Petersburg, 1888-1889, No. 70). In quantities of 0·05 to 0·15 gram, it induces a quiet sleep, but is said to impart a disagreeable odour to the breath (Pharm. J. 1886, 582).

Aminoacetophenone (Camps, Arch. Pharm. 40, 15), b.p. 250°–252°; 135°/17 mm., has anæsthetic properties, which are not diminished by condensing it with aldehydes containing a phenolic hydroxyl, but are destroyed when it is condensed with benzaldehyde, tolualdehyde, or cinnamaldehyde (Hildebrandt, Chem. Zentr. 1905, ii. 502; Scholz and Huber, Ber. 37, 390; Schäfer, Ber. 39, 2181).

p-Amino acetophenone v. KETONES.

Acetophenonephenetidene, m.p. 88°, an antipyretic substance, can be obtained by heating molecular proportions of acetophenone and *p*-phenetidene *in vacuô*, then distilling *in vacuô* at 210°–212° (Valentiner, J. Chem. Soc. Ind. 15, 50; 17, 602).

β-ACETO-PROPIONIC ACID. *Lævulic acid*

$$CH_3{\cdot}CO{\cdot}CH_2{\cdot}CH_2{\cdot}CO_2H.$$

This substance is formed by the action of dilute acids on a number of carbohydrates—*e.g.* levulose, inulin, galactose. It is also a product of oxidation of the terpene alcohols, but is best prepared by heating on the water-bath cane sugar with dilute hydrochloric acid (4 vols. water, 1 vol. conc. acid) until a brown flocculent precipitate is no longer formed. (Compare Tollens, Ber. 17, 668; Wehmer a. Tollens, Annalen, 243, 214.) The filtered liquid is then evaporated on the water-bath extracted several times with ether, and after distilling off the ether the residue is fractionated in a vacuum.

It can be obtained by the hydrolysis of various nucleic acids (Kossel and Neumann, Zeitsch. physiol. Chem. 27, 2215; Inouye, *ibid.* 42, 117; Levene, *ibid.* 43, 119). For other methods of preparation, compare Tiemann and Semmler (Ber. 28, 2129); Verley (Bull. Soc. chim. [3] 17, 190); Erlenmeyer (J. pr. Chem. 179, 382); Blaise (Bull. Soc. chim. [3] 21, 647).

Lævulic acid crystallises in plates which melt at 33°. It boils at 239°, 148°–149°/15 mm. (Michael, J. pr. Chem. 152, 113), and has at 15° a sp.gr. 1·135. It is very soluble in water, alcohol, or ether, and is not attacked by bromine in the cold. Nitric acid converts it into carbon dioxide, acetic acid, succinic and oxalic acids. Iodine and sodium hydroxide form iodoform even in the cold. Hydriodic acid and phosphorus at 200° convert it into normal valeric acid; whereas sodium amalgam forms sodium γ-hydroxyvalerate acid in an alcoholic solution, and normal valeric acid in an acid solution. When added to boiling iodic acid solution diiodoacetoacrylic acid is formed (Angeli and Chiassi, Ber. 25, 2205). When placed over sulphuric acid in a vacuum it decomposes, leaving a residue of dihydroxyvaleric acid (Berthelot and André, Compt. rend. 123, 341).

The mercury salt $Hg(C_5H_7O_3)_2$, which crystallises in silvery plates, breaks up on treatment with sodium hydroxide, forming the two mercurilævulic acids $C_5H_6O_3Hg$ and $C_5H_4O_3Hg_2$. Lævulic acid readily condenses with benzil (Japp and Murray, Chem. Soc. Proc. 1896, 146), and with aldehydes (Meingast, Monatsh. 26, 265). It forms a semi-carbazone, m.p. 187° (Blaise, *l.c.*). The ethyl ester when treated with ethyl magnesium bromide yields a lactone, b.p. 105°–106°/18 mm. (Grignard, Compt. rend. 135, 627). Halogen substitution derivatives of lævulic acid have also been obtained (Wolff, Ber. 26, 2216; Wolff and Rüdel, Annalen, 294, 192; Conrad and Schmidt, Annalen, 285, 203).

The substance is employed on a manufacturing scale as a mordant instead of acetic acid, as it possesses the advantage of not being volatile with steam.

It is also used in the preparation of the antipyretic *antithermin*. Phenylhydrazine is dissolved in dilute acetic acid, and on adding a solution of lævulic acid a yellow precipitate is formed, which is purified by recrystallisation from alcohol (Pharm, J. [3] xvii. 801) (*v.* ANTITHERMIN).

ACETOPURPURINE *v.* AZO- COLOURING MATTERS.

ACETOPYRINE or **ACOPYRINE.** A combination of phenyl-dimethyl pyrazolone (antipyrine) and acetyl salicylic acid.

ACETOSAL or **ACETYSAL.** Syn. for acetyl salicylic acid.

ACETO-*p*-TOLUIDIDE is obtained by the action of acetic acid upon toluidine. Melts at 153° and boils at 307°.

ACETOZONE. Mixture of acetylbenzoyl

peroxide $\begin{matrix}C_6H_5\cdot CO\\CH_3\cdot CO\end{matrix}\!\!>O=O$ and kieselguhr, used as an antiseptic.

ACETPHENETIDENE *v.* PHENACETIN.

ACETYLCHOLINE *v.* ERGOT, MUSCARINE.

ACETYL-1-NAPHTHYLAMINE-5-SULPHONIC ACID is prepared by boiling a mixture of 5 parts of 1-naphthylamine-5-sulphonic acid, glacial acetic acid, acetic anhydride and sodium acetate under a reflux condenser until a sample cannot be diazotised. The mixture is then heated so long as acetic acid and acetic anhydride distil over.

ACETYL-1 : 4-NAPHTHYLENEDIAMINE-6-SULPHONIC ACID is obtained by adding monoacetyl 1 : 4 naphthylenediamine sulphate to fuming sulphuric acid containing 20 p.c. SO_3, warming to 40°-50° and pouring into ice-cold water. Or a mixture of 1-naphthylamine-6 and 7-sulphonic acids (Cleve's Acids) may be acetylated with glacial acetic acid, distilling off the excess of acetic acid, dissolving the product in sulphuric acid and adding a cooled mixture of nitric and sulphuric acids. The mixture is diluted with cold water and the sodium salts of the nitro-acids precipitated by adding common salt. The mixture of the nitro-acids is reduced by iron filings and acetic acid, made alkaline by sodium carbonate, filtered hot, slightly acidified and the 1 : 4-naphthylenediamine-6-sulphonic acid precipitated. This is acetylated by boiling with a mixture of acetic acid and sodium acetate (Levinstein, Eng. Pat. 12119 (1898); Cassella and Co. D.R.P. 116922). Used in making Diaminogen blues. (Çain, 'Intermediate Products for Dyes.') *Cf.* NAPHTHALENE.

ACETYL-*p*-PHENYLENEDIAMINE (*p*-amino acetanilide)

$NH_2\cdot C_6H_4\cdot NH\cdot CO\cdot CH_3$

is prepared by reducing *p*-nitroacetanilide with iron filings and acetic acid at 60°, rendering the solution alkaline with sodium carbonate and adding common salt and hydrochloric acid when the hydrochloride of acetyl-*p*-phenylene diamine crystallises out (Grandmougin, Rev. prod. chim. 1917, 20, 260). Acetyl-*p*-phenylenediamine melts at 162·5°.

ACETYLENE C_2H_2 is the first member of the series of unsaturated aliphatic hydrocarbons to which it gives its name, and having the general formula : C_nH_{2n-2}. This formula also applies to the dialkylenes the difference being that members of the acetylene series are characterised by the presence of one triple linkage whilst the dialkylenes possess two double linkages :—

$CH\vdots CH$	$CH\vdots C\cdot CH_3$	$CH_3\cdot C\vdots C\cdot CH_3$
Acetylene (C_2H_2).	Propine (C_3H_4) (or Methyl acetylene or Allylene).	Butine (C_4H_6) (Dimethyl acetylene or Crotonylene.)
and	$CH_2\cdot C:CH_2$	$CH_2:CH\cdot CH:CH_2$
	Propadiene (C_3H_4).	Butadiene (C_4H_6).

The dialkylenes will not therefore be considered in this section. (*See* SYNTHETIC RUBBER, ISOPRENE, BUTADIENE.)

Nomenclature.—According to the Geneva system acetylene is to be termed Ethine, the ending -ine being the systematic termination for members of the acetylene series, thus : propine, butine, etc. In practice, however, the original name acetylene is always used as being well established and unlikely to cause confusion. With the exception of allylene C_3H_4, and crotonylene C_4H_6, higher members of the series are usually named as substituted acetylenes, *e.g.* methyl-acetylene, dimethyl-acetylene, isopropyl-acetylene, phenyl-acetylene, &c.

Historical.—Acetylene was first observed by Edmund Davy as a gas produced on treating with water the impure residues obtained in the preparation of potassium (Brit. Assoc. Rep. 1836, p. 62 : Annalen, 23, 144). The first systematic examination of the gas was made by Berthelot (Compt. rend 54, 640 ; Annalen, 123, 212 ; Ann. Chim. Phys [7] 23, 444 ; [8] 6, 182), who examined the composition and properties of acetylene and showed its production in many pyrochemical processes.

Of particular interest to the technical chemist is the discovery by Wöhler, in 1862 (Annalen, 124, 220), that acetylene is produced by treating calcium carbide with water, a discovery that served thirty years later as the starting point for the whole acetylene industry when it was shown by Willson, in 1802, that calcium carbide could be produced on a large scale and in fairly pure condition in the electric furnace. For more than a decade after the introduction of calcium carbide on a commercial scale, the chief interest in the subject lay in the direction of the utilisation of the gas for illuminating purposes, as it was widely believed that the pure white light of acetylene, and its convenience of manufacture in small quantities, would soon cause it to oust coal-gas from the field to a great extent. This expectation has not been fulfilled, though acetylene continues to be of great use for various purposes such as flares, &c. The next stage was the use of the oxy-acetylene flame for the 'autogenous welding' of iron, an industry that to-day utilises a considerable amount of the gas. In the first decade of the present century attempts were made to effect the chemical utilisation of acetylene in various ways, chiefly by the addition of chlorine and the formation of various chlorine derivatives of different boiling-points which are suitable as solvents for many purposes and serve to replace inflammable materials such as benzene, gasoline, and so on, for dry-cleaning, fat-extraction, &c. On these lines much useful work has been done in this country by Tompkins, and by the Clayton Aniline Company, and abroad by the Chemische Fabrik Griesheim-Elektron, and the Consortium für elektrochemische Industrie G.m.b.H. Lastly, since 1910, it has been found possible to produce acetaldehyde direct from acetylene on a technical scale by the use of mercury salts as catalysts, with the result that progress in this field has been remarkably rapid, and the production of such diverse substances as alcohol, acetic acid, acetic anhydride, and acetone from acetylene on a commercial scale is already an accomplished fact which may have vast economic consequences. (*See* ACETALDEHYDE.)

Production.—(1) *By the direct union of carbon and hydrogen* in the electric arc

$$2C+H_2=C_2H_2$$

(Berthelot, Compt. rend. 54, 640 ; Annalen, 123, 212; Ann. Chim. Phys. [7] 23, 444; [8] 6, 182; Bone and Jerdan, Chem. Soc. Trans. 71, 41; 79, 1042; Pring and Hutton, Chem. Soc. Trans. 89, 1600; v. Wartenberg, Zeitsch. angew. Chem. 52, 310.)

(2) *From ethylene dibromide or dichloride* by the action of alcoholic potash, with the intermediate formation of vinyl chloride or bromide:

$$CH_2Br{\cdot}CH_2Br-HBr = CH_2:CHBr$$
$$CH_2:CHBr-HBr = CH:CH$$

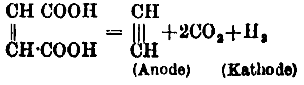
(Sawitsch, Compt. rend. 52, 157; Miasnikow, Annalen, 118, 330; de Wilde, Ber. 7, 352; Sabanejew, Annalen, 178, 109; Zeisel, Annalen, 191, 368; de Forcrand, Compt. rend. 104, 697; Mouneyrat, Bull. Soc. chim. [3] 19, 184; Meunier and Desparment, Compt. rend. 144, 273; Bull. Soc. chim. [4] 1, 342.

(3) *By treating various halogen compounds with metals, e.g.* by treating tetrachlorethane with metallic zinc:

$$CHCl_2{\cdot}CHCl_2+2Zn = CH:CH+2ZnCl_2$$

(Sabanejew, Annalen, 216, 252), or by the action of silver, copper, or zinc dust on iodoform, or by the action of the copper-zinc couple on bromoform (Cazeneuve, Compt. rend. 97, 1871; 113, 1054).

(4) *By electrolysis of unsaturated carboxylic acids*, such as fumaric or maleic acid:



$$\begin{array}{l}CH{\cdot}COOH\\ \|\\ CH{\cdot}COOH\end{array} = \begin{array}{l}CH\\ |||\\ CH\end{array} + 2CO_2 + H_2$$

(Anode) (Kathode)

(Kekulé, Annalen, 131, 85).

(5) *From acetylene mono- or di-carboxylic acids:*

$$C_2(COOH)_2 = C_2H_2+2CO_2$$

(Lossen, Annalen, 272, 140). (*Cf.*, however, Vanzetti and Fasoli, Gazz. chim. ital. 46, i. 49.)

(6) *From propargyl aldehyde* by the action of alkali:

$$CH:C{\cdot}CHO+NaOH = CH:CH+H{\cdot}COONa$$

(Claisen, Ber. 31, 1023).

(7) *By decomposition of various complex organic substances*: *e.g.* brom-cyclo butene (*cf.* Knorr and Matthes, Ber. 32, 740; Willstatter and v. Schmaedel, Ber. 38, 1994; Gabriel, Ber. 38, 2405.)

(8) *From copper acetylide* by the action of aqueous potassium cyanide (Baeyer, Ber. 18, 2273; *cf.* also Zeisel, Annalen, 191, 368; Römer, Annalen, 233, 182; Noyes and Tucker, Amer. Chem. J. 19, 123). This method is stated to yield extremely pure acetylene: if hydrochloric acid be used instead of potassium cyanide, the gas is not so pure and possibly contains traces of vinyl chloride.

(9) *By the action of water on calcium carbide:*

$$CaC_2+H_2O=Ca(OH)_2+C_2H_2$$

Strontium and barium carbides act similarly. (Wöhler, Annalen, 124, 220; Travers, Chem. Soc. Proc. 1893, 15; Maquenne, Compt. rend. 115, 558; Moissan, Bull. Soc. chim. [3] 11, 1007; Lewes, J. Soc. Chem. Ind. 16, 33; Clowes, *ibid.* 209, 319; Wilson, *ibid.* 15, 103; Lüpke, Elektr. Chem. Zeit. 1895, 145; Wyatt, J. Soc. Chem. Ind. 14, 135, 796; 20, 109; Bamberger, Zeitsch. angew. Chem. 1898, 720). This is by far the most convenient and practicable method for the production of acetylene, and is invariably used for the commercial production of the gas.

A convenient laboratory method for the production of acetylene is to cover calcium carbide with absolute alcohol and to add water drop by drop (Matthews, J. Amer. Chem. Soc. 22, 106).

For the technical production of acetylene and its use as an illuminant, *see* ACETYLENE—COMMERCIAL APPLICATIONS.

Details as to the British Patents dealing with the subject will be found in the Patent Office Abridgement Lists, Class 2, (1855–1909) and Class 2 (i) (1910–1915).

Acetylene is produced in the incomplete combustion of various gases such as coal-gas, for instance, when a Bunsen burner 'strikes back.' The view, however, that the accompanying unpleasant odour is due to the acetylene is incorrect. (*Cf.* Meyer and Jacobson, Lehrbuch der organ. Chemie. 2nd edn., I. 1, p. 853, note 2.)

It is also produced by passing methane or natural gas through incandescent carbon (Knapp, U.S. Pat. 1023783).

The chief objection to acetylene produced from calcium carbide is the fact that the various impurities present in the carbide, such as calcium sulphide, phosphide, etc., evolve the corresponding hydrides on treatment with water, so causing the acetylene produced to be contaminated with various small amounts of gases such as ammonia, phosphine, sulphuretted hydrogen, arsine, in addition to other hydrocarbons, carbon monoxide, hydrogen, nitrogen and oxygen.

Phosphine is probably the most serious impurity from the chemical as well as the physiological point of view.

A method of producing odourless acetylene has been patented by S. Ide (Jap. Pat. 30209, 1916), consisting in carbonising calcareous materials which contain phosphorus, sulphur, etc., as impurities, in the electric furnace, spraying with water, whereby the impurities escape in gaseous form, and then using the pure lime so produced for the manufacture of carbide in the usual way; this method would, however, probably be too costly to be of much use, and in practice the crude acetylene can be satisfactorily cleared of all its active impurities by suitable purification such as scrubbing with various liquids—for instance, acidified copper sulphate solution, chromic acid in acetic or sulphuric acid—or with lime, lead or mercury salts, bleaching powder, etc.

(Clowes, J. Soc. Chem. Ind. 16, 209, 319; Lunstroem, Chem. Zeit. 23, 180; Bergé and Reychler, Bull. Soc. chim. [3] 17, 218; Gottig, Ber. 32, 1879; Rossel and Landrisset, Zeitsch. angew. Chem. 1901, 77; Caro, J. Soc. Chem. Ind. 22, 17; 23, 15; Ullmann and Goldberg, Chem, Zentr. 1899, ii. 19; Pfeifer, J. f. Gasbel, 44, 548; Jaubert, J. Soc. Chem. Ind. 24, 116; Willgerodt, Ber. 28, 2107; Hoffmeister, Zeitsch. anorg. Chem. 48, 137; Matthews, J. Amer. Chem. Soc. 22, 106; Ditz, D.R.P. 162324; Lunge and Cedercreutz, Zeitsch. angew. Chem. 1897, 651; J. Soc. Chem. Ind. 16, 37; 24, 1294; 27, 798; Wolff, J. f. Gasbel. 1898, 41, 683. Full details regarding British Patents dealing with the purification of acetylene may be found in the Patent Office 'Fifty Year Subject Index, 1860-1910,' Class 2 (i).)

Properties.—Acetylene is a colourless gas having, in a pure state, a pleasant ethereal odour (Grehaut, Berthelot and Moissan, Compt. rend. 121, 564), which is, however, usually disguised by the presence of fœtid smelling impurities (Zeisel, Annalen, 191, 368; Römer, Annalen, 233, 182; Noyes and Ticker, Amer. Chem. Jour. 19, 123). It solidifies in liquid air to a crystalline mass which can be burnt like a candle (Ladenburg, Ber. 31, 1968). At the ordinary pressure its melting-point (−81°) is higher than its boiling point (−82·4°) (Ladenburg and Krügel, Ber. 32, 1821; 33, 638, Hunter, Chem. Zentr. 1906, ii. 485). McIntosh and Maass give the melting point as −81·5°, sublimation point −83·6°, and boiling point −88·5° (J. Phys. Chem. 11, 306; J. Amer. Chem. Soc. 36, 737); −84·0° Burrell and Robertson. Its critical temperature is 37·05° (Ansdell, Proc. Roy. Soc. 29, 209; Heilbronn, Zeitsch. physical. Chem. 7, 604) or 36·5° (McIntosh, *ibid.*); its critical pressure 67–68 atm. (Leduc, Ann. Chim. Phys. [7] 15, 87) or 61·6 atm. (McIntosh, *ibid.*) and its critical volume 83 c.c. (McIntosh, *ibid.*). Cardosa and Baume give the critical temperature as 35·5° and the critical pressure as 61·5 atm. (Compt rend. 151, 141). For other physical constants of solid and liquid acetylene, see McIntosh, *ibid.*

Liquid acetylene is a mobile fluid of sp.gr. 0·451 at 0° C. (Cailletet, Compt. rend. 85, 851; Ansdell, Jahresbericht d. Chem. 1879, 68) or 0·73 at −75° (McIntosh, *ibid.*). It has a high electrical resistance which is not appreciably altered by the addition of alcohol, ether, halogen hydride, etc. (McIntosh, *ibid.*).

Acetylene is readily soluble in many organic solvents; thus at 18° chloroform and benzene absorb about four times their volume, acetic acid and alcohol about six times their volume (Berthelot, Ann. Chim. Phys. [4] 9, 425; Garelli and Falciola, Atti d. Reale Accad. dei Lincei [5] 13, i. 110). It is extremely soluble in acetone (Claude and Hess, Compt. rend. 124, 626; Claude, Compt. rend. 128, 303) which absorbs twenty-five times its volume of the gas at 15° C. and 760 mm., and under 12 atm takes up 300 volumes, whilst at −80° it absorbs more than 2000 volumes acetylene, which would seem to point to acetone and liquid acetylene being miscible in all proportions. According to McIntosh (*supra*), crystalline compounds are formed. This property of acetone is of great technical importance in the storage of dissolved acetylene for illuminating purposes. (*See* ACETYLENE—COMMERCIAL APPLICATIONS.) (Berthelot and Vieille, Compt. rend. 123, 523; 124, 966, 988, 996, 1000; Wolff, Zeitsch. angew. Chem. 1898, 919; Caro, J. Soc. Chem. Ind. 25, 1138.)

In water the gas is sparingly soluble, about 1 p.c. by volume at 12° and 755 mm. being taken up; it forms a hydrate $C_2H_2+6H_2O$ (Villard, Compt. rend. 120, 1262). The solubility is lowered by the addition of salt (Claude and Hess, *v.s.*). Acetaldehyde has also been suggested as a solvent or diluent for acetylene as it dissolves half its weight of the gas (James and Watson, U.S. Pat. 928867; James, J. Ind. Eng. Chem. 5, 115), the solvent power of organic solvents appearing in general to be associated with the presence of a carbonyl group and low molecular weight.

Acetylene is an endothermic compound, being formed from its elements with an absorption of approximately 50 Cals. As a consequence both the gas and the liquid are highly explosive, particularly under pressure, for which reason solvents are used for storage, as noted above. (*Cf.* Maquenne, Compt. rend. 121, 424; Berthelot and Vieille, Compt. rend. 123, 523; 124, 988, 996, 1000; 128, 777; Ann. Chim. Phys. 11, 5; 17, 303; Claude, Compt. rend. 128, 303; Berthelot and Le Chatelier, Compt. rend. 129, 427; Ann. Chim. Phys. 20, 15; Mixter, Chem. Zentr. 1900, 1, 504; ii. 1007; Chem. Ind. 20, 53).

The molecular heat of combustion is 312·9 Calories at constant pressure. (For other thermal properties see also Berthelot, Compt, rend. 82, 24; Ann. Chim. Phys. [5] 9, 165; 13, 14; 23, 180; Berthelot and Matignon, Ann. Chim. Phys. [6] 30, 556; Maneuvrier and Fournier, Compt. rend. 124, 183; Mixter, Chem. Zentr. 1901, ii. 1250; 1905, ii. 98; 1906, ii. 414; Thomsen, Zeitsch. physical. Chem. 52, 346).

Acetylene when pure has no action on metals (Clowes, J. Soc. Chem. Ind. 16, 109; Moissan, Compt. rend. 124, 566), but ordinary acetylene readily attacks copper owing to the presence of impurities which facilitate the formation of explosive copper acetylide (Scheiber and Reckleben, Chem. Zeit. 39, 42; 40, 325). Nickel and tin in particular are little attacked by acetylene, and it is suggested by Scheiber and Reckleben that metals exposed to the action of acetylene should be coated with one of these metals. It is non-poisonous in small quantities, but may produce asphyxiation when more than 40 p.c. is present (Clowes, *l.c.*; Korda, Mon. Sci. 45, 409; Mosso and Ottolenghi, Ann. di. Chim. e. di. Farmacol. 25, 163; Vitali, Chem. Zentr. 1898, ii. 586; Moissan, *l.c.*; Gréhaut, Compt. rend, 121, 564; Berthelot, Compt. rend. 121, 566; Brociner, *ibid.* 121, 773; J. Soc. Chem. Ind. 16, 319; Rosemann, Chem. Zentr. 1895, ii. 998; Bettinck, Pharm. Weekblad, 54, 413). It has also distinct action on plants (Grafe and Richter, Botan. Zentr. 119, 423).

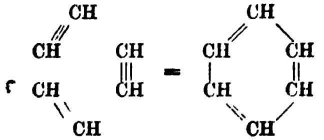
Acetylene explodes very violently when mixed with oxygen or air in any proportion from 3-82 p.c., but the explosiveness is reduced by admixture with inert gases (Meyer, Ber. 27, 2764; Le Chatelier, Compt. rend. 121, 1144; Gréhaut, Compt. rend. 122, 832; Berthelot and Vielle, *ibid.* 123, 523; Bone and Cain, Chem. Soc. Proc. 1896, 176; Clowes, J. Soc. Chem. Ind. 15, 90, 418, 701, 891; Bundt, Ber. 31, 5; Clowes, Chem. Soc. Proc. 1896, 413; Berthelot and Vielle, Compt. rend. 128, 177; *cf.* also Delépine, 8th Intern. Congr. Appl. Chem. 4, 25, and J. Gasbel, 57, 65).

It has been proposed to use acetylene as an explosive for bringing down material, *e.g.*, coal in large pieces (Sprengstoffe, Waffen und Munition, 9, 41).

With ozone acetylene is violently decomposed (Otto, Ann. Chim. Phys. 13, 166).

Pyrogenetic Condensations.—On heating acetylene it undergoes various condensations which are of great importance, particularly in connection with the theory of gas manufacture.

Berthelot found (Jahresbericht f. Chem. 1866, 516; Ann. Chim. Phys. [4] 9, 446, 469) that on leaving acetylene for a time in a glass tube heated to its softening point, a mixture of solid and liquid hydrocarbons was formed in which benzene predominated :—



(*cf.* also Haber, Ber. 29, 2691) It therefore appears probable that the formation and polymerisation of acetylene play an important part in the production of aromatic hydrocarbons in the manufacture of coal-gas (V. B. Lewes, Proc. Roy. Soc. 55, 90; 57, 394). R. Meyer and his co-workers have found that on passing acetylene through a tube suitably heated in an electric furnace large quantities of tarry products are produced, and as a result of collecting several kilos of tar they were able to isolate and identify some 23 products identical with those occurring in ordinary gas-tar, over 20 p.c. being benzene (R. Meyer and others, Ber. 45, 1609; 46, 3183; 47, 2765; 50, 422; 51, 1571) Bone and Coward, however, take a different view, holding that the main gaseous product at high temperatures must be methane which may dissociate into free radicals, CH; and CH_2: which condense together in various ways as the gases cool down (Chem. Soc. Trans. 93–4, 1197).

For a very complete discussion of the subject see 'The Pyrogenesis of Hydrocarbons,' Part I., E. Lawson Lomax; Part II., A. E. Dunstan and F. B. Thole, Journ Ind. and Eng. Chem. 1917, 879, 888; Journ. Inst. Petroleum Technologists, 3, 36–120. A comprehensive bibliography is given in the articles.

At temperatures above 800° or so, acetylene is completely decomposed into hydrogen and free carbon, possibly with the intermediate formation of methane :

$$2C_2H_2=3C+CH_4=4C+2H_2$$

(*Cf.* Bone and Coward, *l.c.*)

This method has been patented for the production of pure hydrogen, the finely divided carbon so produced having a considerable commercial value as *acetylene black* (*cf.* J. Soc. Chem. Ind. 178, 711; 18, 284; 20, 955; Dépierre, *ibid.* 20, 890; Frank, Zeitsch. angew. Chem. 1905, 1733).

Thus Morehead (U.S. Pat. 986480) claims a process for dissociating acetylene by passing it suddenly into a chamber heated to at least dull redness. Before the war the Carbonium Co., at Friedrichshaven, had a factory in which compressed acetylene was decomposed by means of electricity into acetylene black and hydrogen, the latter being used for the Zeppelin airships; it is improbable, however, that the process can compete with other methods for the production of cheap hydrogen such as the Messerschmidt process or the Frank-Caro method (*v.* HYDROGEN).

Pictet (Eng. Pat. 24256, 1910) claims the production of hydrogen and carbon from acetylene by allowing it to flow into an externally heated chamber to be there heated until dissociation takes place, that part of the conduit through which the constituents pass being cooled so as to absorb the excessive heat produced by the reaction.

Acetylene burns with a very smoky but brilliantly white flame which can be modified by mixing carbon dioxide with the gas, the intensity varying with the concentration of the latter (Alvisi, Ann. chim. applicata, 5, 118). When submitted to the action of an electric discharge at ordinary pressure various condensation products are formed (*cf.* Berthelot, Bull. Soc. chim. [3] 4, 480; Jackson and Laurie, Chem. Soc. Proc. 1906, 155; Losanitsch, Monatsh. 29, 753; Javitschitsch, *ibid*, 29, 1; 29, 5; Coehn, Zeit. f. Elektr. 7, 681; Billitzer, Monatsh, 23, 199; Schutzenberger, Compt. rend. 110, 889).

Owing to its unsaturated nature acetylene readily enters into reactions to form addition products. It adds on hydrogen to form ethylene and ethane :

$$C_2H_2+H_2=C_2H_4$$
$$C_2H_2+2H_2=C_2H_6$$

This is most effectively performed with the aid of nascent hydrogen in the presence of a catalyst. Thus Lane (Eng. Pat. 10724, 1911) claims the synthesis of ethylene from acetylene and hydrogen by passing them over a heated catalyst contained in a series of tubes. (*Cf.* also Atterbury, Eng. Pat. 2961, 1898; Wideen, Eng. Pat. 9340, 1903; Bouchard-Praceiq, Eng. Pat. 6075, 1905.) Karo (D. R. P. 253160) claims the production of ethylene from acetylene and hydrogen using as a catalyst a mixture of at least one metal of the palladium or platinum group with at least one metal of the following series: iron, nickel, cobalt, copper, silver, magnesium, zinc, cadmium, or aluminium.

B. E. Eldred and G. Mersereau (U.S. Pat. 1308777) also put forward somewhat similar claims, the catalyst used being nickel or palladium on a carrier of coke, asbestos, pumice, etc.; to prevent the action becoming too energetic the gas mixture is diluted with ⅓ to ½ its volume of carbon dioxide or ethane.

According to Paal and his co-workers acetylene is readily reduced to ethylene and ethane by hydrogen in the presence of colloidal platinum or palladium; in presence of palladium practically pure ethylene can be obtained, the reduction being step-wise; in presence of platinum 35–40 p.c. of ethane is produced simultaneously (Ber. 43, 2684, 2692; 48, 275, 1195, 1202; 46, 128; Chem. Zeit. 36, 60. *Cf.* also de Wilde, 7, 353; Sabatier and Senderens, Compt. rend. 130, 1559, 1628, 1761; 131, 40, 187, 267; Bull. Soc. chim. [3] 25, 678).

W. Traube and W. Passarge (Ber. 49, 1692) describe the reduction of acetylene directly to ethylene by means of an aqueous solution of chromous chloride; the same result is obtained if powdered zinc, diluted hydrochloric acid and a small quantity of chromous chloride be used. No ethane appears to be produced under such conditions. The reaction may be carried out under pressure (D. R. P. 287585; U.S. Pat. 1179051).

When passed over various metallic catalysts such as finely reduced nickel, copper, cobalt or iron, a mixture of acetylene and hydrogen may yield various liquid hydrocarbons as well as ethylene and ethane: in particular copper yields a greenish hydrocarbon, 'Cuprene' (*q.v.*) $(C_7H_6)_n$, as also does nickel (Sabatier and Senderens, Compt. rend. 128, 1173; 130, 250, 1559, 1628; 131, 187; Moreau, *ibid.* 122, 7240; Alexander, Ber. 32, 2381; Erdmann and Köthner, Zeitsch. angew. Chem. 18, 49; Gooch and Baldwin, *ibid.* 22, 235).

By passing acetylene over the kathode of alkaline lye undergoing electrolysis ethylene and ethane are formed (Billitzer, Monatsh. 23, 199).

With fuming sulphuric acid acetylene gives a sulphonic acid, the potassium salt of which, $(C_2H_2)_3\cdot(SO_4KH)_4$, yields phenol on fusion with potash and distilling the product (Berthelot, Compt. rend. 127, 908; 128, 333; Ann. Chim. Phys. [7] 17, 289; Schroeter, Ber. 31, 2189; Muthmann, Ber. 31, 1880). If 50 p.c. fuming sulphuric acid be used the chief product is *acetaldehyde disulphonic acid*:

$$CH{\vdots}CH+2H_2SO_4=(SO_3H)_2\cdot CH\cdot CHO+H_2O$$

(Schroeter, Muthmann, *l.c.*). Atterbury (Eng. Pat. 1208, 1898) claims the production of vinyl alcohol by passing acetylene into hot strong sulphuric acid.

When led into fused alkali at 220° acetylene is completely absorbed and hydrogen is liberated. The reaction product on treatment with water gives alkali acetate. A 60 p.c. yield is claimed but the process hardly seems of commercial value (Feuchter, Chem. Zeit. 38, 273). It reacts with hypochlorous acid to give *dichlor-acetaldehyde*,

$$\begin{aligned}C_2H_2+HClO &= CHCl_2\cdot CH(OH)_2\\ &= CHCl_2\cdot CHO+H_2O\end{aligned}$$

(Wittorf. Chem. Zentr. 1900, ii. 29).

With nitric acid nitroform and various complex nitrogenated substances are produced including an explosive substance $C_4H_2O_3N_4$ m.p. 78° (Tustoni and Mascarelli, Gazz. chim. ital. 31, i. 461; Mascarelli, *ibid.* 33, ii. 319).

According to K. J. P. Orton (Eng. Pat. 125000) a good yield of tetranitromethane may be obtained from acetylene and nitric acid by passing the gas into 90 p.c. to 97 p.c. acid, preferably in presence of a small quantity of mercury, at about 40° C., adding sulphuric acid and then distilling off the tetranitromethane formed.

Water forms an addition product at low temperatures and under pressure, of the formula $C_2H_2\cdot 6H_2O$ (Villard, Compt. rend. 120, 1262; Ann. Chim. Phys. [7] 10, 396; 11, 360; Berthelot, Compt. rend. 128, 336; Ann. Chim. Phys. [7] 17, 297; Forcrand and Thomas, Compt. rend. 125, 109). It does not, however, combine with water directly to form acetaldehyde except in the presence of catalysts such as salts of cadmium, magnesium, zinc, and especially mercury (Kutscherow, Ber. 14, 1540; 17, 13; 42, 2759; Erdmann and Köthner, Zeitsch. angew. Chem. 18, 48):

$$CH{\vdots}CH+HOH = CH_2:CH(OH) \rightarrow CH_3\cdot CHO$$

This property has of recent years given rise to many important developments, as acetaldehyde can be readily converted into most diverse substances such as alcohol, acetic acid, acetone, butadiene and so synthetic rubber, etc. (For further details see ALDEHYDE.)

When mixed with gases such as ammonia, sulphuretted hydrogen, &c., and passed through heated tubes, various condensation products are formed identical with those occurring in coal-tar, such as pyridine, pyrrole, quinoline, thiophene, &c. (Meyer and Tanzen, Ber. 46, 3183; Meyer and Wesche, Ber. 50, 422; Tschitschibabin, J. Russ. Phys. Chem. Soc. 47. 702), whilst a 50 p.c. yield of acetonitrile under certain conditions is claimed by the Chem. Fab. Rhenania (E. P. 109983).

According to G. Capellen (Amer. Chem. Abstr. 2, 1562) and O. de Coninck (Bull. acad. roy. Belg. 1908, 303) thiophene is not producible direct from acetylene and sulphur; a good yield, however, of thiophene can be obtained by passing acetylene over pyrites heated to 280°-310° (Steinkopf and Kirchhoff, Annalen, 403, 1; D. R. P. 252375; Fr. Pat. 446136; Austr. P. 72291, 1916; Eng. Pat. 16810, 1912). Tschitschibabin (*l.c.*) claims to obtain a purer product from sulphuretted hydrogen than by Steinkopf's method.

According to the Chemische Fabrik Rhenania (Eng. Pat. 109983) thiophene is produced also by passing acetylene mixed with sulphuretted hydrogen over nickel hydroxide mixed with cement, or better over partially reduced bauxite.

On treating acetylene with hydrocyanic acid (*e.g.* by treating powdered calcium carbide and potassium cyanide with dilute sulphuric acid and evaporating the residue) a 5 p.c. yield of succinic acid is obtained, pointing to the intermediate formation of succinic nitrile:

$$C_2H_2+2HCN = (CH_2CN)_2 \rightarrow (CH_2\cdot COOH)_2$$

(E. Comanducci, Chem. Zeit. 35, 383).

Heinemann (Eng. Pat. 12365, 1913; Fr. Pat. 458,397; U.S. Pat. 1134677) describes the production of propylene by passing a mixture of acetylene and methane over heated contact substances:

$$CH{\vdots}CH+CH_4 = CH_3\cdot CH:CH_2$$

which can then be converted by circuitous routes into glycerine, acetone, &c. A yield of 70 p.c. is claimed using a catalyst consisting of platinum and copper, aluminium or magnesium on pumice at 100°-200°.

By allowing acetone or its homologues to act upon the alkali compounds of acetylene, 3-*methyl-butenol* or its homologues are produced (Farbwerke vorm Fr. Bayer, D. R. P. 285770):

$$(CH_3)_2CO+CH_2\cdot CHNa \rightarrow (CH_3)_2C(OH)C{\vdots}CH$$

According to D. R. P. 280226 and 291185, the same result is obtained by allowing acetone and acetylene to interact in the presence of alkali alcoholates. (*Cf.* also D. R. P. 284764, 286920, 289800.) On reduction the product yields 3-methyl-butenol (D. R. P. 288271):

$$(CH_3)_2C(OH)CH:CH$$

which can then be dehydrated to 2-methyl butadiene (isoprene) and polymerised to synthetic rubber.

(Other possible modes of obtaining synthetic rubber from acetylene are described by Dreyfus in Eng. Pat. 17193, 1913 (void).)

Compounds with metals and metallic salts.

A characteristic property of acetylene and its congeners is their ability to form additive compounds and substitution products with metals and metallic salts. When heated with sodium part of the hydrogen is replaced yielding *sodium acetylide* and carbide C_2HNa and C_2Na_2 (Matignon, Compt. rend. 124, 775; 159, 769; Skosarewsky, J. Russ. Phys. Chem. Soc. 36, 863; Moissan, *ibid.* 126, 302; de Forcrand, Bull. Soc. chim. [3] 13, 996). The sodium compound reacts with alkyl iodides in liquid ammonia at −50° to −30° to form homologues of the acetylene series (Lebeau and Picon, Compt, rend. 156, 1077; *cf.* also Moissan, *ibid* 127, 913).

Similar compounds are known with lithium, potassium, caesium and rubidium (Moissan, Compt. rend. 122, 362; Gunz. *ibid* 126, 1866; Bull. Soc. chim. [3] 15, 756; Compt. rend 123, 1273; Moissan, Compt. rend. 127, 911; 126, 302; 137, 463; 136, 1217).

Of particular interest are the compounds of acetylene with silver and copper which are formed on passing the gas through ammoniacal solutions of cuprous or silver salts; the former compound is a brick-red precipitate of varying composition and is used as a test for the presence of the gas; it appears to have the composition $Cu_2C_2H_2O$ to which Makowka gives the structure $Cu_2\cdot CH\cdot CHO$ (Ber. 41, 824). On heating gently it loses water yielding Cu_2C_2. Scheiber suggests the formulae:

$CH\vdots C\cdot Cu\cdot Cu(OH)$, and

$$\begin{array}{l} C-Cu \\ \| \quad | \\ C-Cu \end{array}$$

for the two compounds (Ber. 41, 3816; Scheiber and Reckleben, Ber. 44, 210).

The silver compound has the formula $C_2Ag_2H_2O$ or $C_2H_2\cdot 2Ag_2O$ and forms a yellowish precipitate. Both the copper and silver compounds explode on heating (*cf.* Berthelot, Ann. Chim. Phys. [4] 9, 385; Blochmann, Annalen, 173, 174; Kuntzmann, Bull. Soc. chim. [3] 6, 422; Alexander, Ber. 32, 2381; Ilosva, *ibid* 2697; Phillips, Amer. Chem J. 16, 340; Scheiber and Flebbe, Ber. 41, 3816; Makowka, Ber. 41, 824; Freund and Mai, Chem. Zeit 1899, 1, 410; Berthelot, Compt. rend. 132, 1525; Keiser, Amer. Chem J. 14, 285; Noyes and Tucker, Amer. Chem. J. 19, 125; Kuspert, Zeitsch. angew. Chem. 34, 453; Silva, Chem. Zeit. 36, 897; Reckleben and Scheiber, Chem. Zeit. 40, 325)

Acetylene also forms double compounds with salts of copper and silver some of which are explosive, *e.g.* $C_2H_2Cu_2Cl_2$; $C_2H_2\cdot 2Cu_2Cl_2$; $C_2H_2\cdot 3Cu_2Cl_2$; $C_2H_2\cdot 2Ag_2O$; $CuSO_3\cdot 2Cu_2C_2$, and so on. (*Cf.* Chavastalon, Compt. rend. 124, 1364; 125, 245; 126, 1810; 127, 68; 130, 1634, 1764; 131, 48; 132, 1489; Hofmann and Kuspert, Zeitsch. anorg. Chem. 15, 204; Söderbaum, Ber. 30, 760, 814; Willgerodt, Ber. 28, 2107: Arth, Compt. rend. 124, 1534; Berthelot and Delépine, Compt. rend. 129, 369; Nieuwland and Maguire, Amer. Chem. J. 28, 1025; Edwards and Hodgkinson, J. Soc. Chem. Ind. 23, 954; 25, 495; British Association Reports, 1904; Alexander, Ber. 32, 2381; Gooch and Baldwin, Zeitsch. anorg. Chem. 22, 235; Keiser, *l.c.*; Manchot, J. Soc. Chem. Ind. 30, 1302; Bhaduri, Zeitsch. anorg. Chem. 79, 355; 76, 419; Llorens, Anales Soc. Espan. fis. quim. 11, 320.)

The use of acetylene has been suggested as an analytical reagent for the separation of metals such as silver, copper, palladium, osmium, gold, and mercury (Söderbaum, Ber. 30, 760, 814, 902, 3014; Erdmann and Makowka, Zeitsch. anal. Chem. 46, 128, 145; Scheiber, Ber. 41, 3816; Scheiber and Reckleben, Ber. 44, 210; Llorens, Anales soc. Espan. fis. quim. 10, 139; 11, 320; Weaver, J. Amer. Chem. Soc. 36, 2462).

For the detection and estimation of acetylene use is made chiefly of ammoniacal cuprous chloride solution. Llorens (*l.c.*) recommends the use of test papers soaked in a solution of copper sulphate and sodium chloride decolorised with sodium bisulphite. Weaver (J. Amer. Chem. Soc. 38, 352) describes a colorimetric method of estimating acetylene. Schultze (Zeitsch. angew. Chem. 29, 1, 341) also describes a colorimetric method. (See also above references on use of acetylene as a reagent.)

With aluminium chloride in presence of alcohol double compounds are formed:

$$AlCl_3\cdot 2C_2H_2\cdot H_2O;$$
$$AlCl_3\, C_2H_2\cdot 2EtOH;$$
$$AlCl_3\cdot C_2H_2\cdot CH_3OH\cdot H_2O$$

(Ganghoff and Henderson, J. Amer. Chem. Soc. 38, 1382; 39, 1420; *cf.* also Band, Chem. News, 81, 286).

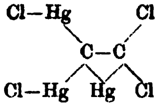
With magnesium bromide compounds are formed such as $CH\vdots CMgBr$, $(\vdots CMgBr_2)$, (Oddo, Atti R. Acad. Lincei. 13, 187; (Gaz. chim. ital. 38, i. 625; Yocichi, J. Russ. Phys. Chem. Soc. 38, 1040).

Action on magnesium, see Novak (Ber. 42, 4209) and Cottrell (J. Phys Chem. 18, 85).

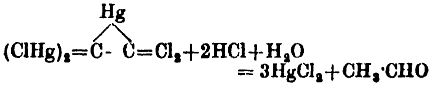
The compounds of acetylene with mercury and mercuric salts have been studied in some detail, and are of considerable importance in view of the use of mercury salts as catalysts for the conversion of acetylene into acetaldehyde. *Mercuric acetylide* (or carbide) itself, C_2Hg, is obtainable as a white very explosive precipitate, by passing acetylene through Nessler solution (Keiser, Amer. Chem. J. 15, 535); on treatment with acids acetylene is evolved. A hydrate, $3C_2Hg\cdot H_2O$, is known also (Plimpton and Travers, Trans. Chem. Soc. 65, 226). A hydrate of mercuro-acetylide, $C_2Hg_2\cdot H_2O$, is formed as a grey precipitate on passing acetylene through an aqueous suspension of mercurous acetate in the dark (Burkard and Travers, Trans. Chem. Soc. 81, 1270). Mercuric acetate solution yields a slimy white precipitate of $3C_2Hg\cdot 2HgO\cdot 2H_2O$ (possibly $3C_2Hg\cdot 2Hg(OH)_2$), which is not explosive and yields acetaldehyde but no acetylene on treatment with acids (Burkard and Travers, *l.c.*; Plimpton, Proc. Chem. Soc. 8, 109).

By the action of acetylene on aqueous mercuric chloride solution an amorphous white precipitate is formed to which the formula $C_2Hg\cdot HgCl_2$ was first given (*i.e.* Bis-chlormercuri-acetylene $ClHg\cdot C\vdots C\cdot HgCl$), but which appears in reality to be *trichlormercuri-acetaldehyde* $(ClHg)_3\vdots C\cdot CHO\cdot$ (Keiser, Amer. Chem. J. 15, 537;

Biginelli, Chem. Zentr. 1898, i. 926; Hofmann, Ber. 31, 2212, 2783; 32, 874; 37, 4459; 38, 663; Biltz and Mumm, Ber. 37, 4417; 38, 133; Annalen, 404, 219; Brame, Trans. Chem. Soc. 87, 427). On heating an aqueous suspension of the compound it is decomposed yielding acetaldehyde in practically quantitative yield (Kutscherow, Ber. 14, 1540; 17, 13; Erdmann and Köthner, Zeitsch. anorg. Chem. 18, 48; *cf.* also Hofmann and others, *supra*; Béhal. Ann. Chim. Phys. [6] 15, 267). According to Hofmann the compound has the structure:

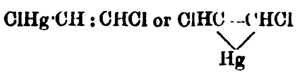


and is formed by the addition of two molecules $HgCl_2$ to one of HgC_2; it is then split up by water:



$$(ClHg)_2{=}C\text{-}C{=}Cl_2+2HCl+H_2O = 3HgCl_2+CH_3{\cdot}CHO$$

More recently Chapman and Jenkins have shown (Trans. Chem. Soc. 115, 847) that on passing acetylene into a saturated solution of mercuric chloride in absolute alcohol a large yield of a white crystalline addition product is obtained which is readily soluble in ether, benzene, and other organic solvents. It has the composition $HgCl_2{\cdot}C_2H_2$, and melts at 113° C. Chapman and Jenkins suggest its formula may be



$$ClHg{\cdot}CH:CHCl \text{ or } ClHC{-}CHCl$$

and it seems probable that this body may be the first product formed during the action of acetylene upon aqueous solutions of mercuric salts. When passed into alcohol in the presence of a mercury catalyst acetal is formed (*v.* ACETALS), and with anhydrous acetic acid ethylidene diacetate is formed which can be readily split up into aldehyde and acetic anhydride (*v.* ACETALS). (See also Hofmann and Kirmreuther, Ber. 41, 314; 42, 4232.)

Acetaldehyde is also formed to some extent by heating charcoal saturated with acetylene to 350° with water (Degrez, Ann. Chim Phys. [7] 3, 216). (For details *see* ALDEHYDES.)

Oxidising agents convert acetylene to acetic acid; thus hydrogen peroxide (Cross, Bevan and Heiberg, Ber. 33, 2015) and fused caustic alkali (Feuchter, Chem. Zeit. 38, 273) yield acetic acid or its salts.

Various processes have been patented, notably by the Farbwerke vorm. Fr. Bayer, to obtain acetic acid direct from acetylene without isolating the acetaldehyde formed as an intermediate product. This process, described in U.S. Pat. 1128780, claims the production of acetic acid by treating acetylene with a mixture formed from mercuric oxide, hydrogen peroxide and ammonium or potassium persulphate in 10 to 30 p.c. sulphuric acid. Fr. Pat. 467515, describing the same process, states that 10·8 grams acetylene yield 24–25 grams pure acetic acid. Fr. Pat. 467778 (D. R. P. 293011; U.S. Pat. 1159376) describes an electrolytic process using 30 p.c. sulphuric acid containing about 1–2 p.c. of a mercury salt at 30° to 40°, with a divided cell using a lead or copper cathode and oxidising the acetylene at the platinum anode; using a current of 48·5 grams acetylene per hour with 100 amps. the yield is stated to be 0·5 kg. acetic acid per litre in 24 hours.

A different process is given by the Chem Fabrik Griesheim Elektron (Swiss Pat 70152 Eng. Pat. 14113, 1914), consisting in passing acetylene and oxygen alternately or simultaneously into acetic or other organic acid containing water to which a suitable mercury catalyst has been added. It does not appear however, to offer much advantage over the methods involving the previous isolation of the acetaldehyde.

HALOGEN DERIVATIVES.

Iodine Compounds.—Acetylene unites with iodine somewhat slowly to form acetylene di-iodide (sym. diiodoethylene) $C_2H_2I_2$, which exists in two stereoisomeric forms, a solid, m.p. 73° (or 78° ?), b.p. 192°; and a liquid form, m.p. 21°, b.p. 185°, $D_{20}=3{\cdot}06$ (Berthelot, Annalen, 132, 122; Sabanejew, Annalen, 178, 118; 216, 275; Plimpton, Trans. Chem. Soc. 41, 391; Paternò and Peratoner, Gazz. chim. ital. 19, 580; 20, 670; Biltz, Ber. 30, 1200, 1207; Nef, Annalen, 298, 341; de Chalmot, Amer. Chem. J. 19, 877; Keiser, Amer. Chem. J. 21, 261; Erdmann, Ber. 38, 237; Chavanne and Vos, Compt. rend. 158, 1582).

With alcoholic potash the liquid form yields acetylene and *di-iodo-acetylene* C_2I_2; chlorine converts it into the tetrachlor derivative. Keiser and McMaster have shown (Amer. Chem. J. 46, 518) that the solid form can be made to yield fumaric acid and therefore has the *trans* form, whilst the liquid *cis* form yields maleic acid.

Di-iodo-acetylene C_2I_2 is formed on treating calcium carbide with a solution of iodine in potassium iodide, tetraiodoethylene being also formed (Biltz, Ber. 30, 1200); or by the action of silver acetylide on an ethereal solution of iodine (Berend, Annalen, 135, 258; Baeyer, Ber. 18, 2275). It can also be produced from tetra-iodo ethylene (Nef, Annalen, 298, 341; Schenk and Litzendorff, Ber. 37, 345) and from iodo-propiolic acid (Nef, Annalen, 308, 325). It is best prepared by the method of Biltz (*l.c.*), by leading acetylene into 2N caustic soda lye into which a solution of iodine in potassium iodide is allowed to drip. Thus obtained it is a white amorphous precipitate which crystallises in needles from ligroin, m.p. 82°. It is an evil-smelling substance with pronounced action on the mucous membrane; it has strong antiseptic properties (Biltz and Küppers, Ber. 37, 4415; Mebert, Archiv. f. experim. Path., etc. 41, 114; Löw, Chem. Zentr. 1899, 1, 214). The action of heat or actinic rays converts it into C_2I_4. With nitrous fumes it yields *nitro-tri-iodo ethylene* $CI_2:CINO_2$ (Meyer and Pemsel, Ber. 29, 1411; Biltz and Werner, Ber. 30, 1200; 33, 2190; Biltz and Küppers, *l.c.*; Chalmot, Amer. Chem. J. 19, 877; Nef, Annalen, 298, 202).

Magnesium acetylene iodide is known and forms a thick oily liquid (Yocichi, J. Russ. Phys. Chem. Soc. 38, 1040).

Bromine Derivatives. *Brom-acetylene* $CBr\vdots CH$ is formed by the decomposition of ethylene dibromide with alcoholic potash:

$$CHBr:CHBr-HBr = CBr\vdots CH$$

It condenses to a colourless liquid, b.p. about −2°. Both liquid and vapour are spontaneously inflammable. It burns with very great energy in air, partially carbonising and forming HBr, CO. and CO_2. Its solutions show phosphorescence and smell strongly like phosphorus. In day light it polymerises, about 10 p.c. of the product being sym. tribrom-benzene (Reboul, Annalen, 125, 81; Schmelz and Beilstein, Annalen, Spl. 3, 280 (1865); Sabanejew, Ber. 18; Ref. 374; Nef, Annalen, 298, 355; 308, 325; Gray, Trans. Chem. Soc. 71, 1029).

Di-brom-acetylene $CBr\vdots CBr$, is formed by treating tribromethylene with alcoholic potash (Lemoult, Compt. rend. 136, 55; 137, 1333; Lawrie, Amer. Chem. J. 36, 490). It forms an oil insoluble in water, possessing an unpleasant isonitrile odour, b.p. 76°–77°. It is very poisonous and is spontaneously inflammable. With bromine it forms *tetra-bromethylene* C_2Br_4, and with iodine it forms dibrom-diodoethylene $BrC:CI_2$, m.p. 95°–96°. Acetylene itself reacts with bromine to form *acetylene dibromide* (dibromethylene) $CHBr:CHBr$, using dilute bromine solutions and keeping the acetylene in excess; the product is a colourless liquid, b.p. 110°, $D_{17}=2{\cdot}271$. It is also produced by the action of zinc and alcohol or amalgamated zinc on acetylene tetrabromide (Sabanejew, Annalen, 178, 115; 216, 251, 267; Ber. 18; Ref. 374; Weger, Annalen, 221, 72; Anschütz, *ibid.* 221, 141; Moureau, Bull. Soc. chim. [3] 21, 99; Elbs and Newmann, J. pr. Chem [2] 58, 246; Swarts, Chem. Zentr. 1899, 1, 589; Gray, 71, 1023). Van de Walle (Bull. Soc. chim. Belg. 27, 209) has shown that acetylene dibromide prepared by the reduction method consists of a mixture of two isomers which can be separated by the fractional distillation of the binary mixtures with ethyl alcohol. The two forms have m.p. −6·5° and −53°, and the equilibrium mixture consists of about one part of the former and two parts of the latter.

If acetylene be treated with excess of bromine the tetrabrom derivative is formed, $C_2H_2Br_4$ (*acetylene tetrabromide, tetrabrom ethane*) (Reboul, Annalen, 124, 269; Sabanejew, Annalen, 178, 112, 121; 216, 255; Bourjoin, Ann. Chim. Phys. [5] 4, 423; Anschütz, Annalen, 221, 138; Wojzic, Ber. 16, 2891; Crossley, Proc. Chem. Soc. 14, 248; Hofmann and Kirmreuther, Ber. 41, 314; Elbs and Newman, J. pr. Chem. [2] 58, 245; Muthmann, Zeitsch. f. Krystallographie, 30, 73). An unsymmetrical tetrabrom ethane is also known (Lennox, Annalen, 122, 124; Sabanejew, Annalen, 216, 255; Anschütz, Annalen, 221, 140).

Perbrom-ethylene C_2Br_4 forms colourless crystals of m.p. 56°, b.p. 226°–7°, and is prepared either by the addition of bromine to dibrom-acetylene (*v.s.*) or by the action of bromine on an aqueous suspension of silver acetylide, and by distilling hexabromethane (Löwig, Pogg. Ann. 16, 377; Lennox, Annalen, 122, 126; Reboul, Annalen, 124, 271; Merz and Weith, Ber. 1[illegible], 2238; Höland, Annalen, 240, 237; Nef, Annalen, 298, 332; Biltz, Ber. 35, 1530). By the action of sodium ethylate tetrabrom ethylene yields asymm. dibrom-vinyl ether, bromacetic ester, tribromvinyl ether, and aldehyde resin (Nef, Annalen, 298, 334). Fuming nitric acid oxidises it to tribrom-acetic acid, or in presence of conc. sulphuric acid tribrom acetyl bromide is formed (Biltz, Ber. 35, 1536).

Various mixed halogen compounds derived from acetylene are also known but are of little importance.

Chlorine Derivatives.—Owing to the cheapness of chlorine its compounds with acetylene are easily and economically produced, and constitute an important technical application of acetylene.

Chlor-acetylene $CCl\vdots CH$ is a gas with explosive properties (Wallach, Annalen, 203, 88; Zincke, Ber. 23, 3783; V. Meyer, Ber. 23, 3783; Hofmann and Kirmreuther, Ber. 42, 4232; Mourelo and Banus, Anales. soc. Espan. fis. quim. 9, 84).

Dichlor-acetylene $CCl\vdots CCl$ has been obtained by Boëseken and Carrière. (Verslag, Akad. Wetenschappen, 22, 1186) by heating the barium salt of trichloracrylic acid:

$$Ba(CCl_2:CCl{\cdot}COO)_2=BaCl_2+2CO_2+2CCl:CCl$$

It is a colourless gas with an unpleasant odour; it can be condensed to a colourless liquid, m.p. −50°, which is explosive. Mixed with hydrogen it inflames spontaneously in the air. It is also possible that dichloracetylene is formed to some extent when calcium carbide is treated with chlorine (Davidson, Amer. Chem. J. 40, 397). For instance, by treatment of benzene with powdered calcium carbide and chlorine, *tolane dichloride* is formed, a reaction best explained by the intermediate formation of dichloracetylene; direct evidence was also obtained that the gas is formed under these conditions.

Acetylene tetrachloride (tetrachlorethane) $CHCl_2{\cdot}CHCl_2$ is the most important halogen derivative of acetylene from a technical point of view, as it is the direct product of the action of chlorine on acetylene and is the starting point for numerous other derivatives. Chlorine is without action on acetylene in the pure state and in the absence of light (Schlegel, Annalen, 226, 154). In diffused daylight the dichlor- and tetrachlor derivatives are formed in succession:

$$C_2H_2+Cl_2 = C_2H_2Cl_2 \quad C_2H_2Cl_2+Cl_2 = C_2H_2Cl_4$$

(Römer, Annalen, 233, 214). Traces of impurities, particularly air (Mouneyrat, Bull. Soc. chim. [3] 19, 447, 452, 454), cause violent explosive decomposition during the reaction, with formation of free carbon and hydrochloric acid:

$$C_2H_2+Cl_2 = 2C+2HCl$$

To avoid this danger and to render the reaction safe and dependable, various devices are adopted chiefly depending upon the presence of suitable catalysts, such as iodine chloride (Sabanejew, Annalen, 216, 241, 262), antimony pentachloride (Berthelot and Jungfleisch, Annalen, Suppl. 7, 252 (1870)), aluminium chloride (Mouneyrat, Bull. Soc. chim. [3] 19, 448; Compt. rend. 126, 1805). For this reason most of the early patents on the subject deal with methods for avoiding the danger of explosion during the reaction and effecting a smooth and continuous combination of the gases. The following processes may be noted: Askenasy and Mugdan (Eng. Pat. 18602, 1904) prepare the sym. tetrachlorethane by passing acetylene and chlorine alternately into antimony pentachloride, which latter should be free from excess of chlorine and may be diluted with tetrachlorethane; or the two gases may be driven in simultaneously into two halves of a vessel separated by a perforated diaphragm. H. K. Tompkins (Eng. Pat. 19568, 1904) advocates the use of a mixture of antimony tri- and pentachloride at 40° to 50° and distilling the product; the reaction appears to be

$$C_2H_2+SbCl_5=C_2H_2{\cdot}SbCl_5$$
$$C_2H_2{\cdot}SbCl_5+SbCl_5=C_2H_2Cl_4+2SbCl_3$$

G. Dreyfus, H. K. Tompkins, and the Clayton Aniline Co. (Eng. Pat. 8438, 1909) describe the production of antimony chloracetylide by passing acetylene into antimony pentachloride. The use of antimony chlor- or brom-acetylides is claimed by Dreyfus, Tompkins, and the Clayton Aniline Co., as a catalyst for use in the production of halogen indigos and thioindigos (*l.c.*).

J. M. Lidholm (Eng. Pat. 22094, 1905) recommends diluting the gases with an indifferent gas such as carbon dioxide and exposing the mixture to actinic rays. Chemische Fabrik Griesheim Elektron (Eng. Pat. 13411, 1907) claim the production of tetrachlorethane by mixing the reacting gases with solid diluents such as sand, infusorial earth, clay, &c., and exposing to actinic rays in presence of the solid. After the gases have been mixed they may be passed into liquids such as the chlorides of antimony or solutions of these in the tetrachlor compound. G. Ornstein (Eng. Pat. 2375, 1911) also advises the use of a non-volatile catalyst such as iron. Salzbergwerk Neu Stassfurth (D. R. P. 174068) suggest the use of sulphur chloride to which a small amount of iron has been added. The Consortium f. Elektrochemische Industrie (Eng. Pat. 25967, 1910) claim that ferric chloride is an efficient catalyst; it is possible that the two preceding patents also depend on the formation of ferric chloride as the real catalytic agent. (*Cf.* also E. P. 132757, Soc. d. prod. chim. d'Alais.)

In practice the use of antimony pentachloride appears to find most favour. The apparatus used consists of a vessel fitted with a stirrer and divided by a partition which, however, allows the intermixing of the liquids. The vessel is partially filled with a solution of antimony pentachloride in tetrachlorethane and acetylene is passed into one side whilst chlorine is led into the other; the acetylene compound is thus continuously formed in the one chamber and decomposed by the excess of chlorine on coming into the other. The vessel gradually fills with the acetylene tetrachloride so formed until a liquid containing as little as 1 p.c. of the catalyst remains. The acetylene is then stopped, a small amount of chlorine is added to decompose the double compound and the tetrachloride is distilled off, purified with lime or chalk and distilled in steam. The yield is about 95 p.c. The process is used in England by the Weston Chemical Co., in France by the Compagnie Générale d'Elektrochemie de Bozel, Paris, and in Germany by the Consortium für Elektrochemische Industrie in Nürnberg, and by the Bosnische Elektrizitäts A.G. in Jajce. The Salzbergwerk Neu Stassfürth make use of Ornstein's process using iron as a catalyst, though probably ferric chloride is the real agent.

Acetylene tetrachloride forms a colourless liquid of b.p. 147°, $D_0=1{\cdot}614$, m.p. −36°. It is the most important of the acetylene halides as it is the mother substance of a large number of derivatives (*v. infra*). Like the latter it is non-inflammable, and as it possesses very great solvent power for organic substances, especially fats, varnishes, &c., it attained to some importance in industry. It is a good solvent for sulphur, phosphorus, and the halogens. It also dissolves acetyl-cellulose and was used for this purpose under the name 'Acetosol' (*cf.* Lederer, D. R. P. 175379; Walker, U.S. Pat. 1035108). It can be distilled unchanged either alone or with steam, and does not attack metals in the dry state. In the presence of moisture, however, certain metals, notably zinc and iron, remove halogen leaving acetylene dichloride. It is stable to strong acids but is readily attacked by alkalis or magnesium hydroxide, yielding trichlorethylene. Heated alone or with $AlCl_3$ or ThO_2 trichlorethylene is formed slowly, and prolonged heating causes the formation also of perchlorbenzene (Berthelot and Jungfleisch, Annalen, Suppl. 7, 252 (1870); Nicodemus, J. pr. Chem. 83, 312).

The Salzbergwerk N. Stassfürth (D. R. P. 185374) recommend the addition of organic compounds such as turpentine to the tetrachloride to take up any hydrochloric acid that may be formed, thus keeping the solvent in a neutral condition suitable for use. A. Schmitz (Fr. Pat. 417649) claims the production of emulsions of tetrachlorethane with soap solutions.

Owing, however, to the strong narcotic and poisonous action of the tetrachloride, causing jaundice, fatty degeneration of the organs, albuminuria and hæmoglobinuria, its use as a solvent is now considerably restricted, particularly as its various derivatives are equally suitable for most purposes and are less poisonous (*cf.* Grimm, Heffter and Joachimaglu, Vrtljschr. Med. Offent. Sanitatsw. 48, 1; Report of H.M. Inspector of Factories, 1914).

Trichlorethylene C_2HCl_3 is obtained from acetylene tetrachloride by heating in a vat with milk of lime or solid lime (Consort. f. Elektrochem. Ind. D. R. P. 171900, 208854). The yield is practically quantitative. It is also produced by passing ammonia into a mixture of acetylene tetrachloride and alcohol (Tompkins, Eng. Pat. 19568, 1904), and, admixed with hexachlorbenzene, by passing the tetrachloride through a tube heated to 400° or 500° (Tompkins and Clayton Aniline Co., Eng. Pat. 23780, 1906). Another process by the Griesheim Elektron Co. (D. R. P. 263457) consists in passing the vapours of acetylene tetrachloride over heated metallic chlorides such as copper or barium chlorides; it is, however, less easy to obtain a pure product by this method. It may also be obtained by passing the tetrachloride over ThO_2 heated to a temperature not exceeding 390° (Chem. Fab. Bückau, D. R. P. 274782).

Trichlorethylene forms a colourless liquid b.p. 85°, $D_0=1{\cdot}47$, which is practically immiscible with water. It has great solvent power for fats, waxes, resins, rubber and other organic products, and also for sulphur and phosphorus, on which account it is used on a considerable scale for fat-extraction and the like in place of benzene or carbon tetrachloride. It has the advantage over acetylene tetrachloride in that it is less toxic (Chem. Zeit. 31, 1095, 32, 256, 529; Arch. Hyg. 1911, 74; Lach, Seifensieder, 1911, 15). Neumann (Chem. Zeit. 35, 1025) states that the trichlor compound gives satisfactory results as a fat solvent (*cf.* also van Lennep and Ruys, Chem. Weekblad, 9, 654). Soaps containing 'Tri' (trichlorethylene) such as 'Westrol,' 'Triol,' 'Tripur,' &c., are used for cleansing textile materials from grease (*cf.* Schmitz, D. R. P. 255901). Trichlorethylene has also advantages over tetrachlorethane in that it is more resistant to chemical action, is unattacked by dilute acids, or by alkalis or lime, and is practically without action on the common metals such as iron, copper, lead, tin, or zinc, even in the presence of moisture. At room temperature it oxidises slowly yielding carbonyl chloride, hydrochloric acid, and dichloracetyl chloride (Erdmann, J. pr Chem. 85, 78; Staudinger, *ibid.* 85, 330). Under suitable conditions it can be made, however, to undergo various important transformations; thus, by heating with strong alkali glycollic acid is formed (Consort. f. Elektrochem. Ind., D. R. P. 257878),

$$\begin{aligned}CHCl:CCl_2+4KOH\\ =CH_2(OH){\cdot}COOK+3KCl+H_2O\end{aligned}$$

Traces of dichloracetylene are also formed. On passing through a heated tube it is partly converted into hexachlorbenzene (Nicodemus, J pr. Chem. 83, 312). In the presence of catalysts chlorine is added on with the formation of pentachlorethane (*v. infra*). On heating with sodium ethylate or a mixture of caustic soda and alcohol, *dichlorvinylether* (dichlorethoxyethylene) is formed (Tompkins, Eng. Pat. 678, 1906; Imbert, Eng. Pat. 5014, 1907), which on further treatment with water or alcohol readily gives chloracetic ester in good yield (Tompkins, *ibid.*)

$$C_2HCl_3+NaOC_2H_5=NaCl+C_2HCl_2{\cdot}OC_2H_5$$
$$C_2HCl_2{\cdot}OC_2H_5+H_2O=HCl+ClCH_2{\cdot}COOC_2H_5$$

According to Imbert (Eng. Pat. 5013, 1907) heating the dichlorethoxy ethylene with the theoretical quantity of water yields the chloracetic ester, whilst excess of water yields chloracetic acid directly. Chloracetic acid or its ester react readily with aniline yielding phenylglycine which can be converted into indigo, thereby offering an alternative route to the usual process starting from acetic acid (*cf.* Chem. Zeit. 35, 1053).

Later processes claim the production of monochloracetic acid in good yields by the use of concentrated sulphuric acid at 150°–200° C., as the hydrating agent (L. V. Simon and G. C. Chavanne, Eng. Pat. 129301), 100 gms. trichlorethylene under such conditions affording 57 gms. monochloracetic acid; the Soc. des prod. chim. d'Alais also describe a continuous process for producing the acid from trichlorethylene by allowing the latter to act upon sulphuric acid of 90 p.c. concentration at 160°–200° C., water being added continuously as required and the resultant monochloracetic acid being carried off by the excess of trichlorethylene (Eng. Pat. 132042).

Dichlorvinyl ether, b.p. 128·2°, $D_{10}=1{\cdot}08$, is an extremely reactive substance opening the way for a number of interesting organic syntheses. Thus hydrochloric acid or chlorine add on directly and the products on distillation split up into chlor- or dichlor-acetyl chloride:

$$\begin{aligned}C_2HCl_2{\cdot}OC_2H_5+HCl&=C_2H_2Cl_3{\cdot}OC_2H_5\\ &=ClC_2H_5+ClCH_2{\cdot}COCl\end{aligned}$$

(*cf.* Tompkins and Clayton Aniline Co., Eng. Pat. 5404, 1908). Chloracetyl chloride made by this process has been placed on the market by the Consortium.

A further use for trichlorethylene is given in Eng. Pat. 90, 1908, by the Badische Anilin und Soda Fabrik, in which by treating trichlorethylene with a salt of thiosalicylic acid, *omega-chlorovinylthiosalicylic acid* is produced which can be readily converted into thioindigo. With mercuric cyanide trichlorethylene yields *mercuritrichlorethylenide* $Hg(CCl:CCl)_2$ (Hofmann and Kirmreuther, Ber. 41, 315).

Dichlorethylene $C_2H_2Cl_2$ is prepared technically from tetrachlorethane by refluxing with zinc dust and water:

$$C_2H_2Cl_4+Zn=C_2H_2Cl_2+ZnCl_2$$

(Askenasy and Mugdan, Eng. Pat. 19576, 1907). Aluminium or iron powders may also be used instead of zinc, but in that case require heating to 140° in an autoclave. The dichloride may also be prepared by the direct union of acetylene and chlorine, avoiding any excess of the latter and using antimony pentachloride as a catalyst (Tompkins) Eng. Pat. 19568, 1904), or diluting the gases and exposing to actinic rays (Lidholm, Eng. Pat. 22094, 1905), or by heating the gases to 150° in capillary tubes (Chem. Fab. Griesheim Elektron, Eng. Pat. 16620, 1912). The commercial product consists of a mixture of the two stereoisomers of b.p. 48° and 60° respectively, and densities 1·265 and 1·291, in consequence of which it has no constant boiling-point (Chavanne, Compt. rend. 154, 776; Bull. Soc. chim. Belg. 26, 287; 28, 234). The equilibrium mixture contains about four parts 'cis' form (b.p. 60°) to one part 'trans' (b.p. 48°) form. Askenasy and Mugdan (Zeit. f. Elektrochemie, 15, 773) suggest the production of the dichloride by electrolysing the tetrachloride in zinc chloride solution, the zinc being regenerated electrolytically.

Dichlorethylene resembles trichlorethylene and perchlorethylene and is unattacked by metals or alkalis. It can be used as a rubber solvent (Fischer, D. R. P. 211186) and owing to its low boiling point has been recommended as a substitute for ether for fat extraction, &c. Its vapour is inflammable but the flame is readily extinguished. (For other details see also Berthelot and Jungfleisch, Annalen, Sppl. 7, 253 (1870); Sabanejew, Annalen, 216, 262.)

Pentachlorethane C_2HCl_5 is prepared by passing chlorine into trichlorethylene, preferably in the presence of actinic rays, from which it is formed in almost quantitative yield; after washing with water and lime to remove excess of chlorine it is distilled in steam and forms a liquid b.p. 159°, D=1·685, and in other respects closely resembles tetrachlorethane (Salzbergwerk Neu Stassfürth, Eng. Pat. 1105, 1912). It has somewhat similar solvent powers to the tetrachlor compound, and is also very sensitive to alkalis, yielding perchlorethylene C_2Cl_4. It does not attack metals in a dry state but does so in the presence of moisture. (For other methods of preparation see Regnault, Annalen, 33, 321; Pierre, Annalen, 80, 130; Paternò, Annalen, 151, 117 Mouneyrat, Bull. Soc. chim. [3] 19, 261.)

Perchlorethylene (tetrachlorethylene) C_2Cl_4: is prepared by treating pentachlorethane with milk of lime; b.p. 119°, D=1·624. Its other properties are similar to those of trichlorethylene. It does not attack metals even in a moist state and is stable to alkalis. It has a certain limited use as a cleaning agent for textiles. It is also a by-product in the manufacture of carbon tetrachloride (*cf.* Faraday, Ann. Chim. Phys. [2] 18, 53; Regnault, Annalen, 33, 325, 333; Geuther, Annalen, 107, 212; 111, 175; Prudhomme, Annalen, 156, 342; Schiff, Annalen, 220, 97; Burgoin, Ann. Chim. Phys. [5] 6, 142; Geuther and Fischer, Zeitsch. f. Chemie, 1864, 269; Geuther and Brockhoff, J. pr. Chem. [2] 7, 102; Goldschmidt, Ber. 14, 929; V. Meyer, Ber. 27, 3160; Besson, Compt. rend. 118, 1347; Mouneyrat, Bull. Soc. chim. [3] 19, 182; Biltz, Ber. 35, 1529). Heating with fuming sulphuric acid yields trichloracetic acid (Prudhomme, Zeitsch. f. Chemie. 1870, 380; Biltz, Ber. 35, 1533).

Hexachlorethane (Perchlorethane) C_2Cl_6 is produced by exhaustive chlorination of the lower chlorinated ethane derivatives (*cf.* Faraday, Ann. Chim. Phys. [2] 18, 48; Regnault, *ibid.* 69, 165; Annalen, 33, 323; Hübner and Müller, Zeitsch f. Chemie, 1870, 328; Mouneyrat, Bull. Soc. chim. [3] 17, 797; 19, 454; *ibid.* [3] 17, 794; Michel, Zeitsch. angew. Chem. 19, 1095). It is also formed on passing chloroform through a red-hot tube (Ramsay and Young, Jahr. d. Chemie, 1886, 628). It occurs as a by-product in the production of carbon tetrachloride (V. Meyer, Ber. 27, 3160), and is formed from carbon tetrachloride by heating to 160° with amorphous arsenic (Auger, Compt. rend. 145, 809), or by passing through a heated tube (Kolbe, Annalen, 54, 147).

It is formed readily by refluxing carbon tetrachloride with aluminium amalgam (Hofmann and Seiler, Ber. 38, 3058), and is also formed by direct synthesis if an electric arc be formed in a chlorine atmosphere (*v.* Boltom, Zeitsch. f. Elektrochemie, 8, 169; 9, 209; Lorenz, Annalen, 247, 245; Zeitsch. angew. Chem. 6, 313; Zeitsch f. Elektrochemie, 8, 203). On a commercial scale it can be conveniently prepared by the exhaustive chlorination of acetylene tetrachloride in the presence of aluminium chloride (*cf.* Mouneyrat, *l.c.*). The Salzbergwerk Neu Stassfürth (D. R. P 174068) claim the production of the hexachlor compound by leading acetylene and chlorine alternately into a heated mixture of sulphur chloride and powdered iron. The same firm also claim a process for chlorinating tetrachloroethane in the presence of an artificial source of light rich in actinic rays (Eng. Pat. 1105, 1912). The penta-chlor compound is formed at the same time and may be separated by allowing the mass to crystallise and then pressing the product.

Hexachlorethane forms colourless crystals melting at 187° to 188°; its b.p. is 185° so that it usually sublimes without melting on being heated. Sp.gr.=2·091. It has a camphor-like odour and is used to some extent in the explosives industry as a camphor substitute in the preparation of safety explosives. Heated with alkali to 200° it yields oxalic acid; nascent hydrogen, alcoholic alkali hydrosulphite, or heating with silver to 280° converts it into perchlorethylene. Heating with antimony pentachloride to 450° converts it completely into carbon tetrachloride (Hahn, Ber. 11, 1735; Schröder, Ber. 13, 1070; Berthelot, Annalen, 109, 121; Geuther, Annalen, 107, 212; 111, 174; Armstrong, J. pr. Chem. [2] 1, 251; Geuther and Brockhoff, J. pr. Chem. [2] 7, 174; Prudhomme, Annalen, 156, 342; Hartmann, Ber. 24, 1023; Gossner, Zeitsch. f. Kryst. 38, 151)

Heated in the presence of water it is converted gradually into perchlor-ethylene.

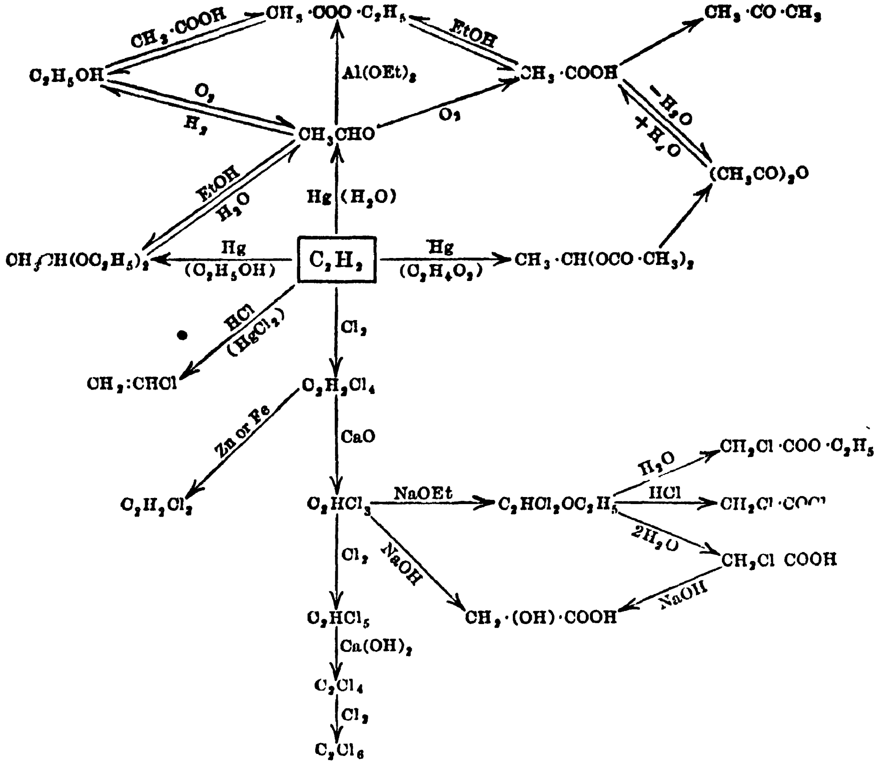
A general discussion of the above chlorinated derivatives of acetylene and their applicability in industry will be found in the following: Chem. Zeit. 31, 1095; 32, 256; 35, 1053; J. Soc. Chem. Ind. 35, 94.

Vinyl chloride (Chlorethylene) $CH_2:CHCl$ is produced by the addition of hydrochloric acid to acetylene in the presence of a suitable catalyst such as pumice soaked in mercuric chloride. Hydrogen chloride and acetylene in molecular proportions are passed through tubes containing the contact mass heated to 180°. The yield is stated to be quantitative (Chem. Fab. Griesheim Elektron, D. R. P. 278249, 288584, Eng. Pat. 21134, 1913). It is a colourless gas which condenses to a liquid in a freezing mixture. It is sparingly soluble in water, readily so in alcohol. In sunlight it polymerises to a transparent white mass (Regnault, Annalen, 14, 28; Wurtz and Frapolli, Annalen, 108, 223; Baumann, Annalen, 163, 317; Glinsky, Zeitsch. f. Chemie, 1867, 676; Villard, Ann. Chim. Phys. [7] 11, 387; Biltz, Ber. 35, 3524). So far it does not appear to have any special technical application.

The diagram on next page may serve to illustrate the chief chemical transformations which acetylene may be made to undergo on a technical scale.

ACETYLENE HOMOLOGUES.

The higher members of the acetylene series are of relatively slight importance. They may be made by the various general methods given for acetylene itself, such as by heating the monohalogen derivatives of the ethylene series with alcoholic potash, &c. They may also be prepared by treating sodium acetylide with alkyl halides in liquid ammonia at −50° to −30° (Lebeau and Picon, Compt. rend. 156, 1077; Picon, *ibid.* 158, 1346). Another general method is described by Schlechter (D. R. P. 253802), who claims the production of dimethyl acetylene and



ethyl acetylene by heating calcium carbide with methyl or ethyl alcohols respectively, under pressure at 60° to 250°, the products obtained depending partly on the temperature:

$$CaC_2+2CH_3OH = Ca(OH)_2+C_4H_6$$

The following members of the acetylene series have been identified as occurring in coal-gas: allylene, ethyl-acetylene, propyl-, isopropyl-, butyl-, isobutyl, methyl-ethyl, and methyl-propyl-acetylenes, and crotonylene (Harzer, J. f. Gasbeleuchtung, 57, 622).

The Chem. Fabrik. Flörsheim (Amer Chem. Abstr. 1912, 1072) state that a general method for the preparation of the dialkyl acetylenes is to heat the monoalkyl acetylenes at 170° with alcoholic potash, the methyl alkyl acetylenes being always formed. The reverse action takes place on boiling with metallic sodium.

Methyl-acetylene, or Allylene, $CH_3·C:CH$, is formed by the action of alcoholic potash on brompropylene:

$$CH_3·CBr:CH+KOH=CH_3·C:CH+KBr+H_2O$$

also by acting with sodium on dichloracetone chloride:

$$CH_3·CCl_2·CHCl_2+4Na = CH_3·C:CH+4NaCl$$

or by electrolysing the alkali salts of citraconic or mesaconic acids, or by the action of magnesium on acetone vapour and treating the solid mass thus obtained with water (Keiser, Amer. Chem. J. 18, 328; Desgrez, Bull. Soc. chim. [3] 11, 391; Lespieau and Chavanne, Compt. rend. 140, 1035).

Allylene is a colourless gas, b.p. −23·5°; m.p. −100°; very similar to acetylene and, like it, forming compounds with metals. The mercuric compound $(C_3H_2)_2Hg$ is obtained by passing allylene through water containing mercuric oxide in suspension. It crystallises from hot alcohol in fine needles. It is soluble in hydrochloric acid with evolution of allylene, but does not explode on heating (Keiser, *l.c.*; Lossen and Dorno, Annalen, 342, 187; Plimpton and Travers, Chem. Soc. Trans, 1894, 264; Biltz and Mumm, Ber 37, 4417; Hofmann, Ber 37, 4459). The silver compound $(C_3H_2)_2Ag$ forms microscopic needles which explode at about 150°.

According to Berthelot (Compt. rend. 126, 561, 567, 609, 616) allylene when subjected to the silent electric discharge condenses to a solid with a pungent empyreumatic odour; with nitrogen the substance $C_{15}H_{20}N$ is formed.

Allylene forms with bromine additive products, $C_3H_4Br_2$ and $C_3H_4Br_4$, and with halogen acid compounds of the type $CH_3·CCl_2·CH_3$. Concentrated sulphuric acid absorbs allylene readily, and on distilling the solution with water, acetone, mesitylene and allylene sulphonic acid, $C_3H_3SO_3H$, are formed (Schrohe, Ber. 8, 18, 367). With hypochlorous and hypobromous acids, allylene forms dichlor- and dibrom-acetones, and trimethyl allylene yields the halogen pinacolins (Wittorf, Chem. Zeit. 23, 695).

Butines.—1. *Ethyl acetylene* $C_2H_5·C:CH$. Formed by the action of alcoholic potash on $C_2H_5·CCl_2·CH_3$ (Bruylants, Ber. 8, 412) by passing acetylene and ethylene through a red-hot tube (Berthelot, Ann. Chim. Phys. [4] 9, 466) from dibrom-butane by the action of alcoholic potash (Dupont, Compt. rend. 148, 1522).

The compound is a liquid boiling at 18°, and forms precipitates with ammoniacal copper and silver solutions; f.p. −130°.

With ammoniacal silver chloride and alcoholic silver nitrate it forms explosive compounds (Wislicenus and Schmidt, Annalen, 313, 221); it also yields a sodium derivative (Jociez, Chem. Zentr. 1897, i. 1012).

2. *Crotonylene* or *dimethylacetylene* $CH_3{\cdot}C{:}C{\cdot}CH_3$ is formed by acting with alcoholic potash on βγ-dibrombutane $CH_3{\cdot}CHBr{\cdot}CHBr{\cdot}CH_3$; by the action of sodium ethoxide on monobrompseudobutylene $CH_3{\cdot}CBr : CH{\cdot}CCH_3$ (Hölz, Annalen, 250, 230); or by the decomposition of the salts of β-bromoangelic acid (Wislicenus and Schmidt, *l.c.*). With bromine it forms a product $C_4H_6Br_4$, which is solid, m.p. 243°; isocrotonylene dibromide, b.p. 149° to 150°, is also known and is not readily attacked by zinc dust (Wislicenus and Schmidt, *l.c.*).

Crotonylic mono- and hydro-bromides, as well as the iodide and chloride derivatives, have also been obtained (Wislicenus, Talbot and Henge, *l.c.*; Peratoner, Gazz. chim. ital. 22, ii 86; Charon, Ann. Chim. Phys. 1899, 17, 228; Favorsky, J. pr. Chem. [2] 42, 143).

On shaking the hydrocarbon with sulphuric acid and water (3 : 1), *hexamethyl benzene* is obtained,

$$3C_4H_6 = C_{12}H_{18} = C_6(CH_3)_6$$

The compound $CH{:}C{\cdot}C{:}CH$, formed by the action of cupric chloride on copper acetylene, is described by Noyes and Tucker (Amer. Chem. J. 19, 123); pentachlorbutine C_4HCl_5 by Zincke and Kuster (Ber. 26, 2104). Derivatives of the butines, some of which are used as dyestuffs, are described by Freund (Ber. 34, 3109).

Pentines, C_5H_8, *n-Pentine*, prepared by Picon by the action of propyl iodide on sodium acetylide in liquid ammonia, is a liquid of b.p. 40°, and m.p. −95° (Picon, *l.c.*).

Isopropyl acetylene, prepared by the action of alcoholic potash on the dibromide of isopropylethylene or methyl-ethyl-ethylene, b.p. 115° (Kalinine, J. Russ. Phys. Chem. Soc. 38, 1042). In presence of aqueous solutions of cadmium or zinc chlorides at 150° it is converted quantitatively into methyl propyl ketone (Kutscherow, Ber. 42, 2759).

On treating diallyl-tetrabromide with potash a liquid *dibromodiallyl* is obtained, which boils at 210° and by the action of alcoholic potash this yields *dipropargyl* C_6H_6, a liquid boiling at 85° and isomeric with benzene, but having the constitution,

$$CH{:}C{\cdot}CH_2{\cdot}CH_2{\cdot}C{:}CH$$

Isopropenyl acetylene $CH_2=C(CH_3)-C{\equiv}CH$ forms a liquid, b.p. 67–69°, nD_{20} 1·4332, and is obtained by dehydration of 3-methylbutinol (*v.s.*) by means of anhydrous magnesium sulphate at 230° C. (D.R.P. 290558, Fr. Bayer & Co.). It gives a white precipitate with ammoniacal silver nitrate and a yellow precipitate with ammoniacal cuprous salts. It is of some interest owing to its close relationship with isoprene.

F. A. M.

ACETYLENE—COMMERCIAL APPLICATIONS. Although acetylene was discovered by Davy as far back as 1836, its use as an illuminant became practicable only in 1892, when Moissan in France, and T. L. Willson at Spray, showed that it was possible to make calcium carbide on a commercial scale in the electric furnace. (*See* CALCIUM CARBIDE.)

Calcium carbide, as made in the electric furnace, is a dark crystalline substance with a metallic lustre, having a density of 2·22. The pure compound, however, has been produced by Moissan in thin white semi-transparent plates, the colour of the commercial material being due to the presence of iron and other impurities.

Water decomposes the carbide with reproduction of lime and generation of acetylene:

$$\underset{\text{Calcium carbide}}{CaC_2} + \underset{\text{Water}}{2H_2O} = \underset{\text{Slaked lime}}{Ca(HO)_2} + \underset{\text{Acetylene}}{C_2H_2}$$

In the early days of carbide manufacture little attention was paid to the purity of the materials, with the result that the carbide formed contained impurities, some of which were decomposed by water and gave products contaminating the acetylene. Since the importance of purity in the acetylene has been recognised, everything possible is now done to reduce such impurities to a minimum.

The impurities found in commercial carbide may be divided into those which can be decomposed by water, and those on which water has no action. Amongst the former are substances evolving phosphorus compounds on contact with water, aluminium sulphide, organic sulphur compounds and metallic nitrides: whilst the latter class contains such bodies as graphite, carbides of boron and silicon, carbides and silicides of various metals contained in the lime and in the ash of coke, these being left with the lime residue after the decomposition of the carbide by water, and in no way influencing the purity of the gas.

The purity of commercial acetylene depends primarily on the purity of the carbide from which it is generated, and as long as it is impossible to get absolutely pure materials for the manufacture of the carbide, so long will impurities be found in the gas made from it. The most important of these impurities are:

(*a*) Phosphoretted hydrogen, obtained from the decomposition of calcium phosphide, &c., by water, and, in burning with the acetylene, gives rise to phosphorus pentoxide, which forms a slight haze in the room in which the gas is being burnt.

(*b*) Sulphuretted hydrogen, formed by the action of water on aluminium sulphide, &c., and yielding when burnt sulphur dioxide, which if dissolved by condensing moisture will absorb oxygen from the atmosphere, forming traces of sulphuric acid.

(*c*) Ammonia, from the magnesium nitride, which rapidly corrodes brass gas-fittings, and on burning produces traces of nitrogen acids.

Siliciuretted hydrogen is also found in small quantities in crude acetylene.

Several processes have been devised for the purification of acetylene by the removal of these compounds as well as of the hydrocarbon vapours formed by the polymerisation of the gas due to high temperature during generation. The only impurity that offers any real difficulty in removal is the phosphoretted hydrogen, and three substances have been suggested and used in practice for this purpose: (*a*) bleaching powder, (*b*) acid copper or iron salts, and (*c*) acid solution of chromic acid.

The bleaching powder is employed in the form of small lumps, as offering the least resistance to the flow of the gas when in a slightly moistened state. Its action is purely that of oxidation, the phosphoretted and sulphuretted hydrogen being converted respectively into phosphoric and sulphuric acids, the acetylene being unaffected. To obtain as large a surface as possible the bleaching powder is sometimes mixed with an inert body, such as sawdust or oxide of iron, but in whatever condition the bleaching powder is used the gas requires an after-purification for the elimination of chlorine compounds, for which purpose a lime purifier is generally employed.

Bleaching powder, though an efficient purifying agent when in good order, is apt to be uncertain in its action, and cases have frequently occurred of spontaneous firing and explosion when air has been admitted to purifiers containing this material that have been in use for some time, so that precautions are necessary when using this method of purification.

An acid solution of cuprous chloride, or solids made by impregnating kieselgühr or similar porous bodies with the acid copper salt, are also very effective in removing the various impurities, the phosphorus and sulphur compounds being transformed into copper phosphide and sulphide. The disadvantages of the process are that a second purification with lime is required to remove acid vapours, and that the material being highly acid cannot be used in ordinary metal containers, whilst if the copper salt became neutralised by ammonia there might be danger of the explosive copper acetylide being formed. Under suitable conditions 1 kilogram of the material will purify 20 to 25 cubic metres of the gas, the acetylene not being acted upon, and the action being regular and certain.

Chromic acid in solution containing sulphuric or acetic acid, or kieselgühr charged with this mixture, is the third purifying agent, and eliminates the phosphoretted and sulphuretted hydrogen and the ammonia. When exhausted the spent material can be regenerated by exposure to the air.

In practice these three materials seem to give equally good results, and the passage of the gas through the solution or solid scrubs out of it to a great extent the tarry fog and lime dust often mechanically held in the gas when it has been generated too rapidly or at too high a temperature.

Absolute purification is by no means necessary; for ordinary use all that is required being to reduce the amount of impurity below the limit at which the products of combustion are injurious to health or cause haze; and with a fairly pure specimen of carbide mechanical scrubbing is sufficient if a generator of the non-automatic type is employed, and the gas is stored in a holder before use.

Although the generation of acetylene by bringing calcium carbide in contact with water seems so simple, yet in actual practice it was complicated by several difficulties, amongst which may be mentioned the heat of the reaction, which caused the polymerisation of some of the acetylene, and by the fact that the evolution of gas did not cease immediately the water supply was cut off, this being due to water mechanically held in the residue formed, to the dehydration of the calcium hydroxide by the unchanged carbide, as well as to the moisture condensed from the gas as the temperature of the generator fell.

Acetylene generators.—These can be divided into two main classes—those in which water is brought in contact with the carbide, the latter being in excess; and those in which the carbide is thrown into water, the water being always in excess. The first class may be subdivided into those in which water is allowed to rise to the carbide, those in which it drips on to the carbide, and those in which a vessel full of carbide is lowered into water and then withdrawn as the generation of the gas becomes excessive.

Each of these types may be 'automatic' or 'non-automatic.' In the former are to be found devices for regulating and stopping at will the generation of the gas within limits, whilst the 'non-automatic' variety aim at developing the gas from the carbide with as little loss as possible and storing it in a holder.

The points to be aimed at in a good generator are:

(*a*) Low temperature of generation.

(*b*) Complete decomposition of the carbide.

(*c*) Maximum evolution of gas from carbide used.

(*d*) Low pressure in every part of the apparatus.

(*e*) Removal of all air from the apparatus before collection of the gas.

Generators of the 'drip' type, in which water is allowed to fall slowly upon a mass of carbide, possess most of the disadvantages due to heat of generation, fluctuation of pressure, &c., and this type has been abandoned except for the smallest forms of portable generator. Those in which water rises to the carbide are most efficient, and overheating can be avoided by ensuring that the water never rises above that portion of the carbide which is undergoing decomposition: in other words, that the gas leaves the carbide immediately upon its formation and passes away to the holder with the least opportunity for becoming overheated by contact with decomposing carbide.

Generators in which the carbide dips into water and is then withdrawn are apt to overheat to a dangerous extent, especially if the generator be over-driven.

Although it might be expected that the dropping of the carbide into an excess of water would produce the coolest and purest gas, yet evidence of overheating of the gas is often found in generators of this class, as a coating of lime can form around the lumps, preventing the free access of water, and allowing the interior of the mass from which generation is proceeding to become heated to redness; the efficiency also is lowered as a certain amount of the gas is dissolved in its upward passage through the large volume of water.

Theoretically 64 parts by weight of carbide require only 36 parts by weight of water for complete decomposition and conversion of the lime into hydroxide, but it is found in practice that, owing to the heat of the reaction driving off some of the water as steam, and a further portion mechanically adhering to the slaked lime, double this amount of water is necessary, and the only safe way to ensure entire decomposition of the carbide is to add sufficient water to flood the residue.

Carbide is also supplied in the form of 'briquettes,' coated with material to prevent deterioration in air; at the same time the after-generation of gas when the water supply is stopped is largely prevented. These briquettes are particularly suited for motor car headlight outfits and table lamps.

Combustion of acetylene.—When acetylene is burnt in air under such conditions as to complete its combustion, it is converted into carbon dioxide and water vapour, the same compounds that are produced by all combustible hydrocarbons, 1 cubic foot of the gas requiring 2½ cubic feet of oxygen, or five times that amount of air.

When acetylene was first used for illumination, burners of the Union jet type (similar to coal-gas burners) were employed, some of these being of specially small size. In such burners the orifices for the issue of the gas were very small, and were drilled at a more obtuse angle than for coal gas. Burners of this type, whilst giving good results for a time, soon developed a smoky flame, a filiform growth of carbon appearing on the jet, so that they were generally unsuitable.

Smoking is very likely to develop with acetylene, especially when the gas is turned down. This is due principally to the polymerisation of the gas by heat, producing liquid hydrocarbons (principally benzene) and solid carbon by decomposition, when the gas issuing from the small orifices becomes unduly heated. With a high efflux velocity sufficient air will be drawn in to ensure primary combustion close to the orifice and the trouble is largely overcome, but the reduction of the gas pressure prevents this action. An accumulation of particles of carbon, or other foreign matter, such as lime particles from the generator, will act similarly by impeding the gas flow, so that once carbon begins to form the actions leading to smoking rapidly accelerate.

On breaking open a steatite jet of a burner in which smoking has developed carbon deposit will be found to have extended to some depth, showing that a liquid hydrocarbon has soaked into the steatite and been there further decomposed by heat.

The actions leading to the formation of the liquid product in general arise at the jet, but with a bad type of generator, where overheating takes place, polymerised products may be carried forward in the gas, and deposited in and around the narrow orifice in the steatite or other porous material.

Attempts to overcome these difficulties were on the lines of introducing air, either admixed with gas, which was soon abandoned on account of danger, or constructing the burner so that air was drawn in through adjacent orifices by the injector action of the issuing gas, a method adopted by Bullier (1896-97).

Bullier's principle of making the tips of the burner jets into small bunsens was adopted by Dolan in America, and Billwiller on the Continent.

The Billwiller burner has two steatite arms rising at right angles from a common base from which the acetylene issued at two small orifices exactly opposite each other and giving the double jet. Immediately above the gas orifice a small platinum plate was fixed at a distance of about 0·5 mm. from the steatite, with a hole in it rather larger than the orifice in the steatite just below. The acetylene issuing from the hole in the steatite rushed through the hole in the platinum above and drew air in under the platinum plate. The air so drawn in flowed to the confines of the rapidly travelling stream of acetylene and passed upwards around it, so preventing contact between the edge of the hole in the platinum and the acetylene, whilst the metal, being part of a collar of platinum fixed round each steatite arm, and being a good conductor of heat, prevented such heating as would lead to the deposition of carbon from the gas.

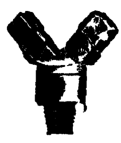


FIG. 1.

In 1897 Dolan in America made a burner on the same principle as the Billwiller burner, though of slightly different construction. It consisted of a metal base, the upright from which forked into two arms, which near their extremities were bent inwards at right angles. These arms carried steatite or 'lava' tips, bored with a fine hole from the interior to the base of the mushroom head, where its diameter was more than doubled, whilst four small lateral air tubes were bored at regular intervals from the base of the head to the broad aperture of the nipple, with the result that the flow of acetylene from the narrow into the wider tube sucked air in through the side tubes and surrounded the ascending gas with an envelope which prevented its contact with the heated tip. These burners, which are more generally known as the 'Naphey' burners, gave very good results, and have been more widely adopted than the Billwiller burners that preceded them, partly because they did away with the expense of the platinum, were cheaper to make, and were less liable to break.

The great drawback to all the Naphey tip burners is that the heat from the flame causes a slight and gradual warping of the metal mounting, with the result that after a time the jets become slightly thrown out of their true position, which at once distorts the flame and causes it to throw up smoky points. This trouble is not found with burners having steatite or composition arms, as these, being pressed or cut, do not warp with the heat.

These burners proved the forerunner of a host of others in all of which the same principle was adopted, one of the simplest and most popular being shown in Fig 2, whilst Fig. 3 is a section of the same burner, showing the construction and air inlets.

Although these burners possess many advantages and can be used for several hundred hours without smoking, they have the drawback that the flame cannot be turned down, as, after the flame has been left turned down for an hour or two, it will be found that it will generally start smoking when the normal consumption is restored.

In order to overcome this trouble Bray introduced a burner in which, by placing a second air-supply chamber of larger dimensions above the first, such a complete encircling of the jet of gas by air was ensured that the variations in gas pressure caused by turning down the flame do not lead to carbonisation.

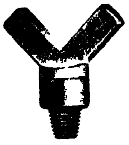

Fig. 2.

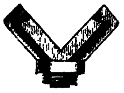

Fig. 3.

Another burner has been brought out in which the idea of air injection has been successfully adapted to a slit burner: the gas issues from a series of fine holes placed below a cap provided with a broad slit and side air tubulure, the gas drawing in sufficient air in its passage through the slit to prevent smoking or carbonisation of the burner (Fig. 4). Such slit type burners are particularly suited for use in motor-car headlights, &c. With twin jet burners an obstruction in one orifice may cause a somewhat long flame to issue from the other orifice, which may impinge on lenses or mirrors situated close to the burner. The slit type is free from this disadvantage.

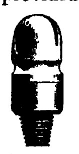

Fig. 4.

From the earliest introduction of acetylene attempts have been made to utilise it with incandescent mantles, but under the pressures which are usually obtained from the ordinary generating apparatus this has not proved successful. Acetylene, when consumed in an atmospheric burner, gives an excessively hot flame, not only on account of its composition, but also from its endothermic character. Several difficulties, however, are met with in trying to burn acetylene mixed with air in sufficient proportion to yield a non-luminous flame, namely:

(*a*) The wide range over which such mixtures are explosive.

(*b*) The low temperature of ignition.

(*c*) The high speed at which the explosive wave travels through the mixture of gas and air.

In order to make a bunsen burner for acetylene the tube has to be very narrow, and even then flashing back is very liable to occur, whilst a high pressure is needed to bring about a satisfactory mixture of the gas with sufficient air to ensure combustion with an absolutely non-luminous flame. The range of explosibility lies between 3 p.c. and 82 p.c. of acetylene in the mixture, and the propagation of the explosive wave cannot be stopped by the ordinary device of using wire gauze, on account of the low ignition point of the mixtures. By using a tube ½ mm. in diameter the explosion ceases to be propagated at all, but such tubes, on account of their small diameter, cannot be utilised singly. The difficulty can be surmounted by using a bundle of small tubes united to form a single burner, or by employing a large tube having a constriction at one point of not more than 5 mm. diameter. The diameter of the tube at the constriction must be in a definite proportion to the particular mixture of air and acetylene consumed, as the more air the greater must be the constriction in the strangulated portion of the tube, owing to the increased velocity of the explosive wave.

With an acetylene bunsen, and using a Welsbach No 2 mantle, as much as 90 candles per cubic foot of acetylene has been obtained. It may be taken that when used with a mantle acetylene will give double the illuminating power per cubic foot as compared with the light obtained when the gas is burnt in the ordinary acetylene flat-flame burners under the best conditions, but very widely different results have been obtained, owing to irregularities in the pressure or lack of air regulation, and at the moment of lighting or turning out there is a liability of a small but violent explosion, which has disastrous effects upon the mantle. A further difficulty is caused when phosphoretted hydrogen is present as an impurity, for this leads to the formation of fusible phosphates of thorium and cerium, with consequent destruction of the mantle. Apart from these considerations, the mantle appears to be hardened and strengthened by the intense heat to which it is subjected, but it is not yet determined how the life of the mantle is affected by the temperature of the flame.

Under the light yielded by the combustion of acetylene colours appear practically the same as in daylight, and all tints and shades can be as clearly distinguished from one another as in sunlight. For this reason the gas has been found to be of invaluable utility in dyeing and colour printing. The spectrum of acetylene, however, although the same as that of daylight for red and yellow, has an increase in the blue rays of 0·46, which brings them to about the same value as the Northern Light. The violet rays show a slight increase, so that acetylene is even richer than sunlight in the rays which are so essential to the chemical action of light, and yet the red rays which are so detrimental in colour work do not predominate, as in the electric arc.

Acetylene has been found of great service in the illumination of small towns and country villages, and for isolated houses and farms. It has been employed in photography on account of its richness in actinic rays. For headlights on motors, for train lighting, for buoys, and in fact in a number of cases where bright and trustworthy light is required without the complication of a coal-gas works or the dangers of oil, acetylene has proved its worth.

It has been found that the rays from an acetylene light possess remarkable penetrative powers in fog or mist, being in this respect superior to the arc light or incandescent mantle.

Storage of dissolved Acetylene.—In the early days of the development of acetylene for commercial purposes attempts were made to employ it in a liquefied form or compressed, but under pressure the gas proved too dangerous. Even at 2 atmospheres pressure acetylene free from oxygen can be exploded. It was enacted in 1807 that the gas should never be subjected to a pressure exceeding 100 inches of water (about 4 lbs. per square inch); later this was raised to 250 inches.

In 1896 Claude and Hess, in France, suggested the idea of making use of the solubility of acetylene in certain liquids as a means of storing this gas, and acetone was tried as the solvent. Acetone dissolves 24 times its volume of acetylene at 15° and under ordinary atmospheric pressure, the solubility increasing proportionately with pressure. The volume of the acetone also increases very largely. It was found that the simple solution of acetylene in acetone, although less liable than the compressed or liquefied acetylene to explosion, could not be said to be sufficiently free from danger to admit of its general use. Janet and Fouche discovered that when acetylene is dissolved in acetone absorbed by porous material of the right kind under 10 atmospheres pressure, it was impossible to produce explosion. The practice in this country for the storage of acetylene is to fill a cylinder with porous material (porosity about 80 p.c.), then to add a volume of acetone equal to 40 p.c. of the original cylinder volume, and pump in the gas to a pressure of 150 lbs. per square inch. In 1901 this was fixed as the legal pressure limit. Thus a cylinder of 1 cubic foot capacity containing 0·4 cubic foot of acetone will hold 100 cubic feet of the gas, most of which will be given off when the valve is opened.

There are practically only three porous materials in use for absorption of dissolved acetylene in the United Kingdom: (*a*) a porous agglomerate of asbestos, kieselguhr, and charcoal, and a suitable cement; (*b*) charcoal filling; (*c*) kapok filling. The porosity should not exceed 80 p.c. The solvent must not completely fill the porous material under any rise of temperature likely to be experienced. With the present type of cylinder, the pressure at present allowed, *i.e.* 150 lbs. per sq. in., should not be increased; for solid drawn cylinders and for those of 100 cubic feet capacity and over in which the acetylene-welding at the top and bottom is strengthened, the pressure allowed might safely be increased to 225 lbs. per square inch provided a solvent is used in addition to the porous material. The best material for the construction of cylinders is a mild steel of high ductility, of which the carbon content does not exceed 0·25 p.c. and the phosphorus and sulphur each do not exceed 0·05 p.c. The test pressure should be four times the working pressure and should be maintained for not less than fifteen minutes (Home Office Report, J. Soc. Chem. Ind. 1918, 116*A*).

Acetylene Welding and Metal Cutting.—Acetylene is largely employed for autogenous welding and for metal cutting; in the latter case extra oxygen being supplied so that the metal itself is burnt away. The temperature of the oxy-acetylene flame is approximately 3000°, and from the nature of the combustion the flame has a reducing action tending to exclude the possibility of oxidation of the metals undergoing treatment. Theoretically 2·5 volumes of oxygen are required for each volume of acetylene, but in practice it is found that the proportions are approximately 1·4 to 1·0, this low proportion of oxygen ensuring a reducing action in the flame.

There are two systems of operating: in the high-pressure system the oxygen is delivered from an ordinary cylinder under pressure, and the acetylene, dissolved in acetone under pressure, is also supplied from cylinders. Both cylinders are fitted with special governors, as a perfect regulation of the flame is one of the main conditions of success. This system has the great advantage of a portable outfit, and can be applied in confined spaces, but it is more expensive than the alternative system.

With the low-pressure plant the acetylene is made in an ordinary generator, which may be of the automatic or non-automatic type, the size of the works to a great extent influencing the kind of generator used, but, whatever type be adopted, it is necessary that the generation of the gas should not be accompanied by overheating, as this leads to low temperatures at the burner and other troubles. The gas should be purified before use, as the presence of the phosphoretted and sulphuretted hydrogen would tend to spoil the weld, and the purifying agent should be renewed when necessary. After leaving the purifiers the gas is distributed to the various points in the workshops in gas- or steam-barrel piping, and at each point a hydraulic back-pressure valve is inserted, in order to prevent the oxygen through any mischance flowing back through the acetylene service. The use of an efficient water-trap is a sufficient safeguard in practice.

The first successful blowpipe was the Fouche, employed with the low-pressure system, and this type has held its own in spite of the competition of other patterns. After the weld has been made the plate is annealed, this being essential. Although the results of tests up to the present are not very consistent, it may be taken that, on the average, the welded joint has a tensile strength from 95 to 80 p.c., depending on the thickness of the plate.

There are many classes of work in which oxy-acetylene welding can be advantageously employed. In the motor-car industry, both in the garage and repair shop, it has proved of great service, it being a comparatively simple matter, for instance, to mend a cracked cylinder or gear-box. For the welding of tubes, repairs to boilers *in situ* needed by corrosion, &c., for the mending of fractured stems and stern posts, the process has been invaluable.

Iron and steel (including thick armour plate) are now commonly cut with oxy-acetylene blowpipes with great saving in time and cost. The method is not so suitable for cast-iron. The blowpipes are made with a central oxygen supply jet, the acetylene serving to heat the metal to its ignition point, when the excess oxygen burns it to oxide, which flows away in a molten condition. The ratio of acetylene to oxygen employed varies from 25 p.c. for thin plate to 10 p.c. for the thickest. The following rates of cut and oxygen consumption are attained:—

Thickness of plate.	Foot run of cut per hour.	Oxygen consumed per ft. run.
1	40	2·2
3	20	9·0
6	18	28·0
9	16	60·0
12	16	100·0

Acetylene for Power Purposes.—Owing to the violence of the explosion when mixed with air acetylene is liable to give unduly high pressures in the cylinders of internal combustion engines. Moreover, it is too expensive to compete with other fuels. Tests on engines of a few horse-power have shown consumptions of about 6·3 cubic feet per B.H.P. hour. It has, however, been successfully employed, particularly in the United States, for starting up motor car engines, the advantage of the gas for this purpose is obvious where it is carried in the compressed form (in acetone) for the usual lighting sets. The violence of the explosion has to be guarded against, otherwise damage to the engine may result. J. S. S. B.

ACETYLSALICYLIC ACID *v.* SALICYLIC ACID.

ACHRODEXTRIN *v.* DEXTRIN.

ACHYRANTHES ASPERA or *Aghara.* An Indian plant used as a simple and as a remedy for toothache.

ACID ALBUMEN *v.* PROTEINS.

ACID CERISE *v.* TRIPHENYLMETHANE COLOURING MATTERS.

ACID GREEN *v.* TRIPHENYLMETHANE COLOURING MATTERS.

ACIDIMETRY and ALKALIMETRY. This branch of quantitative analysis dealing with the estimation of acids and alkalis is of great technical importance. In pure aqueous solutions the amount of acid or alkali can usually be ascertained with considerable accuracy by determining the specific gravity of the liquid at a definite temperature and referring to a table especially drawn up for this purpose.

Direct estimations may also be made by suitable gravimetric methods, but volumetric processes are almost exclusively employed, and are indeed the only methods available for distinguishing between free and combined acid or alkali. In these operations the quantity of acid or alkali present is calculated from the amount of standard alkali or acid required respectively to neutralise it exactly, the precise point of neutralisation being determined by the addition of a small quantity of an *indicator*, *i.e.* a substance which by undergoing a marked change of colour renders evident the transition from acidity to alkalinity, or *vice versâ*.

Indicators. Although many natural and artificial colouring matters have been recommended as indicators, comparatively few are actually used, those most frequently employed being *methyl orange*, *phenolphthaleïn*, and *litmus.*

Artificial indicators are either very weak organic acids or (more rarely) weak bases, and the prevalent view regarding their behaviour is that in solution their colour in the non-ionised state differs from that which they exhibit in the ionic condition.

In accordance with the ionic theory of solution, a very weak acid HM exists in solution, mainly, but not entirely, in the non-ionised state, the equilibrium between ions and undissociated molecules $HM \rightleftharpoons \overset{+}{H} + \overset{-}{M}$ being expressed quantitatively by the equation

$$\overset{-}{M} \times \overset{+}{H} / HM = \text{constant}$$

in which the symbols denote the molecular concentrations of the ions and molecules, and where as in the case under discussion $\overset{-}{M}$ and $\overset{+}{H}$ are very small in comparison with HM.

Any increase in the value of $\overset{+}{H}$, which is effected by adding a small quantity of a fairly strong (ionised) acid to the solution, leads to a corresponding diminution in the value of $\overset{-}{M}$. The reverse change, leading to an increase in the value of $\overset{-}{M}$, with a corresponding decrease in the value of $\overset{+}{H}$, is effected by adding a slight amount of a fairly strong (ionised) alkali hydroxide, since the equilibrium $\overset{+}{H} \times \overset{-}{OH} = \text{constant}$ obtains in aqueous solutions, and the alkali added increases considerably the value of the factor $\overset{-}{OH}$. If the acid HM and the ion M differ in colour, then, in any solution containing this acid a change from acidity to alkalinity, *i.e.* from a state in which $\overset{+}{H}$ predominates over $\overset{-}{OH}$ to the reverse condition, may be indicated by an appreciable change of colour. The degree of ionic dissociation of the indicator HM must, however, be considerably smaller than that of either acid or alkali employed in the titration; moreover, another acid HR, having a smaller degree of ionisation than HM, will indicate the transition with even greater precision, providing that the recognition of the colour-change is not more difficult. The quantity of indicator employed must be so small that the amount of alkali required to neutralise it is negligible.

For Theory of Indicators, *v.* Ostwald (Scientific Foundations of Analytical Chemistry, translated by McGowan), Küster (Zeitsch. anorg. Chem. 1897, 13, 127), Waddell (J. Phys. Chem. 1898, 2, 171), Vaillant (Compt. rend. 1903, 136, 1192), Stieglitz (J. Amer. Chem. Soc. 1903, 25, 1112; Amer. Chem. J. 1908, 39, 651; 1909, 42, 115), McKoy (Amer. Chem. J. 1904, 31, 503), Hewitt (Analyst, 1908, 33, 85), Salm (Zeitsch. physical. Chem. 1906, 57, 471; Zeitsch. Elek. Chem. 1907, 13, 125), Salessky (Zeitsch. Elek. Chem. 1904, 10, 204), Fels (Zeitsch. Elek. Chem. 1904, 10, 208), Schoorl (Chem. Zentr. 1907, i 300, 502, 585), Hantzsch (Ber. 1907, 40, 1556; 1908, 41, 1187; 1915, 48, 158), Rohland (Ber. 1907, 40, 2172), Acree (Amer. Chem. J. 1908, 39, 528, 649, 789), Handa (Ber. 1909, 42, 3179); and *cf.* Noyes for the physico-chemical theory (J. Amer. Chem. Soc. 1910, 32, 815), Wegscheider (Zeitsch. physikal. Chem. 1915, 90, 641).

Indicators may be divided broadly into three classes: (i.) Those insensitive to very weak acids, such as carbonic, boric, and hydrosulphuric acids; these indicators comprise among others *methyl orange*, *lacmoid*, *cochineal*, and *iodoeosin.* (ii.) Those somewhat sensitive to weak acids, although as a rule these acids cannot be accurately titrated with their aid; if weak volatile acids such as carbonic acid are removed by boiling, these indicators act like those of the first class towards fairly strong acids and bases. *Litmus* is the chief representative of this group. (iii.) Those highly sensitive even to weak acids. This class contains *phenolphthalein*, *turmeric*, and *rosolic acid* (*v.* Glaser, Zeitsch. anal. Chem. 1899, 38, 273; Wagner, Zeitsch. anorg. Chem. 1901, 27, 238).

The more important indicators are described below in alphabetical order.

Aurin (*Commercial or para-Rosolic acid*) is a mixture of several substances, produced by heating together phenol and oxalic and sulphuric acids; it appears in commerce in yellowish-brown resinous lumps. A 1 p.c. solution in 60 p.c. alcohol is employed, 1·5 c.c. being added to the solution to be titrated. In acid solution the colour is pale *yellow*, in alkaline solution *rose-red*. This indicator is very sensitive and well adapted for titrating barium hydroxide solutions, but it is affected by carbon dioxide and hydrogen sulphide.

Cochineal. The colouring matter in the product obtained from the dried female insect *Coccus cacti* (Linn.), is termed *carminic acid*. The best trade product, which is called 'silver cochineal,' was first recommended as an indicator by Luckow (J. pr. Chem. 1861, 84, 424; Zeitsch. anal. Chem. 1862, 1, 386); 3 grams of the substance (not pulverised) is extracted with 250 c.c. of dilute alcohol (1 vol. alcohol : 3–4 vols. water), and the clear liquid decanted. In alkaline solution the colour is *violet*, in acid *yellowish-red*. This indicator, which is very sensitive to strong acids and bases, is extremely useful in titrating ammonia; it is scarcely affected by carbon dioxide. The colour-change is well defined even in artificial light. Cochineal is, however, useless for titrating organic acids; and iron, aluminium and copper salts must be absent, since their solutions remain pink even when acid.

Curcumin (*Turmeric yellow*). The colouring matter from the roots of *Curcuma longa* (Linn.) is turned *yellow* by acids and *reddish-brown* by alkalis; it is nearly always employed as a *test-paper*, and is useful in detecting ammonia and boric acid.

Gallein (*Alizarin violet, Pyrogallolphthalein*). This compound, prepared by heating together pyrogallol and phthalic anhydride (Baeyer, Ber. 1871, 4, 457, 555, 663), was proposed as an indicator by Dechan (Pharm. J. 15, 849). A 0·1 p.c. alcoholic solution is used, 10 drops being added to 100 c.c. of liquid. In alkaline solution the colour is *reddish-violet*, in acid *pale-brown*. This indicator is scarcely affected by carbon dioxide, and can be used in the accurate titration of organic acids.

Iodoeosin (*Tetraiodofluorescein, Erythrosin B.*). This substance, prepared by iodating fluorescein, is a brick-red powder soluble in hot alcohol or in ether, but almost insoluble in water or cold alcohol; it was first recommended by Mylius and Forster (Ber. 1891, 24, 1482); 0·5 gram of the sodium derivative of iodoeosin is dissolved in 1 litre of water, 2·5 c.c. are added to the solution to be titrated together with 5 c.c. of chloroform, the mixture being shaken in a stoppered bottle during titration. While alkaline the aqueous layer is *rose red*, when acid the aqueous layer becomes *colourless*, and the chloroform assumes a yellowish tint (Ellms, J. Amer. Chem. Soc. 1899, 21, 359; M. and F. used ether instead of chloroform). With this indicator, centinormal or even millinormal solutions can be titrated; it is indifferent to carbon dioxide, and phosphoric acid can be titrated as a monobasic acid with sodium hydroxide (Glücksmann, Chem. Zentr. 1902, (i.) 1131). Feeble bases, such as the alkaloids, may also be titrated, using iodoeosin as indicator.

Lacmoid (*Resorcin Blue*). This substance is obtained by heating gradually to 110° a mixture of 100 parts of resorcinol, 5 parts of sodium nitrite, and 5 parts of water. When the violent reaction moderates, the mass is heated to 115°–120° until evolution of ammonia ceases. The product is a glistening reddish powder (Traub and Hock, Ber. 1884, 17, 2615). It owes its distinctive properties to *lacmosol*, which can be isolated and purified by a method described by Hottinger (Biochem. Zeitsch. 1914, 65, 177). The turning-point of the pure indicator is far sharper than that of the ordinary preparation.

A 0·3 p.c. alcoholic solution is employed; a better colour change is produced if 5 grams of naphthol green are dissolved in a litre of this solution (Zeitsch. angew. Chem. 1890, 3, 163). In alkaline solution the colour is *blue*; in acid, *red*. Although these colour changes resemble those of litmus, the indicator is more closely allied to methyl orange. It is only slightly affected by carbon dioxide, although direct titration of carbonates is not satisfactory in cold solution; lacmoid test paper may, however, be used in almost any experiment for which methyl orange is suitable. This indicator is useless for organic acids.

Litmus occurs in commerce in the form of small cubical granules mixed with a large proportion of calcium carbonate. An aqueous solution of this product not only contains free alkali, but also a variable proportion of colouring matters which interfere with the delicacy of the reaction. Special precautions must therefore be taken in preparing the solution for use in acidimetry. Various processes have been recommended by Berthelot and De Fleurieu (Ann. Chim. Phys. 1865, [4] 5, 189), Wartha (Ber. 1876, 9, 217), Mohr (Titrirmethode), Luttke (Zeitsch. anal. Chem. 1892, 31, 692). The following method gives excellent results: The litmus is extracted three or four times with boiling methylated alcohol of 85 p.c. in order to remove the injurious colouring matters, the residue is extracted with cold water, slightly acidified with sulphuric acid, and boiled to expel carbon dioxide. The extract is neutralised with baryta water, a few bubbles of carbon dioxide passed in to remove excess of baryta, and the liquid again boiled and filtered. The solution should contain about 20 grams of solid matter per litre, and must be kept in vessels to which the air has free access. If kept in closed vessels it undergoes fermentation and is decolourised. The colour is restored when the liquid is exposed to air. The colour of the solution should be *purple*; it turns *blue* with alkalis, and *red* with acids, and is affected by carbon dioxide, sulphur dioxide, and hydrogen sulphide. (For the relative merits of litmus and methyl orange, *v.* Reinitzer, Zeitsch. angew. Chem. 1894, 547, 574; Lunge, *ibid.* 1894, 733.)

The colour change is rendered more delicate by conducting the titration in the monochromatic light obtained by heating a bead of sodium carbonate in a bunsen flame (L. Henry, Compt. rend. 1873, 76, 222). The red solution seems colourless, whilst the blue solution is almost black. Litmus is not well adapted for use by gas- or lamp-light.

Luteol. The preparation of this substance, a hydroxychlorodiphenylquinoxaline, is described by Autenrieth (Arch. Pharm. 1895, 233, 43), and by Glaess and Bernard (Mon. Sci. 1900, 14, 809); it forms fine, woolly, yellowish needles, m.p. 246°. A 0·33 p.c. alcoholic solution is used as an indicator. In alkaline solution the colour is *yellow*; in acid it is *colourless*. This indicator is said to be remarkably sensitive, excelling Nessler's solution as a test for ammonia; but it is sensitive to carbon dioxide (Higgins, J. Soc. Chem. Ind. 1900, 19, 958). It was especially recommended by Autenrieth for use in Kjehldahl's process (*v.* ANALYSIS).

Methyl orange (*Helianthin, Poirrier's Orange III*). This substance, prepared by diazotising sulphanilic acid and coupling the resulting diazonium salt with dimethylaniline, was introduced as an indicator by Lunge (Ber. 1878, 11, 1944; J. Soc. Chem. Ind. 1882, 1, 16). One gram of pure methyl orange (either the free acid or its sodium salt) is dissolved in 1 litre of water, and two drops of this solution are added in each titration; if, owing to dilution during the titration, the colour becomes too faint, another drop of the indicator is added; on no account should too much indicator be used, since the colour change, from *yellow* in alkaline to *pink* in acid solution, is not sharp in such circumstances. Methyl orange is exceedingly useful, since its indications are practically unaffected by the presence of carbonic, hydrosulphuric, boric, and silicic acids; carbonates and sulphides may therefore be titrated in cold solution as if they were hydroxides. All titrations must be made with this indicator in cold aqueous solution, and, since methyl orange is not very sensitive as compared with various other indicators, the acid or alkali employed should be fairly concentrated. It is advisable to employ normal solutions, though with N/2 or even N/5 solutions it is possible to determine an end-point to within a single drop. With N/10 solutions, especially when carbonates are being titrated, there is a distinct *brownish* transition tint between the yellow and pink, and results may be uncertain to the extent of one or two drops (*cf.* Küster, Zeitsch. anorg. Chem. 1897, 13, 140).

The addition of indigo-carmine to methyl orange has been recommended by Luther (Chem. Zeit. 1907, 31, 1172), who states that the colour change is very pronounced. Ethyl orange is stated by Wieland to be even better than methyl orange (Ber. 1883, 16, 1989).

Methyl red. This substance, prepared by diazotising anthranilic acid and coupling the resulting diazonium salt with dimethylaniline, was introduced as an indicator by Rupp and Loose (Ber. 1908, 41, 3905). A 0·2 p.c. alcoholic solution is employed, and two drops of this are added in each titration. The colour change is from a pure *yellow* in alkaline to a *reddish-violet* in acid solution, and is very pronounced. This indicator is very sensitive, and can be used for titrating weak bases in centinormal solution. Ordinary sodium hydroxide solutions containing a little carbonate can be accurately titrated in the cold.

According to Thomson (Analyst, 1914, 39, 518) methyl red gives a sharper end point than methyl orange, and its sensitiveness, unlike that of methyl orange, is not greatly affected by the presence of neutral salts. When methyl red is used in the titration of carbonates, the solution must be boiled after each addition of the acid. *See* also Lehmann and Wolff, Arch. Pharm. 1917, 255, 113.

For observations on the behaviour of indicators of the methyl-red type, *see* Howard and Pope, Chem. Soc. Trans. 1911, 1333.

Phenacetolin, first recommended by Degener (Zeit. d. Ver. f. d. Rübenzucker Industrie, 1881, 357; J. Soc. Chem. Ind. 1882, 1, 85), is prepared by boiling together for several hours molecular proportions of phenol, acetic anhydride, and sulphuric acid. The product is extracted with water to remove excess of acid, dried and dissolved in alcohol in the proportion of 1 gram to 500 c.c. It is *pale yellow* with alkalis, *red* with carbonates of the alkalis and alkaline earths, *colourless* or *pale yellow* with acids. It is used for estimating both hydroxide and carbonate when present in the same solution.

Phenolphthaleïn, obtained by heating phenol with phthalic anhydride and concentrated sulphuric acid (Baeyer, Annalen, 1880, 202, 69), was proposed as an indicator by Luck (Zeitsch. anal. Chem. 1877, 16, 322). One or two drops of a 0·5 p.c. alcoholic solution are used in each titration. In alkaline solution the colour is *red*; the acid solution is *colourless*. Owing to its very weak acid character, phenolphthaleïn is the indicator *par excellence* for organic acids; it is useless, however, in the presence of ammonium salts, and since even carbonic and hydrosulphuric acids discharge the red colour, it is necessary to work with solutions free from these acids or titrate in boiling solution; hence its use is somewhat restricted (*cf.* McBain, Chem. Soc. Trans. 1912, 101, 814). A convenient method of titrating organic acids with ordinary sodium hydroxide solutions using phenolphthaleïn as indicator, is described by Philip (Chem. Soc. Trans. 1905, 87, 991); *cf.* McCoy (Amer. Chem. J. 1904, 31, 503); and Schmatolla (Ber. 1902, 35, 3905).

Turmeric *v.* CURCUMIN.

Many other indicators have been proposed from time to time, among others the following:—

Alizarin (Schaal, Ber. 1873, 6, 1180); *Alizarin-red* I. W.S. (Knowles, J. Soc. Dyers, 1907, 23, 120); *Congo-red*; *cyanine* (Schönbein, J. pr. Chem. 1865, 95, 449); *cyanogen iodide* (Kastle and Clark, Amer. Chem. J. 1903, 30, 87); *diaminazoatoluenesulphonic acid* (Troeger and Hille, J. pr. Chem. 1903, 68, 297); *ferric salicylate* (Weiske, J. pr. Chem. 1875, 12, 157; Wolff, Compt. rend. 1900, 130, 1128; Gerock, Chem. Zentr. 1900, ii. 1294); *flavescin* (Lux, Zeitsch. anal. Chem. 1880, 19, 457); *fluorescein* (Krüger, Ber. 1876, 9, 1572; Zellner, Chem. Zeit. Rep. 1901, 25, 40); *hæmatoxylin* (Wildenstein, Zeitsch. anal. Chem. 1863, 2, 9); *metanil yellow* (Linder, J. Soc. Chem. Ind. 1908, 27, 485); *methyl*-3-*aminoquinoline* (Stark, Ber. 1907, 40, 3434); *extract of mimosa flowers* (Robin, Compt. rend. 1904, 138, 1046); *para-nitrophenol* (Langbeck, Chem. News, 1881, 43, 161; Spiegel, Ber. 1900, 33, 2640; Zeitsch. angew. Chem. 1904, 17, 715; Goldberg and Naumann, Zeitsch. angew. Chem. 1903, 16, 644); *paranitrobenzeneazo-α-naphthol* (Hewitt, Analyst, 1908, 33, 85); and *Poirrier's blue* C4B (Engel, Compt. rend. 1886, 102, 214); 2·5-*Dinitroquinol* (Henderson and Forbes, J. Amer. Chem. Soc. 1910, 32, 687); *di-o-hydroxystyryl ketone* (*lygosin*) (Ferenz); 1-*oxynaphtho-*

chinomethane (Nierenstein); 6-*sulpho-α-naphthol-*1-*azo-*m-*hydroxybenzoic acid* (Mellet); 2·6-*dinitro-aminophenol* (*isopicramic acid*) (Meldola and Hale); *alizarinmonosulphonic acid* (Knowles); *myrtle berry* (*Vaccinius myrtillus*, L.) juice, the colouring matter of which is œnocyanin, the red colouring matter of wine; *red beetroot extract* (Chauvierre).

The relative sensitiveness of the more important indicators and their behaviour under various conditions have been investigated by Wieland (Ber. 1883, 16, 1989), and especially by Thomson (Chem. News, 1883, 47, 123, 135, 184; 1884, 49, 32, 38, 119; 1885, 52, 18, 29), whose results are summarised in the following table:—

—	Litmus	Lacmoid	Aurin	Methyl orange	Phenacetolin	Phenolphthalein
Sensitiveness	0·05	0·01	0·01	0·05	0·01	0·01
Hot solutions	Available	Available	—	—	—	—
Ammonia	Available	Available	Available	Available	Available	Not available
Ammonium salts	Not affected	Not affected	Less sensitive	Less sensitive	Not affected	Not available
Neutral alkaline salts	Not affected	Not affected	Not affected	Less sensitive	Not affected	Not affected
Carbon dioxide	Indefinite	Indefinite	Indefinite	Not affected	Colour changed	Indefinite
Hydrogen sulphide	Indefinite	Decolourised	Indefinite	Not affected	Not affected	Indefinite
Alkaline carbonates	Indefinite	Indefinite	Indefinite	Alkaline	Red colour	Alkaline
Alkaline bicarbonates	Indefinite	Indefinite	Indefinite	Alkaline	—	Neutral
Sulphites	Indefinite	Alkaline	Neutral	Alkaline	Not available	Neutral
Acid sulphites	Indefinite	Neutral	Acid	Neutral	Not available	Acid
Silicic acid	Neutral	Neutral	Neutral	Neutral	Neutral	Not available
Alumina	Indefinite	Alkaline	Indefinite	Alkaline	Neutral	Neutral
Boric acid	Indefinite	Indefinite	Indefinite	Neutral	Indefinite	Indefinite
Sodium thiosulphate	Neutral	Neutral	Neutral	Neutral	Neutral	Neutral
Sulphides	Alkaline	Not available	—	Alkaline	Alkaline	Alkaline
Hydrosulphides	Indefinite	Not available	—	Alkaline	—	Neutral

Arsenic acid	Indefinite	Monobasic	Indefinite	Monobasic	Monobasic	Dibasic
Arsenious acid	Neutral	Neutral	Indefinite	Neutral	Neutral	Indefinite
Phenol	Neutral	Neutral	Neutral	Neutral	Neutral	Indefinite

The sensitiveness is measured in c.c. of decinormal acid required to produce a distinct change when the volume of the liquid is 100 c.c. It should be borne in mind, however, that the sensitiveness of many indicators changes (usually diminishes) in the presence of considerable quantities of dissolved salts. Where a reaction is given as 'indefinite,' it is not meant that there is no effect, but that the change is not sufficiently sharp to be available in analysis. In many cases where the reaction is indefinite in cold solutions it becomes definite if the liquid is boiled, *e.g.* litmus with sulphides, sulphites, and carbonates; phenolphthalein with sulphides and carbonates. Lacmoid is most serviceable in the form of paper, and several of the reactions which are unsatisfactory with the solution are sharp and distinct with the paper, *e.g.* with carbonates, sulphides, and sulphites

Gawalowski recommends (Zeitsch. anal. Chem. 1883, 22, 397) the use of a mixture of methyl orange and phenolphthaleïn, which is deep-red with excess of alkali, pale-yellow when neutral, and rose-red with excess of acid. Compare also Schlotz (Zeitsch. Elek. Chem. 1904, 10, 549) on mixed indicators.

Walpole (Biochem. J. 1914, 8, 628) gives a chart of hydrogen ion concentration data representing the sensitive ranges of all the indicators in general use, both in colorimetric and 'end-point' processes.

Preparation of Standard Acids and Alkalis.

Standard solutions of acids and alkalis are usually prepared on the *normal* basis, the *normal* solution of a chemical reagent containing one gram-equivalent of the substance in one litre of the solution (*v.* ANALYSIS, Volumetric section).

In acidimetry and alkalimetry it is essential to have a standard solution of some acid or alkali, the concentration of which is known with great accuracy; this solution serves to standardise the others. Various suggestions have been made, but the general choice, at least for technical purposes, has fallen on hydrochloric acid as the standard acid; sulphuric acid is frequently employed and, less often, oxalic acid.

The commonest method of fixing the exact concentration of the hydrochloric (or sulphuric) acid consists in titrating the acid against weighed amounts of pure anhydrous sodium carbonate, a process originally employed by Gay-Lussac, and strongly recommended by Lunge, Sutton, and Treadwell. Separate weighed quantities of the pure carbonate are dissolved in 50–100 c.c. of cold distilled water, and each titrated with the acid, using methyl orange as indicator. The concentration of the acid solution is calculated from each result, and the mean of the concordant values adopted as correct. Chemically pure sodium carbonate is obtainable in commerce, and should be free from all but traces of chloride and sulphate; it is dried in a platinum crucible with continual stirring for 20–30 minutes at such a temperature that the crucible bottom is barely red hot, or the crucible, embedded in sand, may be heated at 300° for half an hour. Pure sodium carbonate may also be prepared by heating the bicarbonate at a temperature not exceeding 300° (Lunge, Zeitsch. angew. Chem. 1897, 10, 522). Sulphates and chlorides are removed from the bicarbonate by washing with cold water. (For the preparation of pure sodium bicarbonate, *v.* Reinitzer (Zeitsch. angew. Chem. 1894, 7, 551), and North and Blakey (J. Soc. Chem. Ind. 1905, 24, 396).)

The foregoing method, although extensively used, has been adversely criticised, the chief objection being that it is impossible to dehydrate the carbonate or bicarbonate without losing a little too much carbon dioxide. It is asserted that sodium oxide is present even when the temperature of drying has not exceeded 170°; *v.* Kissing (Zeitsch. angew. Chem. 1890, 3, 262);

Higgins (J. Soc. Chem. Ind. 1900, 19, 958); Sörensen and Andersen (Zeitsch. anal. Chem. 1905, 44, 156); North and Blakey (J. Soc. Chem. Ind. 1905, 24, 396); Sebelin (Chem. Zeit. 1905, 29, 638); but *cf.* Seyda (Chem. Zentr. 1899, (i.) 1164); Lunge (Zeitsch. anal. Chem. 1904, 17, 231; 1905, 18, 1520).

A satisfactory method of checking the values obtained by the carbonate method depends on the fact that sodium oxalate, when heated, is converted into sodium carbonate. As this oxalate can be prepared in a high degree of purity, the residue of carbonate theoretically obtainable from a known weight of oxalate can be calculated, and the presence of any sodium oxide is immaterial providing that all calculations are based on the original weight of sodium oxalate.

The weighed oxalate is carefully heated in a platinum crucible until all the separated carbon has been burnt off and the residual carbonate begins to fuse; the cooled residue is dissolved in water and titrated as already described; *v.* Sörensen (Zeitsch. anal. Chem. 1897, 36, 639; 1903, 42, 333, 512; 1905, 44, 156), Lunge (Zeitsch. angew. Chem. 1905, 18, 1520); and ANALYSIS, (Volumetric section, standardisation of permanganate).

From time to time many other standards have been proposed, and among others the following:—

Potassium tetroxalate; succinic acid (Phelps and Hubbard, Zeitsch. anorg. Chem. 1907, 53, 361; Phelps and Weed, *ibid.* 1908, 59, 114, 120); *borax* (Rimbach, Ber. 1893, 26, 171); *potassium hydrogen tartrate* (Borntrager, Zeitsch. anal. Chem. 1892, 31, 43); *potassium dichromate* (Richter, Zeitsch. anal. Chem. 1882, 21, 205); *potassium iodate* (Fessel, Zeitsch. anal. Chem. 1899, 38, 449); *potassium biiodate* (Meineke, Chem. Zeit. 1895, 19, 2); *sodium* (Hartley, Chem. Soc. Trans. 1873, 26, 123; Neitzel, Zeitsch. anal. Chem. 1893, 32, 422; *cf.* Hopkins, J. Amer. Chem. Soc. 1901, 23, 727); and *sulphuric acid*, prepared by electrolysing copper sulphate solution (Hart and Croasdale, Chem. News, 1891, 63, 93; Kohn, J. Soc. Chem. Ind. 1900, 19, 962).

Hydrochloric acid. In preparing a normal solution advantage may be taken of the fact that an aqueous solution of hydrogen chloride which boils at a constant temperature has a practically constant composition. A quantity of ordinary concentrated acid is distilled from a capacious retort until one-third has passed over. The residual liquid will contain 20·2 p.c. of hydrogen chloride, and 165 c.c. when diluted to 1 litre will form an almost exactly normal solution; it should be standardised by one of the following processes.

The strong acid is diluted until its specific gravity is approximately 1·1, and distilled; after three-fourths of liquid have passed over, the remaining distillate is collected apart, and the barometric height observed. The final quarter of the distillate is of perfectly definite composition, and the following table gives the actual content of hydrogen chloride for a definite barometric height, together with the weight of distillate which contains one gram-equivalent of hydrogen chloride, *i.e.* which yields a normal solution when diluted to 1 litre:—

Barometer	%HCl	Grams of mixture containing 1 mol. HCl
770	20·218	180·390
760	20·242	180·170
750	20·266	179·960
740	20·290	179·745
730	20·314	179·530

These results were calculated from the observed weights of liquid, without reduction to vacuum standard; the compositions were determined gravimetrically by precipitation as silver chloride (Hulett and Bonner, J. Amer. Chem. Soc. 1909, 31, 390).

The simplest method of preparing a large quantity of nearly normal hydrochloric acid is to find the approximate composition of the ordinary concentrated acid by taking its specific gravity with a hydrometer and referring to a suitable table; the requisite quantity of the acid is then measured out and appropriately diluted with distilled water.

To standardise the solution, it is titrated against successive weighed quantities of pure sodium carbonate (or sodium oxalate), as described above. Each separate amount of carbonate should weigh from 2·0 to 2·5 grams in order to ensure a burette reading of 40 to 50 c.c. It is best to use methyl orange for indicator, since the titrations can be rapidly and accurately carried out in the cold; if litmus is used, the titration must be made in boiling solution. In the latter case, it is quicker to add a measured excess of acid to the carbonate, and titrate back with sodium hydroxide the value of which is known in terms of the acid; but the titration must nevertheless be done in boiling solution. The calculation is very simple: if x grams of sodium carbonate require y c.c. of hydrochloric acid, then 1 c.c. acid $= x/y$ grams of sodium carbonate. Now, 1 c.c. N-acid $=0{\cdot}05300$ grams sodium carbonate, and hence

$$\text{concentration of acid} = \frac{x}{0{\cdot}053y} \text{ times normal}$$

$=z$ times normal, say. As a rule, this is a very convenient method of expressing the result; *e.g.* if the acid is used to estimate an alkali of equivalent e, then 1 c.c. acid $= \frac{e}{1000} \times z$ grams of alkali. If necessary, the acid solution may be diluted with distilled water so that the ratio final volume ÷ initial volume $= z$; it will then be exactly normal. A simple arithmetical calculation is required, and if this process is contemplated, care should be taken initially to ensure that z shall be slightly greater than unity.

Hydrochloric acid is most accurately standardised gravimetrically by precipitating chlorine with excess of silver nitrate and weighing the silver chloride in a Gooch crucible. The solution may be titrated against pure silver according to the Mint process for assaying this metal. The method may be modified by adding the silver solution in very slight excess, this excess being determined in the filtrate with N/10-thiocyanate (Thorpe's Quantitative Analysis; Dittmar's Quantitative Analysis; Knorr, J. Amer. Chem. Soc. 1897, 19, 814; Hopkins, *ibid.* 1901, 23, 727). These methods are trustworthy only when the hydrochloric acid is free from chlorides.

The following method depending on the loss of weight on converting silver nitrate into chloride is due to Andrews (J. Amer. Chem. Soc.

1914, 36, 2089). Two similar silica dishes are provided with watch-glass covers, and one of them with a stirring-rod, short enough to lie under the cover. Into this dish about 2 grams silver nitrate are put, and both dishes are placed in an oven at 160°, the temperature being subsequently raised to 244°. After cooling in a desiccator, both dishes are weighed. Fifty c.c. of $\frac{N}{5}$ hydrochloric acid to be standardised are run into each dish, the contents of which are then evaporated on the water-bath, and finally dried at 240°. The normality of the solution is given by the expression:

$$N=\frac{W-W_1+w_1-w}{0{\cdot}02656V}$$

in which V = volume of acid delivered by the 50 c.c. pipette; W = weight in air of silver nitrate and dish, W_1 = weight of dish with mixed chloride and nitrate, w = weight of control-dish before, and w_1 its weight after experiment (Analyst, 1815, 24).

A simple and accurate process of standardisation consists in immersing weighed pieces of Iceland spar in a measured volume of the acid, and noting the loss in weight of the spar after the acid is neutralised (Masson, Chem. News, 1900, 81, 73; Green, *ibid.* 1903, 87, 5; *cf.* Thiele and Richter, Zeitsch. angew. Chem. 1900, 13, 486).

Small quantities of standard hydrochloric acid may be prepared by absorbing dry hydrogen chloride in a weighed quantity of water and ascertaining the increase in weight (Moody, Chem. Soc. Trans. 1898, 73, 658; Higgins, J. Soc. Chem. Ind. 1900, 19, 958; Acree and Brunel, Amer. Chem. J. 1906, 36, 117).

Sulphuric acid. An approximately normal solution is obtained by diluting to 1 litre 28 c.c. of pure concentrated sulphuric acid (sp.gr. 1·84). The solution may be standardised with pure sodium carbonate or oxalate (*v.* HYDROCHLORIC ACID), or a measured quantity treated with a slight excess of ammonia, evaporated to dryness, and the residual ammonium sulphate heated at 120° and weighed. This method gives trustworthy results only when pure redistilled acid is employed in preparing the solution (Weinig, Zeitsch. angew. Chem. 1892, 5, 204; Shiver, J. Amer. Chem. Soc. 1895, 17, 351; Hopkins, *ibid.* 1901, 23, 727; Marboutin and Pécoul, Bull. Soc. chim. 1897, 17, 880).

A measured volume of the acid is added to a weighed excess of sodium carbonate in a platinum dish, the solution evaporated, the residue dried at 300° and weighed. The change in weight due to the transformation of sodium carbonate into sulphate indicates the amount of acid present in the solution. This method is much preferable to precipitating and weighing the acid as barium sulphate (Thorpe, Quantitative Analysis, 1873. (*Cf.* Richardson, J. Soc. Chem. Ind. 1907, 26, 78.)

Sulphuric acid solutions of definite concentration may be prepared by specific gravity measurements (Pickering, Chem. Soc. Trans. 1890, 57, 64). A quantity of the purest acid is diluted with half its volume of water, and the specific gravity of the mixture accurately determined at 15° or 18° in a Sprengel pyknometer. The percentage of sulphuric acid in the solution is then obtained by reference to tables giving the values for 15°/15° or 18°/18° (*v.* Sutton's Volumetric Analysis, 9th ed., or J. Soc. Chem. Ind. 1899, 18, 4). The table given in J. Soc. Chem. Ind. 1902, 21, 1511, may be employed when the specific gravity (15°/15°) has been calculated without introducing any vacuum corrections, which must be allowed for if the other tables are employed. Between the limits of 66 p.c. and 81 p.c. the following formulæ reproduce the values in the tables with an error not exceeding 0·04 p.c.:—

$$P=86\,S_{15}-69{\cdot}00$$
$$P=86\,S_{18}-68{\cdot}82$$

where P = percentage of sulphuric acid, and S_{15} and S_{18} = the specific gravities referred to water at 15° and 18° respectively, calculated without allowing for 'air displaced' (Marshall, J. Soc. Chem. Ind. 1899, 18, 4). The diluted acid may be kept in a stoppered bottle without change, and by weighing out the appropriate amount and diluting to a litre, a normal solution of sulphuric acid can be rapidly prepared.

Oxalic acid. A normal solution is prepared by dissolving 63·02 grams of the recrystallised hydrated acid $H_2C_2O_4+2H_2O$ in water and diluting to 1000 c.c. As the crystallised acid is somewhat efflorescent, especially on slightly warming, it may contain less than two molecular proportions of water. The solution may be checked against a standard alkali, using phenolphthaleïn as indicator, or against an accurately standardised permanganate solution (*cf.* Treadwell-Hall, Analytical Chemistry, vol. 2).

Oxalic acid solutions do not keep very well. A small quantity of metallic mercury added to the solution tends to stabilise it.

Sodium hydroxide. To prepare a normal solution, clear transparent lumps of the best white commercial caustic soda are selected, any opaque portions of their surface scraped off, and 50 grams of the substance weighed out for each litre of solution. The cooled solution is standardised against the standard hydrochloric acid, using methyl orange as indicator, and taking 50 c.c. for each titration.

For the preparation of sodium hydroxide solutions free from carbonate, *v.* Küster (Zeitsch. anorg. Chem. 1897, 13, 134; 1904, 41, 472, and Bousfield and Lowry, Phil. Trans. 1905, 204, 253).

Potassium hydroxide *cf.* SODIUM HYDROXIDE.

Barium hydroxide. An approximately N/10-solution is best prepared from the crystalline hydroxide $Ba(OH)_2, 6H_2O$. The powdered substance is shaken with distilled water, the solution allowed to settle, the clear liquid siphoned off and diluted with an equal volume of recently boiled-out water. The solution must be kept permanently in contact with that portion already in the burette, and guard tubes are required to prevent access of carbon dioxide. The solution is standardised against succinic acid, phenolphthaleïn being used as indicator; or a measured volume may be evaporated to dryness with a slight excess of pure sulphuric acid, the residual barium sulphate being gently heated and weighed.

The chief use of this solution is in titrating organic acids, using phenolphthaleïn as indicator. For this purpose carbon dioxide must be excluded, and barium hydroxide is consequently the most convenient alkali to employ.

Ammonia. This solution is not often employed; an approximately semi-normal solution, readily obtained by diluting 28 c.c. of concentrated ammonia solution to 1 litre, is titrated against hydrochloric acid in the cold, using methyl orange as indicator; phenolphthaleïn cannot be employed.

Schultze has determined the rates of expansion of normal solutions of acids, and alkalis and other solutions employed in volumetric analysis (Zeitsch. anal. Chem. 1882, 21, 170). The following are the results for average temperatures:—

—	Oxalic acid	Hydrochloric acid	Nitric acid
0°	10000	10000	10000
10°	10010	10010	10018
15°	10019	10019	10031
20°	10031	10030	10045
25°	10046	10043	10061

—	Sulphuric acid	Potassium hydroxide	Sodium hydroxide
0°	10000	10000	10000
10°	10017	10019	10021
15°	10029	10031	10034
20°	10044	10046	10048
25°	10060	10062	10065

TYPICAL ACIDIMETRIC AND ALKALIMETRIC ESTIMATIONS.

Determination of total alkali. A weighed quantity of the substance (10 grams) is dissolved in water, filtered if necessary, and diluted to 500 c.c.; 50 c.c. are withdrawn, mixed with a measured excess (25 c.c.) of normal acid, boiled gently for ten minutes to expel carbon dioxide, and the excess of acid determined with standard alkali. The volume of standard acid *minus* the excess of acid gives the volume of acid required to neutralise the total alkali, *i.e.* the alkali present as hydroxide, carbonate, sulphide, sulphite, thiosulphate, aluminate, and silicate. If methyl orange is used as indicator, boiling is unnecessary, and the alkaline solution is titrated directly with standard acid. If direct titration with litmus as indicator is preferred, the solution must be continuously boiled during the titration.

Alkaline hydroxide in presence of carbonate. 100 c.c. of the above solution are heated, mixed with excess of barium chloride, allowed to cool, diluted to 250 c.c. and well shaken. When the precipitate has settled, 50 c.c. of the clear liquid are withdrawn and titrated with standard acid. The quantity of acid used × 25 gives the volume equivalent to the hydroxide in the weight of substance originally taken. The reaction which takes place is expressed by the equation

$$x\mathrm{M_2CO_3} + y\mathrm{MOH} + (x + \frac{y}{2})\mathrm{BaCl_2}$$

$$= x\mathrm{BaCO_3} + \frac{y}{2}\mathrm{BaH_2O_2} + (2x + y)\mathrm{MCl}.$$

The barium carbonate is precipitated and a quantity of barium hydroxide equivalent to the alkaline hydroxide remains in solution. The solution cannot be filtered, since the barium hydroxide would absorb carbon dioxide from the air with formation of the insoluble carbonate.

In order to avoid error due to the presence of the precipitate, and to economise time, Watson Smith (J. Soc. Chem. Ind. 1882, 1, 85) prefers to add just sufficient barium chloride to precipitate the carbonate without affecting the hydroxide. No barium remains in solution, and even if carbon dioxide is absorbed the alkaline carbonate formed remains in solution. The barium chloride is added gradually to the hot solution until precipitation is just complete, and the liquid is filtered into a 250 c.c. flask and an aliquot portion titrated. It is preferable for the liquid containing the precipitate to be diluted to 250 c.c., the precipitate allowed to settle, and 50 c.c. of the supernatant liquid withdrawn. (For various details and precautions, *v.* Sörensen and Andersen, Zeitsch. anal. Chem. 1908, 47, 279.)

Carbonate in presence of hydroxide. The solution is coloured a very faint yellow with phenacetolin, and standard acid is added until the yellow colour changes to a rose tint. The volume of acid required gives the amount of hydroxide present. A further quantity of acid is now added, and the red colour increases in intensity, but eventually changes to yellowish-red, and finally to golden-yellow. At this point a second reading is taken, and the difference between this and the first reading gives the volume of acid corresponding with the carbonate present (Lunge, J. Soc. Chem. Ind. 1882, 1, 56). This method is not available for the estimation of small quantities of hydroxide in presence of large quantities of carbonate (Thomson).

The following method, due to Warder, gives fairly satisfactory results: To the cold dilute solution phenolphthaleïn is added and standard hydrochloric acid run in slowly, the burette tip being immersed in the liquid, till decolourisation takes place. This occurs when all the hydroxide and *half* the carbonate have been neutralised. Methyl orange is then added and the solution titrated again till an acid reaction is indicated. If this second titration requires y c.c. and the first one x c.c., then the carbonate is equivalent to $2y$ c.c. and the hydroxide to $x - y$ c.c. (Küster, Zeitsch. anorg. Chem. 1896, 13, 127; Lunge, Zeitsch. angew. Chem. 1897, 10, 41; North and Lee, J. Soc. Chem. Ind. 1902, 21, 322; *cf.* Cameron, Amer. Chem. J. 1900, 23, 471).

In order to estimate the proportion of carbonate in quick-lime or slaked lime, the purpose for which phenacetolin was originally recommended by Degener, 100–150 grams of the lime are made into a cream with water and diluted to 500 c.c. After vigorous agitation 100 c.c. are withdrawn and diluted to 1000 c.c., and 25 c.c. of this liquid are taken, mixed with phenacetolin, and standard acid added until a pale-rose tint is obtained. In order to estimate both hydroxide and carbonate, the substance is dissolved in standard acid and the excess of acid determined by reverse titration in the usual way (Lunge, *l.c.*).

Acid carbonate in presence of normal carbonate. The *cold and dilute* solution of normal carbonate and acid carbonate is mixed with phenolphthaleïn, and standard acid added, the burette tip dipping into the liquid to prevent escape of carbon dioxide, until the liquid becomes colourless. At this point, which correponds with the complete conversion of the normal carbonate into acid carbonate, the volume of acid added is read off. The liquid is then boiled and acid is added gradually until the solution remains colourless even after long boiling, and the volume of acid is again read off. If x represents the first reading and y the econd reading, then $2x$ = the normal carbonate, and $y-2x$ = the acid carbonate (Warder, Chem. News, 1881, 43, 228).

Lunge (J. Soc. Chem. Ind. 1882, 1, 57) proposes a different method based on the reaction:

$$xM_2CO_3 + yMHCO_3 + zNH_3 + (x+y)BaCl_2$$
$$=(2x+y)MCl + yNH_4Cl + (x+y)BaCO_3 + (z-y)NH_3.$$

The solution to be tested is mixed with a meaured excess of standard (half-normal) ammonia, excess of barium chloride added, and the liquid diluted with recently boiled water to a definite volume. When the precipitate has settled, an aliquot portion of the clear liquid is withdrawn and titrated with standard acid in order to ascertain the excess of ammonia. The difference between the volume of ammonia added and that remaining after precipitation gives the volume corresponding with the quantity of acid carbonate n the liquid analysed.

By adding a definite excess of pure sodium hydroxide free from carbon dioxide, a mixture of normal carbonate and hydroxide is obtained which may be analysed as described above.

Ammonia. In order to determine the quanity of free ammonia in a solution of the gas, an accurately measured quantity (10 c.c.) of the iquid is transferred to a light tared flask, and weighed. This gives at once the weight taken or analysis and the sp.gr. The liquid is then titrated with standard acid in the usual way, using litmus, lacmoid, or methyl orange as ndicator.

Ammonia in combination is determined by boiling the substance with sodium hydroxide, eading the ammonia into a measured excess of tandard acid, and determining the residual acid with standard alkali. The substance is weighed nto a flask fitted with a cork, through one hole n which passes a pipette containing a strong solution of sodium hydroxide, whilst through another passes a tube leading to a flask or bulb U-tube containing a known volume of standard acid. The flask or U-tube is fitted with a cork which carries a calcium chloride tube containing beads moistened with some of the acid in order o ensure complete absorption of the ammonia. After addition of the sodium hydroxide solution the liquid is gently boiled for half an hour, and he residual acid determined. From the volume of acid which has combined with the ammonia the quantity of the latter is readily calculated. The sodium hydroxide may be replaced by milk of lime, and the most effectual method of removing the ammonia is to distil the mixture n steam. The use of magnesia in place of sodium hydroxide is not advantageous (Kober, J. Amer. Chem. Soc. 1908, 30, 1279). (For a different method of distilling off the ammonia, v. Kober (J. Amer. Chem. Soc. 1908, 30, 1131). *See* also Ronchèse (J. Pharm. Chim. 1907, 25, 11) and Wilkie (J. Soc. Chem. Ind. 1910, 29, 6) or a method of estimation entirely different in principle from the foregoing.)

Hydrochloric, Hydrobromic, Hydriodic, Sulphuric, and **Nitric acids** are readily estimated by direct titration with standard alkali, using methyl orange as indicator.

Oxalic, Tartaric, Citric, Acetic, and **Lactic acids** can likewise be titrated accurately with standard alkali if phenolphthaleïn is used as the indicator (Thomson, *l.c.*). Oxalic acid may also be titrated using litmus as indicator.

Boric acid gives no very definite reaction with the majority of indicators, but it is quite neutral to methyl orange, and hence the quantity of alkali in akaline borates can be accurately estimated by direct titration with standard acid if methyl orange is used as indicator (Thomson).

The titration of boric acid itself becomes possible if the solution contains at least 30 p.c. of its volume of glycerol. The boric acid then behaves towards phenolphthaleïn as a monobasic acid (Thomson, J. Soc. Chem. Ind. 1893, 12, 432; Jorgensen, Zeitsch. angew. Chem. 1897, 10, 5; Hönig and Spitz, *ibid.* 1896, 9, 549; Copaux, Compt. rend. 1898, 127, 756). A similar result is effected by saturating the solution with mannitol. Since phenolphthaleïn is employed, carbon dioxide must not be present in the solutions to be titrated (Jones, Amer. J. Sci. 1898, 7, 147; Stock, Compt. rend. 1900, 130, 516).

Sulphurous acid can be titrated directly if methyl orange, phenolphthaleïn, or aurin is used as indicator (Lunge, Dingl. poly. J. 250, 530). With methyl orange the hydrogen sulphite $MHSO_3$ is the neutral salt, whilst with the other two indicators the normal salt is neutral. This difference can be utilised for the determination of the relative proportions of normal and acid sulphite in the same solution (Blarez, Compt. rend. 1886, 103, 69; Chem. Soc. Abst. 1886, 50, 918). Caustic soda or potash must be used, since ammonia gives inaccurate results.

Phosphoric and **Arsenic acids** are monobasic with methyl orange, and dibasic with phenolphthaleïn (Joly, Compt. rend. 1882, 94, 529; Chem. Soc. Abst. 1882, 42, 692). These acids can be most accurately titrated with barium hydroxide, using phenolphthaleïn as indicator. Towards the close of the reaction, time must be allowed for the gelatinous tribarium phosphate to change into the crystalline dibarium salt (Joly, Compt. rend. 1886, 102, 316; Chem. Soc. Abst 1886, 50, 418). Advantage can be taken of the different basicity with methyl orange and phenolphthaleïn to estimate phosphoric acid in presence of monobasic acids such as hydrochloric acid (Joly, Compt. rend. 1885, 100, 55; Chem. Soc. Abst. 1885, 48, 348).

(For another simple and accurate method, *v.* Segalle, Zeitsch. anal. Chem. 1895, 34, 33.)

Carbonic acid in solution is estimated by adding excess of ammonia and calcium chloride. The liquid is then boiled, and the precipitated calcium carbonate collected, well washed, and dissolved in a measured excess of standard hydrochloric acid, the excess of acid being determined by means of standard alkali. The volume of normal acid actually used multiplied by 0·022 gives the quantity of carbon dioxide.

Insoluble carbonates are weighed into a flask fitted with a cork which carries a bulb and delivery tube. The bulb contains moderately strong hydrochloric acid, which is allowed to drop slowly on the carbonate, and the evolved gas is led into a flask containing strong ammonia solution. This flask is closed with a cork, through which passes the delivery tube, which ends just above the surface of the liquid. The cork also carries an exit tube filled with glass beads moistened with ammonia to arrest the last traces of carbon dioxide. When all the gas has been expelled from the carbonate the ammonia is mixed with calcium chloride, boiled, and the precipitate treated as above; *cf.* Gooch and Phelps (Amer. J. Sci. 1895, 50, 101). With slight modification this process can be adapted to the estimation of carbon dioxide in aërated waters.

For the direct titration of carbon dioxide in solution, *v.* Seyler (Analyst, 1897, 22, 312); Ellms and Beneker (J. Amer. Chem. Soc. 1901, 23, 405); and Forbes and Pratt (J. Amer. Chem. Soc. 1903, 25, 742).

Hydrofluoric acid may be accurately titrated with sodium hydroxide free from carbonate, using phenolphthaleïn as indicator (Winkler, Zeitsch. angew. Chem. 1902, 15, 33; *cf.* Haga and Osaka, Chem. Soc. Trans. 1895, 67, 251; and J. Amer. Chem. Soc. 1896, 18, 415; Monatsh. 1897, 18, 749).

Hydrofluosilicic acid may be titrated with sodium or barium hydroxide in the presence of alcohol (an equal volume is added) using phenolphthaleïn or lacmoid as indicator; the alcohol renders the salt produced insoluble in the solution; *v.* Sahlbom and Hinrichsen (Ber. 1906, 39, 2609); *cf.* Schucht and Moller (Ber. 1906, 39, 3693); and Honig and Szabadka (Chem. Zeit. 1907, 31, 1207).

Combined acids in salts may be estimated with approximate accuracy by adding to a solution of the salt a measured excess of sodium hydroxide or carbonate. The liquid is boiled, allowed to cool, and diluted to a definite volume. When the precipitate has settled, an aliquot portion of the clear liquid is withdrawn, and the excess of alkali determined by titration. From the volume of alkali used the proportion of acid in the salt is calculated. In order to avoid the error due to the presence of the precipitate, the liquid may be filtered before diluting to a definite volume, but methyl orange or cochineal must be used as indicator in order to avoid any error from carbon dioxide absorbed from the atmosphere. Salts of copper, silver, mercury, cobalt, nickel, iron, and chromium are precipitated with sodium hydroxide; salts of calcium, barium, strontium, magnesium, aluminium, zinc, bismuth, and manganese, with sodium carbonate.

Kieffer's method is useful for coloured solutions, or in presence of normal salts with acid reactions (Annalen, 1855, 93, 386). Sixty grams of crystallised cupric sulphate are dissolved in water, mixed with ammonia until the precipitate is almost but not quite dissolved, diluted to about 900 c.c., the solution left for some time, and the clear liquid siphoned off, or filtered through glass-wool, and diluted to 1000 c.c. If any further precipitate forms, it must be siphoned off or collected. If the solution of cuprammonium sulphate thus obtained is added to an acid liquid, so long as the acid is in excess an ammonium salt and cupric sulphate are formed, but as soon as the free acid is neutralised, the ammonia in a fresh quantity of cuprammonium sulphate reacts on the cupric sulphate already in the liquid and produces a precipitate of a basic salt, the formation of which indicates the point of saturation. The precipitate is most readily seen against a black background. In order to standardise the liquid, 10 c.c. of normal sulphuric acid are placed in a flask or beaker and Kieffer's solution added until a permanent precipitate is produced, and from the volume of solution required, its strength in terms of normal acid is readily calculated. The strength of the solution gradually diminishes, and it must be titrated from time to time. In making an actual determination, the Kieffer's solution is added to the liquid to be tested until a permanent precipitate is formed. The method is not very accurate owing mainly to the fact that the precipitate is not quite insoluble in solutions of ammonium salts, and therefore the end reaction does not take place until the liquid is saturated with the basic salt. The magnitude of the error depends on the concentration of the solution. When the liquids to be titrated contain barium, strontium, &c., the Kieffer's solution must be prepared with cupric nitrate.

ACIDOL. Trade name for betaine hydrochloride.

ACIERAL. An alloy, said to be made by first melting together Al 76, Ni 10, Ag 15, Co 2·5, Cu 3·5, W 0·5, Cd 1·0, Sn 1·5, in an electric furnace and stirring the fused mass into nine times its weight of aluminium, heated in a plumbago crucible lined with magnesia in an ordinary furnace (Fr. Pat. 473412, 1914). The alloy is silver-white, of sp.gr. 2·82, and m.p. 750°. Its tensile strength in castings is stated to be 30,000, in rods and sheets as 28,000–64,000, and heat-treated as 70,000 lbs. per square inch. It may be cast, forged, drawn, rolled, tempered, electroplated, and soldered. It is reported to have been used by the French Government for the manufacture of helmets (Eng. and Min. J. 1917, 103, 736).

ACITRIN. Trade name for the ethyl ester of 2-phenyl-quinoline 4-carboxylic acid. Used on account of its analgesic action in the treatment of sciatica and gout, and as uric acid eliminants.

ACME YELLOW *v.* AZO- COLOURING MATTERS.

ACOCANTHERA SCHIMPERI. The arrow-poisons of East Africa are prepared from the wood of the genus *Acocanthera*, which contains a crystalline glucoside, *acocantherinin* $C_{30}H_{46}O_{12}$, H_2O (Arnaud), $C_{32}H_{50}O_{12}$ (Faust). Crystallises from water and alcohol; insol. in ether or chloroform; sol. neutral and bitter. Strong sulphuric acid gives a red colour eventually becoming green. On boiling with dilute mineral acids is hydrolysed with formation of rhamnose. Is optically inactive, softens at 130° and decomposes at 220°. The pharmacological action of the glucoside resembles that of members of the digitalin group (Fraser and Tillie, Proc. Roy. Soc. 58, 70; Faust, Chem. Zentr. 1902, 2, [19] 1217; *cf.* STROPHANTHUS).

ACOINE. Trade name for *di-p*-anisylmonophenetylguanidine hydrochloride. Used as a local anæsthetic.

ACONITINE AND THE ACONITE ALKALOIDS. The alkaloids of the various species of *Aconitum* which have been examined chemically, fall into sharply differentiated groups. The first, of which aconitine itself is the type, includes a number of highly toxic alkaloids (*the aconitines*), which are diacyl esters of a series of polyhydroxy bases containing four methoxyl groups (*the aconines*). The following 'aconitines' are known :—

Aconitine from *Aconitum Napellus* (Linn.),
*Bikh*aconitine from *Aconitum spicatum* (Stapf.),
*Ind*aconitine from *Aconitum chasmanthum* (Stapf.),
*Jap*aconitine from Japanese aconite roots,
*Pseud*aconitine from *Aconitum deinorrhizum.*

The alkaloids of *A. Vulparia* (=*A. Lycoctonum*) and *A. septentrionale* constitute a second group of toxic alkaloids derived from aconites, while there is a third group which contains non-toxic alkaloids typified by atisine and comprises the following :—

Atisine from *Aconitum heterophyllum* (Wall.),
*Palm*atisine from *Aconitum palmatum* (D. Don.).

Aconitine is the principal alkaloid of *Aconitum Napellus* (Linn.), the common monkshood or wolfsbane (*Coqueluchon*, Fr.; *Eisenhut, Sturmhut*, Ger.), in which it occurs along with its decomposition products, benzaconine and aconine. *Aconiti radix,* B.P., is the full-grown daughter root only. *Aconitum,* U.S.P., is the root containing at least 0·5 p.c. of aconitine. *Aconitina*, B.P., U.S.P., is the alkaloid. Aconitine was isolated by Geiger and Hesse (Annalen, 1833, 7, 276), but first obtained in a crystalline state by Groves (Pharm. J. 1860, [ii.] 8, 121). Wright and Luff assigned to it the formula $C_{33}H_{43}O_{12}N$ (Chem. Soc. Trans. 1877, 31, 143; 1878, 33, 151, 318), and later Dunstan and his collaborators (*ibid.* 1891, 59, 271; 1892, 61, 385) adopted for it the formula $C_{33}H_{45}O_{12}N$, a slight modification of that used by Wright and Luff (*l.c.*). Until now almost all the work on crystallised aconitine had been done on alkaloid prepared from the roots of *Aconitum Napellus* grown in England. In 1894 analyses of the crystallised aconitine of commerce, probably from roots of *Aconitum Napellus* grown in Germany, were made by Freund and Beck, who assigned to the alkaloid the formula $C_{34}H_{47}O_{11}N$ (Ber. 1894, 27, 433), and their results were confirmed by Schulze (Arch. Pharm. 1906, 244, 167), who preferred the formula $C_{34}H_{44}O_{11}N$. This latter formula has been accepted by Dunstan and Henry (Trans. Chem. Soc. 1905, 87, 1650) as representing the composition of the present day aconitine of commerce. The earlier formulæ with less carbon are either due to botanical differences (the English root is now difficult to obtain) or to the escape of methane in the combustions.

Preparation. The finely-powdered root is exhausted with amyl alcohol mixed with three times its volume of wood spirit. From this extract the wood spirit is distilled under reduced pressure, leaving the whole of the alkaloids dissolved in the residue of amyl alcohol from which they are removed by agitation with dilute (1 p.c.) sulphuric acid. This acid aqueous liquid is shaken with ether to remove ether-soluble, non-basic substances, then made alkaline with dilute ammonia and the liberated alkaloids extracted with ether. The aconine remains dissolved in the water, the aconitine with some benzaconine passing into the ether. The ethereal solution is washed with a small quantity of water and evaporated. The residue is converted into hydrobromide by dissolving it in dilute hydrobromic acid, care being taken to avoid excess of acid. The exactly neutral liquid is evaporated to a small volume and allowed to crystallise. The aconitine hydrobromide is recrystallised until of constant melting-point, and then is converted into the alkaloid by the addition of a slight excess of ammonia to its aqueous solution, the alkaloid being extracted by ether in the usual way. The washed ethereal solution is dried by agitation with fused calcium chloride and evaporated. The small crystals, which are deposited as the ether evaporates, may be recrystallised from dry alcohol by the addition of ether.

Properties. Colourless, anhydrous hexagonal prisms, belonging to the rhombic system (Chem. Soc. Trans. 1891, 59, 288; Ber. 1894, 27, 722; Arch. Pharm. 1906, 244, 169). Easily soluble in chloroform or benzene, less readily in absolute alcohol or ether, very slightly soluble in water, almost insoluble in light petroleum. The aqueous solution is alkaline to litmus; m.p. 196°–197°. Dextrorotatory; in alcoholic solution $[\alpha]_D = +12° 32'$. Salts lævorotatory.

Aconitine is a most powerful poison (Cash and Dunstan, Phil. Trans. 1898, 190, 239). Between $\frac{1}{20}$ and $\frac{1}{50}$ of a grain has been recorded as a fatal human dose.

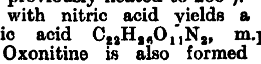
The ordinary salts of aconitine crystallise well. The hydrobromide $B{\cdot}HBr,2\frac{1}{2}H_2O$ is lævorotatory, $[\alpha]_D = -30{\cdot}47°$; m.p. 163° or 206° (anhydrous). The hydriodide, m.p. 226°, is crystalline, and sparingly soluble in water. The aurichloride $B{\cdot}HAuCl_4$ is thrown down as a pale-yellow amorphous precipitate from solutions of the hydrochloride and auric chloride. It crystallises from alcohol with $3H_2O$ and then melts at 135·5°; the anhydrous salt has m.p. 152° (Freund, Ber. 1894, 27, 724).

Reactions. When aconitine is heated at its melting-point it loses 1 mol. of acetic acid and furnishes a new alkaloid *pyraconitine*, and this, on hydrolysis with water or acids, furnishes 1 mol. of benzoic acid and a new base *pyraconine.*

When a salt of aconitine is heated with water, a molecule of acetic acid is split off and the alkaloid *benzaconine*, which also occurs in aconite roots, and has been variously known as *picraconitine*, *isaconitine*, *napelline*, &c., is formed. Benzaconine, in turn, by hydrolysis with alkalis or acids, furnishes 1 mol. of benzoic acid, and the alkaloid *aconine*, which is the final basic product of the hydrolysis. Aconitine is therefore *acetylbenzoylaconine*.

On treatment with acetyl chloride aconitine furnishes a triacetyl derivative (m.p. 207°–208°). When heated with hydriodic acid it yields four mols. of methyl iodide, and must therefore contain four methoxyl groups. It also contains a methyl group linked to nitrogen. On oxidation with acid permanganate aconitine yields acetaldehyde and a neutral crystalline substance *oxonitine* (Carr, Chem. Soc. Trans. 1912, 101, 3241). This substance was also obtained by Brady (Chem. Soc. Trans. 1913, 103, 1821), and is most readily prepared by oxidation with permanganate in acetone solution (Barger and Field, Chem. Soc. Trans. 1915, 107, 231). The formula is most likely $C_{24}H_{29}O_9N$, m.p. 276°–277° (bath previously heated to 260°). Further oxidation with nitric acid yields a nitrosodicarboxylic acid $C_{22}H_{26}O_{11}N_2$, m.p. 205° (Brady). Oxonitine is also formed by the oxidation of japaconitine and deserves further investigation.

It is probable from the foregoing summary of the chief reactions of aconitine that it may be regarded as derived from a parent base $C_{20}H_{31}N$.



$$\left.\begin{matrix}AcO\\BzO\end{matrix}\right>C_{20}H_{21}NMe<\begin{matrix}(OH)_3\\(OMe)_4\end{matrix}$$

Aconitine.

Detection and estimation.—The identification of the alkaloid is best accomplished by the determination of the physical constants of its characteristic derivatives, but where minute quantities only are available the characteristic precipitate given with potassium permanganate (Dunstan and Carr, Pharm. J. 1896, [iv.] 2, 122), and the peculiar tingling sensation produced when even very dilute (1 in 4000) solutions of aconitine are applied to the tip of the tongue may be utilised, but these reactions are equally applicable to the 'aconitines' as a class. Various methods for the estimation of aconitine in aconite roots have been proposed, but, as a rule, these estimate some benzaconine and aconine as well as aconitine, and are useless as methods of determining the medicinal value of the roots, since this depends essentially on the amount of aconitine present. Aconitine itself may be estimated by hydrolysing it and determining the amount of acetic acid formed, but this method cannot be used for the estimation of aconitine in the plant since the latter contains other substances which yield acetic acid (Dunstan and Tickle, Pharm. J. 1896, [iv.] 2, 126).

Benzaconine $C_{32}H_{43}O_{10}N$ has also been called *isaconitine*, *picraconitine*, and *napelline* by various observers. It occurs with aconitine in aconite roots, and may be isolated from the mother liquors from which aconitine hydrobromide has been crystallised, and is also produced by heating an aqueous solution of an aconitine salt in a closed tube.

Properties. Amorphous, dextrorotatory base furnishing crystalline, lævorotatory salts. The hydrobromide crystallises in prisms, m.p. 273° (Schulze, *l.c.*); the hydrochloride occurs in two forms, m.p. 217° and 268° (Freund and Beck, Ber. 1894, 27, 729); the hydriodide has m.p 204°–205°. The aurichloride has m.p. 135°. According to Schulze (*l.c.*) the tetracetyl derivative of benzaconine is identical with triacetylaconitine.

With the removal of the acetyl group from aconitine the characteristic toxicity disappears and benzaconine is not toxic in the ordinary sense. In some respects its physiological action is antagonistic to that of aconitine (Cash and Dunstan, Phil. Trans. 1898, 190, 239).

Aconine $C_{25}H_{39}O_9N$, the ultimate basic product of the hydrolysis of aconitine or benzaconine is amorphous and dextrorotatory, but yields hygroscopic lævorotatory salts. It is readily soluble in water, alcohol, or chloroform, but almost insoluble in ether or light petroleum. The hydrochloride $B{\cdot}HCl,2H_2O$ has m.p. 175°–176°, and the hydrobromide $B{\cdot}HBr,1\frac{1}{2}H_2O$, m.p. 225°. The aurichloride is amorphous. The base furnishes a crystalline tetracetyl derivative, m.p. 231°–232° (Schulze, *l.c.* 1906, 244, 177). On oxidation with permanganate it furnishes acetaldehyde and an amorphous base, but with chromic acid it yields methylamine and two new bases $(OH)_4C_{20}H_{19}O(OMe)_3NMe$ and $C_{19}H_{20}O_4(OMe)_3(NMe){\cdot}CO_2H$, the former an amino alcohol and the latter an amino acid (Schulze, Arch. Pharm. 1908, 246, 281; *cf.* Carr, Proc. Chem. Soc. 1912, 28, 253; Brady, *ibid.* p. 289).

Bikhaconitine $C_{36}H_{51}O_{11}N$. The characteristic alkaloid of *Aconitum spicatum* (Stapf.), the roots of which constitute 'bikh'-aconite of North Western India. It may be extracted from the roots by a slight modification of the process described under aconitine. The alkaloid was isolated and characterised by Dunstan and Andrews (Chem. Soc. Trans. 1905, 87, 1636).

Properties. Separates from ether in button-shaped masses, m.p. 118°–123°, or from alcohol on addition of water in white granules containing $1H_2O$, m.p. 113°–116°. Dextrorotatory ($[\alpha]_D^{20°} = +12{\cdot}21°$ in alcohol). The salts are lævorotatory. The hydrochloride $B{\cdot}HCl,5H_2O$, m.p. 159°–161° (anhydrous), crystallises and has $[\alpha]_D -8{\cdot}86°$ (in water); the hydrobromide $B{\cdot}HBr,5H_2O$, m.p. 173°–175° (anhydrous) is crystalline and has $[\alpha]_D -12{\cdot}42°$; the hydriodide $B{\cdot}HI,2\frac{1}{2}H_2O$, m.p. 193°–194° (anhydrous), crystallises in needles, and is sparingly soluble in water; the aurichloride $B{\cdot}HAuCl_4$ crystallises in canary-yellow needles, m.p. 232°–233°. Like all the 'aconitines' bikhaconitine is highly toxic.

Reactions. Bikhaconitine contains six methoxyl groups. When heated at 180° it loses 1 mol. of acetic acid and forms pyrobikhaconitine (amorphous, giving amorphous salts). It undergoes hydrolysis in two stages, thus—

i. $\underset{\text{Bikhaconitine.}}{C_{36}H_{51}O_{11}N} + H_2O = \underset{\text{Veratroylbikhaconine.}}{C_{34}H_{49}O_{10}N} + \underset{\text{Acetic acid.}}{C_2H_4O_2}$

ii. $\underset{\text{Veratroylbikhaconine.}}{C_{34}H_{49}O_{10}N} + H_2O = \underset{\text{Bikhaconine.}}{C_{25}H_{41}O_7N} + \underset{\text{Veratric acid.}}{C_9H_{10}O_4}$

Bikhaconitine, therefore, resembles pseudaconitine (*see* p. 634) in furnishing veratric acid in the second stage of its hydrolysis. The alkaloid is, therefore, acetylveratroylbikhaconine, and may be represented thus—

$$[MeO]_4C_{21}H_{27}ON<\begin{matrix}OAc\\OVe\end{matrix}$$

Veratroylbikhaconine $C_{34}H_{49}O_{10}N$, the first basic hydrolytic product of bikhaconitine, is amorphous and dextrorotatory ($[\alpha]_D = +29{\cdot}9°$ in alcohol). The hydrochloride and hydrobromide are amorphous, but the hydriodide crystallises in rosettes of needles, m.p. 189°–190°. The nitrate forms rosettes of hexagonal prisms, m.p. 175°–178°. The aurichloride forms orange-yellow rosettes of prismatic crystals, m.p. 145°–148° (anhydrous).

Bikhaconine $C_{25}H_{41}O_7N$, the final basic product of the hydrolysis of bikhaconitine or veratroylbikhaconine. It is dextrorotatory and amorphous, but unlike the 'aconines' as a class, furnishes well-defined crystalline salts. The hydrochloride occurs in rosettes of crystals, m.p. 125°–130°, the hydrobromide in tetragonal prisms, m.p. 145°–150°, and the aurichloride

$$B{\cdot}HAuCl_4,3H_2O$$

in glistening rhombic plates, m.p. 129°–132° (hydrated), or 187°–188° (anhydrous).

Indaconitine $C_{34}H_{47}O_{10}N$ is the characteristic alkaloid of *Aconitum chasmanthum* (Stapf.), a species indigenous to India, where it is known as 'Mohri.' It may be extracted from the roots by the process described under aconitine. The alkaloid was isolated and characterised by Dunstan and Andrews (Chem. Soc. Trans. 1905, 87. 1620).

Properties. Indaconitine crystallises in several characteristic forms, but can be obtained in crystals, which are almost identical in form with those of aconitine (*see* above). It has m.p. 202°–203°, and is dextrorotatory $[\alpha]_D = +18° 17'$. The salts crystallise well and are lævorotatory. The hydrochloride $B{\cdot}HCl,3H_2O$, m.p. 166°–171° (anhydrous), $[\alpha]_D = -15° 50'$, forms rosettes of silky needles; the hydrobromide, m.p. 183°–187° (anhydrous), $[\alpha]_D = -17° 16'$, crystallises from water in large hexagonal prisms; the aurichloride $B{\cdot}HAuCl_4,CHCl_3$, m.p. 147°–152°, forms rosettes of needles from chloroform by addition of ether.

Indaconitine gives a characteristic crystalline precipitate with potassium permanganate, the crystals being smaller and less stable than those given by aconitine. Like aconitine, indaconitine is highly toxic (Cash and Dunstan, Proc. Roy. Soc. 1905, B, 76, 468).

Reactions.—Indaconitine contains four methoxyl groups. On hydrolysis it behaves in a manner analogous to aconitine, yielding in the first stage acetic acid and indbenzaconine, the latter, on further hydrolysis, furnishing benzoic acid and pseudaconine. The latter is also the final basic hydrolytic product of pseudaconitine (p. 634), so that pseudaconitine differs only from indaconitine in containing a veratroyl group in place of a benzoyl group. Indaconitine is therefore acetylbenzoylpseudaconine, and may be represented thus—

$$[MeO]_4C_{21}H_{27}O_2N{<}^{OAc}_{OBz}$$

Indbenzaconine (Benzoylpseudaconine)

$$C_{32}H_{45}O_9N$$

the first basic product of the hydrolysis of indaconitine is amorphous and dextrorotatory, $[\alpha]_D = +33° 35'$, but furnishes well crystallised, lævorotatory salts. The hydrobromide

$$B{\cdot}HBr,2H_2O,$$

m.p. 247° (anhydrous) forms rosettes, the hydrochloride $B{\cdot}HCl$, m.p. 242°–244°, octahedra, and the aurichloride, m.p. 180°–182°, orange rosettes. The aurichloro derivative, m.p. 234°–235°, forms minute colourless crystals. On hydrolysis with alkalis indbenzaconine furnishes benzoic acid and pseudaconine (*see* p. 634). As is the case with aconitine the removal of the acetyl group virtually abolishes the toxicity of indaconitine and indbenzaconine is scarcely poisonous in the ordinary sense (Cash and Dunstan, *l.c.*).

Pyroindaconitine $C_{32}H_{42}O_8N$ exists in two forms. The α- form is produced when the free base, indaconitine, is heated at its melting-point. It is amorphous, but furnishes a crystalline hydrobromide $B{\cdot}HBr$, m.p. 194°–198°, which, like the alkaloid itself, is dextrorotatory. The aurichloride is amorphous. When indaconitine hydrochloride is heated at its melting-point it furnishes β-pyroindaconitine, which is also amorphous, but yields a crystalline hydrobromide, m.p. 248°–250°.

Japaconitine $C_{34}H_{49}O_{11}N$ is the characteristic alkaloid of Japanese aconite roots of commerce. It may be prepared from this source by the method described under aconitine. According to Makoshi the roots of true *Aconitum Fischeri* (Reichb.) contain jesaconitine (*see* below), whilst japaconitine is furnished by the roots of a variety grown in Hondo (Arch. Pharm. 1909, 247, 270), which Holmes regards as *A. uncinatum*, var. *japonicum*. Japaconitine has been frequently investigated, and up to 1900 the balance of evidence was in favour of the view that it was identical with aconitine (Mandelin, Arch. Pharm. 1885, 223, 97, 129, 161; Lübbe, Inaug. Diss. Dorp. 1891; and Freund and Beck, Ber. 1894, 27, 720. The non-identity of the two alkaloids had already been asserted by Wright and Luff (Chem. Soc. Trans. 1879, 35, 387), and was finally proved by Dunstan and Read (*ibid.* 1900, 77, 45). Their conclusions have been confirmed by Makoshi (*l.c.*).

Properties. Forms rosettes of prismatic needles, m.p. 204·2°, and is crystallographically distinct from aconitine and pseudaconitine. Dextrorotatory ($[\alpha]_D^{18{\cdot}5} = +23{\cdot}6°$ in alcohol), but furnishes lævorotatory salts. The hydrochloride $B{\cdot}HCl,3H_2O$, m.p. 149°–150°, $[\alpha]_D = -23{\cdot}8°$ in water, crystallises from alcohol and ether in rosettes of hexagonal plates; the hydrobromide $B{\cdot}HBr,4H_2O$, m.p. 172°–173°, crystallises similarly; the aurichloride exists in two modifications, the α- form, m.p. 231° is stable and crystallises in opaque, golden-yellow needles; the β- form, m.p. 154°–160°, is unstable and crystallises in yellow prisms. The physiological action of japaconitine is qualitatively identical with that of aconitine than which it is slightly more toxic (Cash and Dunstan, Proc. Roy. Soc. 1902, 68, 379).

Reactions. Japaconitine, unlike aconitine, reacts with methyl iodide to form a crystalline methiodide, and from this methyljapaconitine $C_{34}H_{48}O_{11}N{\cdot}CH_3$, m.p. 206°, rosettes of colourless needles may be obtained. Japaconitine forms a crystalline triacetyl derivative, m.p. 166°, and contains four methoxyl groups. When heated alone it furnishes 1 mol. acetic acid and 1 mol. pyrojapaconitine (*v. infra*). On hydrolysis it also behaves in a manner analogous to aconitine, giving first 1 mol. each of acetic acid and japbenzaconine. The latter may be further hydrolysed to benzoic acid and japaconine. Japaconitine is therefore acetylbenzoyljapaconine, and may be represented thus (D. a. R.)—

$$\begin{matrix}[HO]_3\\ [OMe]_4\end{matrix}{>}C_{21}H_{\ 5}NH{<}^{OAc}_{OBz}$$

Japbenzaconine $C_{32}H_{46}O_{10}N$, the first basic hydrolytic product of japaconitine, also occurs with this alkaloid in Japanese aconite roots. Unlike the analogous benzaconine, it crystallises, though with difficulty, m.p. 183°. Dextrorotatory ($[\alpha]_D = +40{\cdot}16°$ in alcohol). The salts crystallise well, and are lævorotatory; the hydrochloride $B{\cdot}HCl,H_2O$, m.p. 253°, forms minute rosettes; the aurichloride $B{\cdot}HAuCl_4$ crystallises from alcohol and then melts at 219°. The colourless aurichloro derivative

$$C_{32}H_{46}O_{10}N{\cdot}AuCl_2,$$

m.p. 178°, forms rosettes of needles (D. a. R. *l.c.*).

Japaconine $C_{25}H_{43}O_9N$, the final basic product of the hydrolysis of japaconite or japbenzaconine, is amorphous, and hygroscopic and yields hygroscopic salts, which crystallise with difficulty. Its solutions reduce gold chloride and Fehling's solution. The base is dextrorotatory (D. a. R. *l.c.*).

Pyrojapaconitine $C_{32}H_{45}O_9N$ is formed by heating japaconite at its melting-point, when 1 mol. of acetic acid is evolved. Crystallises in colourless needles, m.p. 167°–168°, is lævorotatory ($[\alpha]_D = -65{\cdot}89°$ in alcohol), and furnishes well-crystallised salts; the aurichloride

$$B{\cdot}HAuCl_4,$$

m.p. 160°–161° (from chloroform), or 188°–189° (from alcohol and ether). On hydrolysis by alkalis the base gives rise to 1 mol. benzoic acid and a new base *pyrojapaconine*, which is amorphous, hygroscopic, and lævorotatory, and furnishes amorphous salts.

According to Schulze and Liebner (Arch. Pharm. 1913, 251, 453; 1916, 254, 567), pyrojapaconitine $C_{32}H_{43}O_9N$, m.p. 171°, and pyrojapaconine are identical with pyraconitine and pyraconine respectively. As aconitine and japaconitine both give oxonitine (*q.v.*) on oxidation, these two alkaloids must be closely related.

Jesaconitine $C_{40}H_{51}O_{12}N$, isolated by Makoshi (Arch. Pharm. 1909, 247, 251) from '[illegible]ushi' roots obtained from a species of aconite, A. *Fischeri* (?), found in the island of Hokkaido or Jeso in Japan. It was not obtained crystalline, but a crystalline triacetyl derivative, m.p. 213°, was prepared. On hydrolysis jesaconitine yielded benzoic acid, anisic acid, and aconine, identical with that obtained from aconitine, so that it is regarded as benzoylanisoylaconine. Jesaconitine is highly toxic (Makoshi, *l.c.*).

Lappaconitine $C_{34}H_{48}O_8N_2$, obtained by Rosendahl (J. Pharm. Chim. 1896, [vi.] 4, 262) from the roots of *Aconitum septentrionale* (Koelle). It crystallises in hexagonal prisms, m.p. 205°, is dextrorotatory, shows a reddish-violet fluorescence in ether, and furnishes crystalline salts. On hydrolysis it yields two bases; one, m.p. 98°, readily soluble, and the other, m.p. 106°, nearly insoluble in ether; at the same time an acid, m.p. 114°, giving a purple colour with ferric chloride, is produced. Lappaconitine is highly toxic. The roots also contain *cynoctonine* $C_{36}H_{55}O_{13}N_2$ (amorphous, bitter, and much less toxic than lappaconitine) and *septentrionaline* $C_{31}H_{48}O_9N_2$, amorphous, bitter, and about equal in toxicity to cynoctonine (*cf.* Orloff, P. Z. f. R. 1907, 36, 213).

Lycaconitine $C_{36}H_{46}O_{10}N_2$, obtained by Dragendorff and Spohn (P. Z. f. R. 1884, 23, 313) and later by Schulze and Bierling (Arch. Pharm. 1913, 251, 8) along with *myoctonine* ($C_{36}H_{42}O_{10}N_2$) and an unnamed base, from the roots of *Aconitum Lycoctonum* (Linn.), is amorphous and dextrorotatory. On hydrolysis with acids it furnishes anthranoyl-lycoctonine (Dragendorff's lycaconine) and succinic acid. On hydrolysis with sodium hydroxide lycoctonine $C_{25}H_{39}O_7N,H_2O$ and lycoctoninic acid $C_{11}H_{13}O_5N$, both crystalline, are formed. Lycoctonine had been found previously by Hübschmann in the roots (J. 1857, 416; 1866, 483; *cf.* Wright and Luff, Pharm. J. 1878–9, [iii.] 8, 169). All the alkaloids described are heart poisons.

Pseudaconitine $C_{36}H_{51}O_{12}N$. The characteristic alkaloid of *Aconitum deinorrhizum*, the roots of which form Nepaul aconite of commerce. It may be extracted from the roots by the process described under aconitine. Pseudaconitine has been frequently examined (Wright and Luff, Chem. Soc. Trans. 1878, 33; 151; Mandelin, Arch. Pharm. 1884, 222, 97, 129, 161), and most recently by Dunstan and Carr (Chem. Soc. Proc. 1895, 154; and Chem. Soc. Trans. 1897, 71, 350).

Properties. Colourless crystals of rhomboidal shape, m.p. 211°–212° (decomp.); $[\alpha]_D = +18\ 30'$ in alcohol. Readily soluble in alcohol, less so in ether, very slightly in water, almost insoluble in light petroleum. The salts are lævorotatory; the hydrobromide $B{\cdot}HBr,2H_2O$, m.p. 191° (anhydrous), and the nitrate $B{\cdot}HNO_3,3H_2O$, m.p. 192°, are crystalline. The hydrochloride is amorphous, but the aurichloride, m.p. 235°–236°, may be crystallised from alcohol. Pseudaconitine exerts a physiological action similar to that of aconitine, but is much more toxic (Cash and Dunstan, Proc. Roy. Soc. 1902, 68, 379).

Reactions. On heating an aqueous solution of a neutral pseudaconitine salt in a closed tube at 135° the alkaloid undergoes hydrolysis, yielding 1 mol. acetic acid and 1 mol. veratroylpseudaconine. The latter is hydrolysed in the cold by sodium hydroxide in alcohol, furnishing 1 mol. of veratric acid and 1 mol. of pseudaconine. When heated at its melting-point pseudaconitine loses 1 mol. acetic acid and furnishes pyropseudaconitine. Pseudaconitine, in view of these reactions, is to be regarded as acetylveratroylpseudaconine

$$[MeO]_4C_{21}H_{27}O_2N{<}{\substack{OVe\\OAc}}$$

No relationship has yet been traced between pseudaconine and aconine (D. a. C.; *cf.* Freund and Niederhofheim, Ber. 1896, 29, 6, 852).

Veratroylpseudaconine $C_{34}H_{49}O_{11}N$. The first basic product of the hydrolysis of pseudaconitine (*see* above) separates in large, irregularly-shaped crystals from ether, m.p. 199°, readily soluble in chloroform or alcohol, nearly insoluble in water or light petroleum, $[\alpha]_D = -38°\ 18'$ in alcohol. The salts crystallise well; the hydrobromide $B{\cdot}HBr,3H_2O$ in prisms; the nitrate $B{\cdot}HNO_3$ in rosettes of rhombic prisms, m.p. 222° and 232°; the aurichloride $B{\cdot}HAuCl_4$ is amorphous (D. a. C.). Veratroylpseudaconine is not toxic (Cash and Dunstan, *l.c.*).

Pseudaconine $C_{25}H_{41}O_8N$, the ultimate basic product of the hydrolysis of pseudaconitine and indaconitine, forms large colourless crystals, m.p. 94°–95°, containing 1 mol. alcohol of crystallisation. Dextrorotatory ($[\alpha]_D = 38° 12'$ in water). The salts are amorphous.

Pyropseudaconitine $C_{34}H_{47}O_{10}N$. Formed by heating pseudaconitine at its melting-point, when 1 mol. acetic acid is evolved; it is amorphous, but yields a hydriodide, crystallising in prisms (D. a. C. *l.c.*).

Atisine $C_{22}H_{31}O_2N$, the characteristic alkaloid of *Aconitum heterophyllum* (Wall.) of Northern India. It was first isolated by Broughton in 1873, and was subsequently examined by Wasowicz (Arch. Pharm. 1879, 214, 193), Wright (Year Book Pharm. 1879, 422), and later by Jowett (Chem. Soc. Trans. 1896, 69, 1518). Atisine is amorphous, readily soluble in water, alcohol, ether, or chloroform, lævorotatory ($[\alpha]_D^{19°} = -19.6°$ in alcohol). It yields crystalline, dextrorotatory salts; $B \cdot HCl$, prisms, m.p. 296° (decomp.); $B \cdot HI$, tablets, m.p. 279°–281° (decomp.); $B_2 \cdot H_2PtCl_6$, crystalline yellow powder, m.p. 229° (decomp.). When heated with water in a closed tube atisine furnishes a *hydrate* $C_{22}H_{33}O_3N$, which is amorphous, and yields amorphous salts. Atisine is non-toxic (Jowett, *l.c.*).

Palmatisine. A colourless, crystalline, non-toxic alkaloid, m p. 285°, found in the roots of *Aconitum palmatum* (D. Don.), a species indigenous to India (Dunstan and Carr).

The fullest account of the aconite alkaloids is by F. H. Carr, in Allen's Commercial Organic Analysis, vol. vi. 1912, pp. 253-287. G. B.

ACORN OIL. Although acorn oil has not yet become a commercial article, the yield of oil obtainable would repay the cost of collecting the acorns, while the oil-cake would furnish a valuable feeding stuff. Baker and Hulton (Analyst, 1917, 42, 351) found that a ton of fresh acorns from *Quercus robur* yielded, on the average, 16·75 cwt. of kernels, corresponding to 8·5 cwt. of dry kernels. Two specimens of peeled acorns had the following composition: Moisture, 1·45 and 3·32; ash, 2·25 and 2·70; oil, 5·0 and 4·7; proteins, 6·65 and 7·75; reducing sugars, 4·9 and 8·18; cane sugar, 1·9 and 0·1; starch, 57·1 and 55·7; pentosans, 3·2; and crude fibre, 2·2 and 2·28 p.c. By hydrolysing the crushed nuts with dilute sulphuric acid, and neutralising and fermenting the filtrate 12·7 p.c. of alcohol (calculated on the fresh acorns) was obtained. Acorns, unlike chestnuts, do not appear to contain a liquefying enzyme.

An oil extracted from the acorns of *Q. agrifolia* was fluorescent and of a deep brown colour. It had sp.gr. 0·9162 at 15°, and iodine value 100·6, and belonged to the same type of oils as arachis oil (Blasdale, J. Amer. Chem. Soc. 1895, 17, 935). C. A. M.

ACORUS CALAMUS (Linn.). The common sweet flag. The root is used by distillers to flavour gin, and the essential oil by snuff-makers for scenting snuff. It contains a glucoside termed *acorin* $C_{36}H_{60}O_6$ (Faust, Bull. Soc. chim. [2] 9, 392; Thoms, Arch. Pharm. [3] 24, 465) (*v.* CALAMUS).

ACRIDINE $C_{13}H_9N$. Crude anthracene contains basic substances, and among them acridine, which can be isolated by extracting it with dilute sulphuric acid and adding potassium dichromate to the acid solution. The precipitated acridine chromate is then recrystallised from water, treated with ammonia, and the base crystallised from hot water (Graebe and Caro, Annalen, 158, 265; Ber. 13, 99).

Acridine has also been obtained synthetically by passing the vapours of orthotolylaniline and of orthoditolylamine through a tube heated to dull redness (G., Ber. 17, 1370); by severally heating formic acid and diphenylamine (Bernthsen and Bender, Ber. 16, 767, 1802), chloroform, diphenylamine and zinc oxide (Fischer and Körner, Ber. 17, 101), and aniline and salicylaldehyde (Möhlau, Ber. 19, 2451) with zinc chloride; by passing *o*-amidodiphenyl methane through a layer of lead oxide heated to dull redness (Fischer and Schütte, Ber. 26, 3085). By distilling tetrahydroacridine with litharge (Borsche, Ber. 41, 2203), and also from acridone (Decker and Dunant, Ber. 39, 2720; Ullmann, Bader and Labhardt, Ber. 40, 4795).

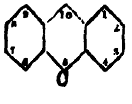
From iodobenzene and *o*-aminobenzaldehyde boiled with nitrobenzene, sodium carbonate and copper powder (Mayer and Stein, Ber. 1917, 50, 1306).

Properties.—Acridine crystallises in small colourless needles, or four-sided rhombic prisms, sublimes at 100°, melts at 111°, boils above 360° without decomposition, and distils with steam. It is sparingly soluble in hot water, but readily soluble in alcohol, ether, or carbon disulphide, yielding solutions showing a blue fluorescence. When inhaled either as dust or vapour it causes violent sneezing, and in solution both it and its salts cause much irritation on the skin. On treatment with nitric acid it yields two nitro-derivatives (m.p. 154° and 214°) and a dinitro-derivative (G. and C.); potassium permanganate oxidises it to 2:3-quinolinedicarboxylic acid $C_9H_5N(CO_2H)_2$, and sodium amalgam reduces it to *hydroacridine* $C_{13}H_{11}N$ (B. and B., Ber. 16, 1971; B., Ber. 16, 2831). The salts are yellow and crystallise well, but are decomposed into their constituents on boiling. Heated with hydrogen and finely divided nickel, it forms 2:3-dimethyl quinoline (Padoa and Fabris, Atti R. Acad. Lincei, 1907, [v.] 16, i. 921). The halogen addition compounds of acridine and its derivatives are formed by the direct action of the halogen on the acridine (Senier and Austin, Chem. Soc. Trans. 1904, 1196); or by the action of a mixture of phosphorus oxychloride and pentachloride on thioacridone (Edinger, Ber. 33, 3370; D. R. P. 120586; Edinger and Arnold, J. pr. Chem. [ii.] 64, 182, 471; D. R. P. 122607); for other methods, compare Dunstan and Stubbs (Ber. 39, 2402; D. R. P. 126795), Graebe and Lagodzinski (Annalen, 276, 48). Alkyl iodomagnesium compounds of acridine have also been obtained (Senier, Austin, and Clarke, Chem. Soc. Trans. 1905, 1469). When exposed to sunlight acridine forms pale-yellow crystals, m.p. 276° (Orndorff and Cameron, Amer. Chem. J. 1895, 17, 558).

3:7-dimethyl-2:8-diaminoacridine[1] or *acri-*

---

[1] The system of numbering the positions in the acridine series adopted in this article and in that on the "Acridine Dyestuffs," is that used in Richter's *Lexikon* viz.:



dine yellow  $NH_2\cdot C_6H_2Me\left\langle {}^{CH}_{N} \right\rangle C_6H_2Me\cdot NH_2$ is obtained by heating under pressure tetraminoditolylmethane with hydrochloric acid and water, the product is then oxidised with ferric chloride or potassium percarbonate $K_2C_2O_6$ or hydrogen peroxide, and the resulting metallic salt decomposed with hydrochloric acid (D. R. P. 52324; Lymn, J. Soc. Chem. Ind. 1897, 16, 406; Ullmann and Marić, Ber. 34, 4308; Haase, Ber. 36, 589). It forms yellow crystals melting above 300°, soluble in alcohol, acetone and pyridin, and forming a yellow solution in sulphuric acid with a green fluorescence. It yields derivatives which form yellow, orange, brownish-, greenish-, and reddish-yellow dyes, and can be used on cotton, leather, wool, and silk. The following are some of the methods of preparation: (1) heating with mineral acids under pressure, when it yields aminohydroxy- and dihydroxydimethyl acridine (D. R. P. 121686; Chem. Zentr. 1901, ii. 78; J. Soc. Chem. Ind. 21, 37); (2) heating with monochloracetic acid and water under pressure (D. R. P. 133788; Chem. Zentr. 1902, ii. 616; D. R. P. 136729; Chem. Zentr. 1902, ii. 1396); (3) heating with formaldehyde and mineral acids under pressure (D. R. P. 135771; Chem. Zentr. 1902, ii. 1233; J. Soc. Chem. Ind. 21, 112, 544, 402); (4) by treatment with formaldehyde and aromatic bases (J. Soc. Chem. Ind. 22, 140; D. R. PP. 131365, 132116; Chem. Zentr. 1902, ii. 172; i. 1288); (5) heating with benzyl chloride in presence of nitrobenzene (J. Soc. Chem. Ind. 21, 701, 1530); (6) treating with aqueous formic acid (*ibid.* 21, 90); (7) heating with glycerol at 150°–180° (D. R. P. 151206): (8) alkylation (Ullmann and Marić, *l.c.*; D. R. P. 79703; J. Soc. Chem. Ind. 19, 1010; 24, 840).

Phenylacridine $C_{19}H_{13}N$ is obtained by heating diphenylamine with benzoic acid and zinc chloride at 260° (Bernthsen, Ber. 16, 3012; 16, 767, 1810), and melts at 181°. The *hydroxyphenylacridines* which form yellow dyes in mineral acids can be obtained similarly by using the corresponding hydroxy acid (Landauer, Bull. Soc. chim. 31, 1083).

Other acridine dyes can be obtained by heating tetraminoditolylmethane or the leuco-compounds of amino-acridines with mineral acid and alcohol under pressure, the shade depending on the quantity and nature of alcohol and of acid used (J. Soc. Chem. Ind. 20, 888; 22, 1126; 23, 932). Also by the interaction of an aromatic or aliphatic *m*-diamine with an aldehyde (*ibid.* 21, 1529; Chem. Zeit. 14, 334; J. Soc. Chem. Ind. 17, 573; 22, 1211). By heating the formyl derivatives of *m*-diamines with ammonia salts or salts of organic bases at 150°–200° (D. R. PP. 149409, 149410). For other methods of preparing acridine derivatives, many of which have dyeing properties, compare: Bizzarri, Gazz. chim. ital. 20, 407; Decker, J. pr. Chem. 153, 161; Mohlau and Fritzsche, Ber. 26, 1034; Volpi, Gazz. chim. ital. 21, ii. 228; J. Soc. Chem. Ind. 19, 732; 21, 338, 701, 911, 1528; Goodwin and Senier, Chem. Soc. Trans. 1902, 285; J. Soc. Chem. Ind. 22, 23, 90; D. R. PP. 133709, 107517; Ullmann, Ber. 36, 1017, 1025; D. R. P. 141297, 141356; Bünzley and Decker, Ber. 37, 575; Fox and Hewitt, Chem. Soc. Trans. 1904, 529; 1905, 1058; Schöpff, Ber. 26, 1121; Ber. 27, 2316; Duval, Compt. rend. 142, 341; Koenigs, Ber. 32, 3599; Ullmann and Maag, Ber. 40, 2515; Austin, Chem. Soc. Trans. 1908, 1760; D. R. PP. 118075, 152662; Pope and Howard, Chem. Soc. Trans. 97, 83.

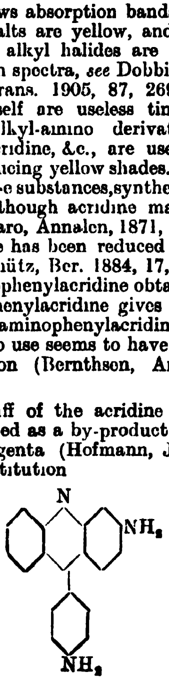
Naphthacridine and its derivatives, which can also be used as dyes, have been prepared (J. Soc. Chem. Ind. 18, 826; 19, 237; Ullmann and Naef, Ber. 33, 905, 912, 2470; J. Soc. Chem. Ind. 20, 37, 573; D. R. P. 126444; Ullmann and Baezner, Ber. 35, 2670; 37, 3077; Ullmann and Felzvadjian, *ibid.* 36, 1027; Ullmann and Farre, *ibid.* 37, 2922; Ullmann and Fitzenham, *ibid.* 38, 3787; Baezner and Gardiol, *ibid.* 39, 2623; Baezner, *ibid.* 2650; Senier and Austin, Chem. Soc. Trans. 1907, 1233, 1240; Senier and Compton, *ibid.* 1907, 1927; Baezner and Gueorgnieff, Ber. 39, 2438).

In the case of many of the naphthacridine derivatives, patents have been taken by Ullmann (D. R. PP. 104667, 104748, 108273, 117472, 119573, 123260, 127586, 128754, 130721, 130943); the further alkylation of some of these, as well as of other acridine compounds has been patented by the A.-G. für Anilin-Fabrikation (D. R. PP. 117065, 129479).

ACRIDINE DYESTUFFS. Acridine, though colourless, shows absorption bands in the ultraviolet. The salts are yellow, and the addition products with alkyl halides are also coloured. (For absorption spectra, *see* Dobbie and Tinkler, Chem. Soc. Trans. 1905, 87, 269.) The salts of acridine itself are useless tinctorially, but amino- and alkyl-amino derivatives of acridine, phenylacridine, &c., are useful dyestuffs, generally producing yellow shades. For the preparation of these substances, synthesis is generally resorted to, although acridine may be nitrated (Graebe and Caro, Annalen, 1871, 158, 275), and *a*-nitro-acridine has been reduced to an amino-acridine (Anschütz, Ber. 1884, 17, 437).

The trinitrophenylacridine obtained by direct nitration of phenylacridine gives a dyestuff on reduction (? triaminophenylacridine), which dyes silk yellow; no use seems to have been made of this observation (Bernthsen, Annalen, 1884, 224, 30).

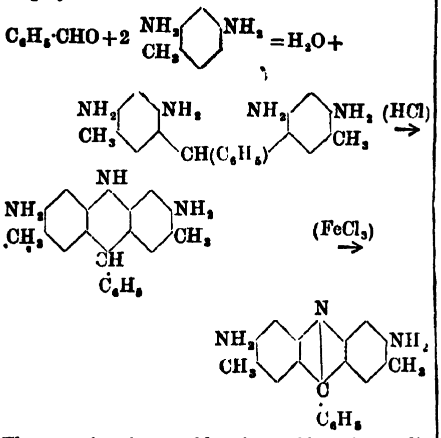
One dyestuff of the acridine series, *chrysaniline*, is formed as a by-product in the manufacture of magenta (Hofmann, Jahresb. 1862, 346). Its constitution



was determined by O. Fischer and G. Körner; probably two molecules of aniline and one of *p*-toluidine condense when oxidised to *opp*-triaminotriphenylmethane, this yielding chrysaniline when further oxidised. This view is supported by the fact that when *opp*-triaminotriphenylmethane is heated with arsenic acid to 150°–180°, chrysaniline is produced (Annalen, 1884, 226, 188).

The processes for preparing amino- derivatives of acridine on a technical scale may be illustrated by the methods of preparing *benzoflavine*, *rheonine*, and *diaminoacridylbenzoic acid*.

Symmetrical diamino-acridines are obtained by the condensation of aldehydes with *m*-diamines, removal of the elements of ammonia from the resulting tetra-amino- compound by heating with hydrochloric acid, and oxidation of the dihydro-acridine thus produced with ferric chloride. In the case of *benzoflavine* benzaldehyde and *m*-toluylene-diamine are employed.



The reaction is capable of considerable modification; thus from formaldehyde and dimethyl-*m*-phenylenediamine, *acridine orange* is produced in an analogous manner. It should be noted, however, that *m*-phenylenediamine gives products which are evidently mixtures, and cannot be purified (R. Meyer and R. Gross, Ber. 1899, 32, 2365).

Diaminoacridine may, however, be obtained from *pp*′-diamino-diphenylmethane (*see* below).

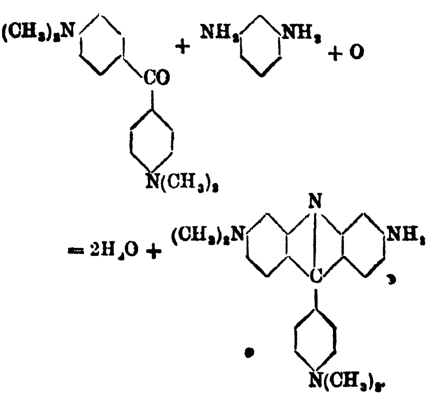
The reaction between an aldehyde and a *m*-diamine may be carried out in two stages; Meyer and Gross (*l.c.* p. 2358), for example, prepared a monobenzylidene derivative of *m*-toluylenediamine and converted this into tetraminoditolyl-phenylmethane by warming its alcoholic solution with the hydrochloride of *m*-toluylenediamine for three hours at 60°–70°. Acridine itself may be obtained in good yield by heating salicylidene-aniline with phosphorus pentoxide to 250° (Blau, Monatsh. 1897, 18, 123).

A closely-related synthesis of acridine derivatives is that of F. Ullmann and E. Naef (Ber. 1900, 33, 905). When dihydroxydinaphthylmethane, the product of the interaction of formaldehyde and *β*-naphthol, is heated with *p*-toluidine hydrochloride, methylhydronapthacridine is produced with elimination of *β*-naphthol.

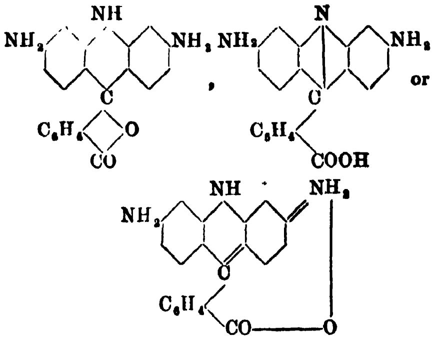
$$CH_2(C_{10}H_6·OH)_2 + NH_2·C_6H_4·CH_3$$

$$= C_{10}H_7·OH + CH_2\begin{cases}C_{10}H_6 \\ C_6H_3(CH_3)\end{cases}NH$$

Rheonine is obtained from *m*-aminophenylauramine or tetramethyldiaminobenzophenone and *m*-phenylenediamine at 200°, using zinc chloride as condensing agent.



Some derivatives of xanthene, when energetically treated with ammonia, suffer replacement of the pyrone oxygen atom by an imino-group. By the prolonged heating of fluorescein with ammonia under pressure, R. Meyer (Ber. 1888, 21, 3376) obtained an acridine derivative, to which one of the three following constitutions is assignable:—



The salts of the tetra-ethyl derivative of this compound form the dyestuff known as *flaveosine*.

Acridine Orange NO (Farbwerk Mühlheim, D. R. P. 59179, 17 Dec. 1889), $C_{13}H_7N[N(CH_3)_2]_2·HCl·ZnCl_2$ was discovered by Bender. It is produced by condensation of dimethyl-*m*-phenylenediamine with formaldehyde and proceeding according to the method referred to above. It forms an orange powder which dissolves in water or alcohol with orange-red colour and greenish fluorescence. The aqueous solution is reddened by hydrochloric acid; sodium hydroxide gives a yellow precipitate. The solution in concentrated sulphuric acid is nearly colourless and has a greenish fluorescence, dilution with water produces successively red and orange colouration. The dye gives orange shades, fairly fast to light and soap, on cotton mordanted with tannin; it is also suitable for printing and leather-dyeing.

The analogous dyestuff from diethyl-*m*-phenylenediamine is described in D. R. P. 67609, the substances derived from monoalkylphenylenediamines in D. R. P. 70935.

Another method of preparing acridine orange is to heat 12 kilos. of aminodimethylaniline either with 10 kilos. of formic acid (sp.gr. 1·2) and 10 kilos. of zinc chloride gradually to 150°–160°, or with 12 kilos. of dehydrated oxalic acid, 10 kilos. of glycerol and 11 kilos. of zinc chloride to 150°. Heating and stirring are continued as long as any darkening of shade can be observed, ammonia is liberated during the reaction, and formic acid having been employed instead of formaldehyde, the product when worked up yields the dyestuff instead of its leuco-compound (D. R. P. 67126).

The formyl derivatives of *m*-diamines may also be used (D. R. PP. 149049, 161699), or the 'methane' carbon atom may be furnished by various formyl derivatives such as formanilide (D. R. P. 149410).

Acridine Orange, R extra (Farbwerk Mühlheim, D. R. P. 68908, 7 Feb. 1890). The dyestuff is the hydrochloride of tetramethyldiamino-5-phenylacridine, and is obtained from dimethyl-*m*-phenylenediamine and benzaldehyde. Its reactions and uses are similar to those of Mark NO.

D. R. P. 68908 also mentions the use of *m*-aminodimethyl-*o*-toluidine. If the latter base be condensed with *p*-nitrobenzaldehyde to a triphenylmethane derivative, the nitro- group reduced and condensation and oxidation effected in the usual way, an acridine dyestuff possessing two tertiary and one primary amino- group is obtained (D. R. P. 70065; compare D. R. P. 71362).

The use of acetaldehyde as a component was claimed by the Ges. f. Chem. Ind. (D. R. P. 143893, 13 March, 1902).

Acridine Yellow (Farbwerk Mühlheim, D. R. P. 52324, 27 June, 1889) was, like the two preceding colours, discovered by Bender. Its constitution is that of a 2 : 8-diamino-3 : 7-dimethylacridine hydrochloride; it is produced from formaldehyde and *m*-toluylenediamine. It forms a yellow powder soluble in water and alcohol with yellow colour and green fluorescence; yellow precipitates are obtained with hydrochloric acid (hydrochloride) and sodium hydroxide (free base). Silk is dyed a greenish yellow with green fluorescence, cotton (tannin mordant) is coloured yellow.

The salts with aliphatic acids, *e.g.* formate and acetate, are more soluble (Farbenfabriken vorm. F. Bayer, D. R. P. 140848, 13 March, 1903). Acridine yellow is converted into an orange yellow, more easily soluble dyestuff by heating with twice its weight of glycerol for 4–6 hours to 170°–180° (Badische Anilin und Soda-Fabrik, D. R. P. 151206, 26 July, 1903).

(For the action of aldehyde on aniline yellow, *see* D. R. P. 144092.) Compounds, probably of acridinium type, are obtained from aniline yellow by the action of monochloracetic acid (M. L. B., D. R. PP. 133788, 136729, 152662) and other dyestuffs by condensation with formaldehyde and *m*-diamines (D. R. PP. 131365, 132116, 135771). Either one or both of the amino- groups in acridine yellow and analogous dyestuffs are replaced by hydroxyl on heating with dilute sulphuric acid to 180°–220° (D. R. P. 121686), and similar compounds may be obtained from formaldehyde by condensation with amino-cresols (D. R. P. 120466).

Dibenzyl aniline yellow is claimed by Bayer & Co. as a useful leather dye (D. R. P. 141297).

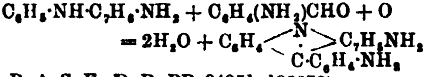
Benzoflavine (several marks) 2 : 8-diamino-3 : 7-dimethyl-5-phenylacridine hydrochloride $C_{13}H_4N(C_6H_5)(NH_2)_2(CH_3)_2,HCl$, was discovered by Rudolph in 1887, and introduced commercially by K. Oehler in 1888 (D. R. PP. 43714, 28 July, 1887; 43720, 45264, 45298). Its preparation has been given above. The dye, which is usually mixed with dextrin, forms an orange powder, difficultly soluble in cold water, more easily in hot. Both aqueous and alcoholic solutions are orange, with strong green fluorescence. Hydrochloric acid gives an orange precipitate, sodium hydroxide liberates the yellowish-white base. The solution in concentrated sulphuric acid is greenish yellow, and shows a very strong green fluorescence. It may be used for dyeing both mordanted and unmordanted cotton. The acetate and lactate are more readily soluble (Bayer, D. R. P. 142453, 19 April, 1902); it behaves like acridine yellow when heated with glycerol.

The **Patent Phosphines** of the Ges. f. Chem. Ind. in Basel are obtained by alkylation of benzoflavine and acridine yellow (D. R. P. 79703; compare D. R. P. 131289).

Coriophosphines (Bayer & Co.). These dyestuffs, which are suitable for leather-dyeing, are probably unsymmetrically alkylated diamino-acridines obtained by condensation of formaldehyde with one molecule of an asymmetrically dialkylated *m*-diamine and one molecule of a non-alkylated or monoalkylated *m*-diamine, with subsequent elimination of ammonia, and oxidation (D. R. P. 133709).

Chrysaniline $C_{19}H_{15}N$ occurs under many other names commercially, *e.g.* Leather yellow, Xanthine, Philadelphia yellow G, Leather brown, Phosphine (several marks), &c. Reference to its occurrence in the manufacture of magenta has already been made. Numerous methods for preparing homologues and analogues of this substance have been patented (D. R. PP. 65985, 78377, 79263, 79585, 79877, 81048, 94951, 102072, 106719, 114261, 116353). The method adopted for this purpose by Meister, Lucius, and Brüning may be mentioned (D. R. P. 65985, 2 April, 1892). *p*-Toluidine and its hydrochloride are heated with ferric chloride (oxygen-carrier), and *m*-nitroaniline gradually added. The resulting dyestuff is the next higher homologue of chrysaniline, containing a methyl- group in position 7.

According to Friedländer (Fortschritte der Theerfarbenfabrikation V. 373), the yields produced by this method are not good, but the reaction between *p*-aminobenzaldehyde or a derivative and phenyl-*m*-phenylene- (or toluylene-) diamine proceeds nearly quantitatively:



$$C_6H_5{\cdot}NH{\cdot}C_7H_6{\cdot}NH_2 + C_6H_4(NH_2)CHO + O$$
$$= 2H_2O + C_6H_4\left<\begin{matrix} N \\ \vdots \\ C{\cdot}C_6H_4{\cdot}NH_2 \end{matrix}\right>C_7H_5NH_2$$

B. A. S. F., D. R. PP. 94951, 102072).

Chrysaniline forms an orange-yellow powder, soluble in water and alcohol with reddish-yellow colour and yellowish-green fluorescence. The solution is unaltered by hydrochloric acid; sodium hydroxide gives a bright yellow precipitate. Chrysaniline is chiefly used in leather dyeing.

Corioflavines (Griesheim-Elektron). These dyestuffs, which occur commercially as marks G, GG, R, and RR, are used in leather-dyeing and calico-printing. They form red or reddish-brown powders, which dissolve in concentrated sulphuric acid with yellow or orange colouration and green fluorescence; these solutions turn red or reddish-brown on dilution.

Flaveosine (Meister, Lucius, and Brüning, D. R. P. 49850, 11 May, 1889) is a tetraethyldiaminoacridylbenzoic acid, which is obtained by heating *m*-acetaminodimethylaniline with phthalic anhydride. It has been examined by Grandmougin and Lang (Ber. 1909, 42, 4014).

The hydrochloride crystallises in shining brownish-yellow needles, the sulphate in prisms exhibiting a cantharides lustre. The base is precipitated from the salts by sodium carbonate, and forms golden-yellow shining leaflets.

Flaveosine dyes silk golden yellow (yellowish-green fluorescence) from a feebly acid bath; wool and cotton (tannin mordant) are coloured reddish yellow. The colours are fast.

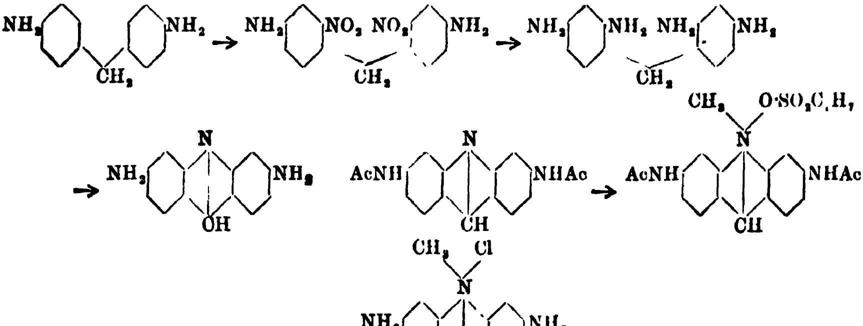
Substances closely related to flaveosine are obtained by the esterification of the product of the interaction of ammonia and fluorescein (B. A. S. F., D. R. PP. 73334, 75933; compare D. R. P. 141356).

Rheonine (Badische Anilin und Soda-Fabrik). This dyestuff was discovered by C. L. Müller (D. R. P. 82989, 16 Dec. 1894). Its method of preparation has already been given. Rheonine forms a brown powder, soluble in water and alcohol, with brownish-yellow colour and green fluorescence. Hydrochloric acid turns the solution brownish-red, caustic soda gives a bright brown precipitate. It is used for obtaining brownish-yellow shades on leather or cotton (tannin). Two marks, N (brighter), and A (darker), are in use.

The use of diaminobenzophenone and of Michler's hydrol for condensation with *m*-diamines have been patented (M. L. B., D. R. P. 89660 and B. A. S. F., D. R. P. 85199 respectively).

Many acridine and naphthacridine dyestuffs containing only one amino- group have been described (D. R. PP. 104667, 107517, 107626, 108273, 118075, 118076, 125697, 130360); and it has also been observed that dyestuffs can be obtained when only one molecular proportion of a *m*-diamine is used with formaldehyde (D. R. P. 136617).

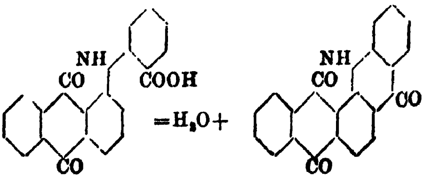
Trypaflavine. The 2 : 8-diamino-10-methylacridonium salts first acquired interest on account of their trypanocidal action (L. Benda, Ber. 1912, 45, 1787). As mentioned above, the condensation of aldehydes with *m*-phenylenediamine gives a mixture of substances. If *pp*′-diamino-diphenylmethane is nitrated in cold sulphuric acid solution, *oo*′-dinitro-*pp*′-diaminodiphenylmethane is produced. The latter compound by reduction with tin and hydrochloric acid and heating the resulting solution for four hours at 135° gives the stannichloride of 2 : 8-diaminoacridine (L. Cassella & Co. D. R. P. 230412). After acetylation of the amino-groups, the nitrogen atom of the pyridine nucleus may be methylated by means of methyl toluene-sulphonate and the acetyl groups subsequently removed by heating with a mixture of equal volumes of water and hydrochloric acid (*e.g.* 1·18). The steps in the formation of trypaflavine may be represented thus:—



The reactions of trypaflavine have been studied by Ehrlich and Benda (Ber. 1913, 46, 1931).

More recently the material has been introduced as an antiseptic under the name of Flavine, since changed to Acriflavine (Browning, Gulbransen, Kennaway, and Thornton, Brit. Med. J. 1917, i. 73). Whilst most antiseptics act more powerfully in water than in blood serum, this behaviour is reversed in the case of flavine. Thus flavine kills *Staphylococcus aurens* at a dilution of 1 : 20,000 in water containing 0·7 p.c. of peptone, but at 1 : 200,000 in blood serum. Moreover, flavine has been found to have a low toxicity.

Acridone $C_6H_4{<}\genfrac{}{}{0pt}{}{NH}{CO}{>}C_6H_4$ and its simpler derivatives have no particular interest tinctorially. Anthraquinone-1 : 2-acridone may, however, be dyed from a vat giving reddish-violet shades on cotton (F. Ullmann and P. Ochsner, Annalen, 1911, 381, 9). The substance is obtained by warming *o*-carboxyphenylamino-1-anthraquinone with sulphuric acid.



The necessary carboxylic acid can be obtained from 1-chloroanthraquinone and anthranilic acid or from 1-aminoanthraquinone and *o*-chlorobenzoic acid. The yields are better by the first method, but those by the latter process may be raised to over 90 p.c., especially if in place of *o*-chlorobenzoic acid, its methyl ester be used (Meister, Lucius, and Brüning, D. R. P. 246327; F. Ullmann and P. Dootson, Ber. 1918, 51, 9). On condensing 1-anilino-anthraquinone-2-carboxylic acid a mixture of *o*-carboxyphenylamino-1-anthraquinone and 1-acridineanthraquinone-2-carboxylic acid is obtained (Farbenf. vorm. Fr. Bayer & Co. D. R. P. 262069).

The shades obtained with anthraquinone-acridone are but little altered when chlorine is introduced in position 4 of the anthraquinone nucleus, but the amino- and *p*-toluidino derivatives dye blue and bluish-green respectively (Meister, Lucius, and Brüning, D. R. P. 243586). Ullmann and Dootson have also prepared derivatives substituted in the phenylene nucleus.

The dicarboxylic acid obtained from anthranilic acid and 1 : 5-dichloroanthraquinone may be condensed by sulphuric acid to anthraquinone-1 : 2, 5 : 6-diacridone, which gives a deep blue vat and dyes bluish-violet shades (Ullmann and Ochsner). J. T. H.

ACRIFLAVINE *v. Trypaflavine,* art. ACRIDINE DYESTUFFS.

ACRODEXTRINS *v.* DEXTRINS.

ACROSE *v.* CARBOHYDRATES.

ACTINIUM Ac 230 or 226 (?). A radioactive element, discovered by Debierne in the precipitate produced by adding ammonia and ammonium sulphide to the filtrate from the hydrogen sulphide precipitate obtained in the course of analysing pitchblende (Debierne, Compt. rend, 129, 593; 130, 906). In fractionating the rare earths thus obtained from pitchblende by means of their double nitrates with magnesium nitrate, actinium accumulates in the more soluble portions, together with neodymium and samarium (Compt. rend. 139, 538). The predominating rare earth in pitchblende is thorium; but actinium also occurs in uranium minerals containing no thorium (Szilárd, Chem. Soc. Abstr. 1909, ii. 663). It is a constant constituent of uranium minerals, and is probably derived from uranium in a branch disintegration series.

Actinium has not been isolated nor have its salts been obtained pure. It is similar in chemical properties to the tervalent rare earth elements of the cerium group, and, of these, resembles lanthanum most closely, being more basic (A. von Welsbach, Sitzungsberichte K. Akad. Wiss. Wien, 1910, 119 [iia] 1; Monatsh. 1910, 31, 1150). It is precipitated by oxalic acid, and by ammonia. In presence of ammonium salts the precipitation of actinium is incomplete, but it is completely precipitated in presence of manganese from basic solutions as a manganate. Actinium preparations are highly radioactive, imparting induced radioactivity to surrounding objects (Curie and Debierne, Compt. rend. 132, 548); and, like radium, they spontaneously give rise to helium (Debierne, Compt. rend. 141, 383); they are not luminescent. Their aqueous solutions slowly evolve hydrogen and oxygen in the proportions necessary to form water. Actinium salts also evolve an *emanation*, an inert gas having a molecular weight of approximately 230 (218 or 222 ?), according to diffusion experiments (Debierne, Compt. rend. 136, 446, 767; 138, 411; Bruhat, Compt. rend. 148, 628; Russ, Phil. Mag. 1909, [vi.] 17, 412; Marsden and Wood, Phil. Mag. 1913, [vi.] 26, 948), and condensing to a liquid at −120° to −150° (Kinoshita, Phil. Mag. 1908, [vi.], 16, 121).

The spontaneous decomposition of actinium gives rise to seven successive products: *radio actinium* (Hahn, Ber. 39, 1605; Phil. Mag. 1907, [vi.] 13, 165), which is chemically non-separable from thorium, and which changes into *actinium X*, a substance soluble in ammonia and non-separable from radium (A. Fleck, Trans. Chem. Soc. 1913, 103, 381, and 1052); this transforms into *actinium emanation*, a short-lived gas of the argon family, from which *actinium A*, *actinium B*, *actinium C*, and *actinium D* successively arise (Hahn and Meitner, Chem Soc. Abstr. 1908, ii. 920); they constitute the induced active deposit. The discovery of *actinium A*, an excessively short-lived product, intermediate between the emanation and what previously had been termed *actinium A*, has led to a change of nomenclature, the products previously termed *actinium A*, *B*, and *C* respectively, being now called actinium *B*, *C*, *D* (Rutherford, Phil. Mag. 1911, [vi.] 22, 621). *Actinium B* is chemically non-separable from lead, *actinium C* from bismuth, and *actinium D* from thallium (Fleck, *l.c.*). Actinium itself is rayless; all the other products except *actinium B* and *D* emit α-particles; and *radio-actinium*, *actinium B*, and *actinium D* emit β- rays (Hahn and Meitner, Chem. Soc. Abstr. 1908, ii. 1007; Geiger, Phil. Mag. 1911, [vi.] 22, 201; Geiger and Nuttal, Phil. Mag. 1912, [vi.] 24, 647).

Actinium is identical with the substance *emanium*, discovered by Giesel (*v.* Giesel, Ber. 35, 3608; 36, 342; 37, 1696, 3063; Debierne, Compt. rend. 139, 538; Ann. Phys. 1914 [ix.] 2, 428; Hahn and Sacker, Ber. 38, 1943; *cf.* Marckwald, Ber. 38, 2264; Soddy, Chem. News, 1913, 107, 97).

It occupies the place in the Periodic Table between radium and thorium, and is chemically non-separable from mesothorium-2. Its parent, 'eka-tantalum,' has been separated from pitchblende by distilling the latter in chlorine and carbon tetrachloride vapour at a low red-heat. It probably occupies the place in the Periodic Table between thorium and uranium, and gives actinium in an α-ray change (Soddy and Cranston, Proc. Roy. Soc. 1918. 94, A 384).

Hahn and Meitner (Phys. Zeits. 1918, 19, 208) independently have separated and studied more extensively the parent of actinium. This substance they call 'prot-actinium,' and regard as a higher homologue of tantalum. It emits α-particles of 3·14 cm. range. Its half-value period lies between 1200 and 180,000 years. The growth of actinium from this substance was observed: (1) by means of α-ray curves; (2) by daily measurement of actinium emanation extending over a month; (3) by the active deposit collected in increasing quantities on a negatively charged plate. The observations confirm Curie's value for the half-value period of actinium.

ADALIN. Bromdiethylacetyl urea

$$(C_2H_5)_2CBr{\cdot}CO{\cdot}NH{\cdot}CO{\cdot}NH_2$$

Used as a hypnotic.

ADAMANTINE SPAR *v.* Corundrum

ADAMITE. A mineral consisting of hydrated basic zinc arsenate $Zn_3(AsO_4)_2{\cdot}Zn(OH)_2$, discovered by C. Friedel in 1866 as a few small, violet orthorhombic crystals on silver ores from Chañarcillo in Chile. Since then it has been found at a few other localities, particularly in the ancient zinc mines at Laurion in Greece. Here it occurs in some abundance as bright green (cupriferous) or yellowish crystals in cavities of the cellular zinc ores. It has been prepared artificially in a crystalline condition.

More recently the name *adamite* has been employed as a trade name for an artificial corundum manufactured for abrasive purposes.

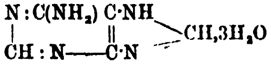
L. J. S.

ADAMON. Trade name for dibromodihydrocinnamic acid bornyl ester.

ADANSONIA DIGITATA (Linn.), the *Baobab tree*, yields a fibre which has been used in paper-making. Its bark (Gowik Chentz or Churre Chentz) is said by Duchaissaing to be a useful substitute for cinchona (Dymock, Pharm. J. [3] 7, 3).

ADENASE *v.* ENZYMES.

ADENINE, 6-*Aminopurine*



$$\begin{array}{l} N:C(NH_2)\,C{\cdot}NH \\ |\qquad\qquad\;\; \| \qquad\quad \searrow CH,3H_2O \\ CH:N\text{——}C{\cdot}N \;\nearrow \end{array}$$

discovered in the pancreatic gland and spleen of the ox, occurs in all vegetable and animal tissues rich in cells (Kossel, Ber. 1885, 18, 79, 1928; Zeitsch. physiol. Chem. 1886, 10, 248; Yoshimura and Kania, Zeitsch. physiol Chem. 1913, 88, 351; Minuroto, J. Coll. Agric. Imp. Univers. Tokio, 1912, 5, 63; Smorodinzew, Zeitsch. physiol. Chem. 1912, 80, 218; Zlataroff, Zeitsch. Nahr. Genussm. 1913, 26, 242; Bass, Arch. f. exp. Pathol. u. Pharmak. 76, 40–64; Winterstein, Landw. Vers.-Stat. 79 and 80, 541–562; Chapman, Chem. Soc. Trans. 1914, 105, 1903-1904); thus it has been extracted from tea leaves (Kossel, *l.c.*), from beet-juice (v. Lippmann, Ber. 1896, 29, 2645), from beet-sugar residues (Andrlík, Zeitsch. Zuckerind, Bohm. 1910, 34, 567–569), 0·05 p.c. pure adenine obtained, from molasses (Stoltzenberg, Chem. Zentr. 1912, 1515, from Zeitsch. ver deut. Zuckerind, 1912, 318), from the young shoots of bamboo (Totani, Zeitsch. physiol Chem. 1909, 62, 113); from human excretory products (Kürger and Schittenhelm, Zeitsch. physiol. Chem. 1902, 35, 159), and from herring brine (Isaac, Chem. Zentr. 1904, ii. 647; from Beitr. chem. physiol. Path. 1904, 5, 500); it is probably one of the degradation products of nucleïn (Schindler, Zeitsch. physiol. Chem. 1889, 13, 432), and is found in small quantity when nucleïn is heated with dilute sulphuric acid (Kossel, Ber. 1885, 18, 1928; Jones and Richards, J. Biol. Chem. 1914, 17, 71; 1915, 20, 25–35).

It has been obtained from rice polishings (Drummond and Funk, Bio-chem. J. 1914, 8, 598-615), and, according to Funk, is of distinct therapeutic value (Casimir Funk, J. Physiol. 1913, 45, 489; also J. Biol. Chem. 1916, 26, 431–456; and Harden and Zilva, Biochem. J. 1917, ii. 172).

Adenine is isolated from tea extract after the removal of caffeine by precipitating the cuprous compound $C_5H_3N_5Cu_2$ by means of copper sulphate and sodium bisulphite, and decomposing the precipitate with ammonium sulphide; the crude adenine is then isolated from the filtrate in the form of the sulphate. For the method of separating adenine from other purine bases compare Schindler (Zeitsch. physiol. Chem. 1889, 13, 432). For recovery of adenine from the picrate, *see* Barnett and Jones (J. Biol. Chem. 1911, 9, 93–96). The synthesis of adenine has been effected by reducing with hydriodic acid 2-amino-2 : 8-dichloropurine obtained by the action of aqueous ammonia on trichloropurine (E. Fischer, Ber. 1897, 30, 2226; 1898, 31, 104; Böhringer and Sons, D. R. P. 96927, 24/3, 97; Traube, Annalen, 1904, 331, 64).

Adenine crystallises from dilute aqueous solution in long rhombic needles that become anhydrous at 110°, and melt with decomposition when rapidly heated at 360°–365° (Fischer, *l.c.*), and sublime in microscopic needles without decomposition at 220°. Adenine is sparingly soluble in cold (1 : 1086) and readily soluble in hot water (1 : 40); sparingly so in alcohol; insoluble in ether or chloroform. It forms compounds with bases, acids, and salts; with hexose (Maudel and Dunham, Biochem. J. 1912, xi. 85), and gives mono- and dichloro-glucosides (Fischer and Helferich, Ber. 1914, 47, 210–235). Adenine *d*-glucoside has m.p. 210°-275° (decomposed), $[\alpha]_D$ 19°–20° $-10{\cdot}5°$ in water, $+5{\cdot}67°$ in *N*/hydrochloric acid. The *nitrate*

$$C_5H_5N_5,HNO_3,\tfrac{1}{2}H_2O$$

is crystalline, and the dry salt dissolves in 110·6 parts of water; the *hydrochloride*

$$C_5H_5N_5,HCl,\tfrac{1}{2}H_2O$$

forms transparent monoclinic prisms $a : b : c = 2{\cdot}0794 : 1 : 1{\cdot}8127$, $\beta = 61°\ 40'$ the anhydrous salt dissolves in 41·9 parts of water; the *chloracetate* $C_5H_5N_5,C_2H_3O_2Cl$ melts and decomposes at 162°–163°; the *sulphate*

$$(C_5H_5N_5)_2,H_2SO_4,2H_2O,$$

the *oxalate* $C_5H_5N_5,C_2H_2O_4,H_2O$, and *dichromate* $(C_5H_5N_5)_2,H_2Cr_2O_7$ are crystalline; the *picrate* $C_5H_5N_5,C_6H_3N_3O_7$ is stable at 220°, and is so sparingly soluble in cold water (1 : 3500) that it is used as a means of estimating adenine in solution (Ber. 1890, 23, 225); the addition of sodium picrate will precipitate adenine from exceedingly dilute solutions (1 : 13,000) (Barnett and Jones, J. Biol. Chem. *l.c.*); the *picrolonate* $C_5H_5N_5,C_{10}H_8O_5N_4$ crystallises from water and melts at 265° (Levene, Biochem. Zeitsch. 1907, 4, 320). The *platinichloride* $(C_5H_5N_5)_2,H_2PtCl_6$ crystallises from dilute solution in needles, and yields the *salt* $C_5H_5N_5,HCl,PtCl_4$ when a concentrated solution is boiled. The *acetyl* derivative $C_5H_4N_5Ac$ does not melt at 260°, the *benzoyl* derivative $C_5H_4N_5Bz$ has m.p. 234°–235° (Kossel, Ber. 1886, 20, 3356). The *methyl* and *benzyl* derivatives have been prepared (Thoiss, Zeitsch. physiol. Chem. 13, 395). *Bromadenine* $C_5H_4N_5Br$ is strongly basic, forms an insoluble *picrate*, and on oxidation with hydrochloric acid and potassium chlorate yields alloxan, urea, and oxalic acid (Bruhns, Ber. 1890, 23, 225; Krüger, Zeitsch. physiol. Chem. 1892, 16, 329). Adenine is converted into hypoxanthine by the action of nitrous acid (Kossel, Ber. 1885, 18, 1928). Adenine-*d*-glucoside treated with excess of nitrous acid yields hypoxanthine-*d*-glucoside, m.p. 245°, $[\alpha]_D^{20°}$ −34·5° in *N*/soda, +12·92° in *N*/hydrochloric acid (Fischer and Helferich, *l.c.*).

Adenine-uracil-dinucleotide is obtained as an amorphous powder by the action of dilute ammonium hydroxide on yeast-nucleic acid; it has $[\alpha]_D$ −6·8°, and gives a crystalline brucine salt $C_{19}H_{25}O_{15}N_7P_2,4C_{23}H_{26}O_4N_2,14H_2O$, m.p. 174°–175° (decomp.). M. A. W.

ADHESIVES, as distinguished from cements, may be defined to be substances or preparations of a gummy or gelatinous character used for the purpose of joining together or effecting the mutual adhesion of the surfaces of bodies. They are usually substances which (1) soften in water, *e.g.* gum arabic, isinglass, glue, &c.; (2) gelatinise in water or other menstruum, and harden either by the evaporation of the solvent or its absorption by the cohering surfaces, *e.g.* liquid glue, gelatine dissolved in acetic acid, rubber or guttapercha in benzene, &c.; or (3) which soften on heating and congeal on cooling, *e.g.* asphalt, marine glue, shellac, &c. The surfaces of the articles to be joined should be perfectly clean; they should be brought into intimate contact, and as little of the adhesive as possible employed. In certain cases perfect contact is ensured by heating the parts to be joined to a temperature such that the adhesive solidifies only when union is effected.

Solutions of gum arabic, or of dextrin, or British gum, mixed with acetic acid, are frequently employed in the case of paper. Flour or starch mixed with water containing a little alum so as to form a thick cream, which is then heated to boiling, and when cold mixed with oil of cloves, thymol, phenol, or salicylic acid so as to preserve it, makes an effective adhesive. A transparent paste may be made by the use of rice starch instead of ordinary flour. Occasionally a small quantity of linseed oil or glycerol is added in the case of labels exposed to moisture. Or the labels may be protected from damp by being coated with a mixture of 2 pts. shellac, 1 pt. borax, dissolved in 16 pts. of boiling water. An alternative method is to apply a coating of copal varnish.

A strong adhesive may be made from shredded gelatine, swollen in water containing 25 p.c. of glacial acetic acid and applied hot. The mixture should be kept in a closely corked phial. Another recipe: Dissolve 60 pts. borax in 420 pts. water, add 480 pts. dextrin and 50 pts. glucose, and heat carefully—not above 90°—with constant stirring until the whole is in solution; replace the evaporated water and filter through flannel (Hiscox).

Wheat flour rich in proteins is mixed with concentrated sulphite liquors and evaporated to a suitable consistency (Robeson). Flour and molasses mixed to a stiff paste or stiff flour paste and concentrated zinc chloride make a permanent cement. Dry casein mixed with half its weight of borax and a sufficiency of water makes an excellent adhesive for broken china or earthenware. Finely powdered casein 12 pts., fresh slaked lime 50 pts., fine sand 50 pts., and enough water to make a thick mass makes a strong cement for ground unions standing a moderate heat. Milk casein dissolved in alkali and an alkaline silicate, such as water-glass, and mixed with a solution of magnesium or calcium chloride, also constitutes an effective adhesive. White of egg made into a paste with slaked lime used immediately after being made up is a very tough and tenacious adhesive. Linseed oil mixed with china clay, or lime, or red or white lead, or oxide of iron, to which powdered glass or graphite may be added adheres strongly when set.

Metallic surfaces after having been rubbed with an alcoholic solution of hydrochloric acid may be caused to adhere by means of a mixture of 10 pts. tragacanth mucilage, 10 pts. honey, and 1 pt. flour (Spon).

A *marine glue* may be used by dissolving 10 pts. caoutchouc in 120 pts. benzene, and adding the solution to 20 pts. melted asphaltum, the mixture being poured into moulds to consolidate. In order to use it the glue is soaked in boiling water and heated over a flame until liquid.

As a leather cement: asphalt, 1 pt.; rosin, 1 pt.; gutta-percha, 4 pts.; carbon disulphide, 20 pts. A plain rubber cement is made by dissolving crude rubber in carbon disulphide or benzene.

Good waterproofing cements are: (1) rosin, 1 pt.; wax, 1 pt.; powdered stone, 2 pts. (2) Shellac, 5 pts.; wax, 1 pt.; turpentine, 1 pt.; chalk, 8–10 pts. For a soft air-tight paste for ground glass surfaces: a mixture of equal parts of wax and vaseline. A solution of 1 pt. of powdered shellac in 10 pts. of ammonia water makes a strong cement for porcelain, glass, and metals (not copper).

Plastic cements, as distinguished from adhesives of the foregoing nature, are used in chemical industry to secure joints and make connections of a more or less temporary character. Such are plaster of Paris used either alone or mixed with asbestos; or when a high temperature is not required, mixed with shavings, straw, hair, cloth, &c. Hydraulic cement used alone or mixed with asbestos or sand, is used as a lute; it is especially resistant to acid vapours. Ordinary clay or fire clay mixed with linseed oil is often employed for steam-joints. A mixture of fire clay, 2 pts.; sulphur, 1 pt.; rosin, 1 pt., may be used for nitric and hydrochloric acid vapours. Mixtures of (1) pitch, 8 pts.; rosin, 6 pts.; wax, 1 pt.; plaster, ¼–½ pt.; or (2) pitch, 8 pts.; rosin, 7 pts.; sulphur, 2 pts.; stone powder, 1 pt., may be used to unite slate slabs and stoneware for engineering and chemical purposes. *See* LUTES.

ADIGAN. A preparation of digitalis (*q.v.*).

ADIPIC ACID *Butane-α-δ-dicarboxylic acid* $CO_2H{\cdot}(CH_2)_4{\cdot}CO_2H$. Obtained by the action of nitric acid on sebacic acid, or on tallow, suet, and other fatty bodies (Arppe, Z. 1865, 300; Laurent, Ann. Chim. Phys. [2] 66, 166; Bromeis, Annalen, 35, 105; Malaguti, Ber. 1879, 572). It is present in beet-juice (Lippmann, Ber. 1891, 3299), and may be obtained from Russian petroleum by distilling the fraction containing naphthalene hydrocarbons (Aschan, Ber. 1899, 1769). It may be prepared by the reduction of mucic acid (Crum-Brown, Annalen, 125, 19), saccharic acid (de la Motte, Ber. 1879, 1572), *iso*saccharic acid with hydriodic acid and phosphorus, or of muconic acid with sodium amalgam (Marquardt, Ber. 1869, 385); by heating β-iodopropionic acid with silver (Wislicenus, Annalen, 149, 221); by the electrolysis of the potassium salt of the monoethyl ester of succinic acid, whereby the diethyl ester of adipic acid is produced (Brown and Walker, Annalen, 261, 117); by oxidising cyclo-hexanone with potassium permanganate in the presence of sodium carbonate (Rosenlew, Ber. 1906, 2202; Mannich and Hancu, Ber. 1908, 575).

Adipic acid crystallises in monoclinic laminæ, melts at 149°, and sublimes at a still higher temperature (Wirz, Annalen, 104, 257). *Cyclo*-pentanone is produced when the calcium salt is distilled, and no anhydride is obtained by the distillation of the acid. It is slightly soluble in water at the ordinary temperature, and has a great tendency to form supersaturated solutions (Dieterle and Hell, Ber. 17, 2221); readily soluble in hot alcohol and ether. It forms salts with most metals which are generally soluble in water and crystallisable. There are eight isomerides of adipic acid, all of which have been prepared.

ADIPOCERE (from *adeps*, fat; and *cera*, wax). A peculiar waxy-looking substance, first observed by Fourcroy in 1786, when the bodies were removed from the *Cimetière des Innocents* at Paris. A large number of coffins had been piled together and had so remained for many years; the corpses in many of these were converted into a saponaceous white substance. Fourcroy placed this substance, together with cholesterol and spermaceti, in a separate class termed by him 'Adipocere.' Gregory (Annalen, 1847, 61, 362), observed a similar substance in the case of a hog which had died of an illness, and had been buried on the slope of a mountain-side. The substance was completely soluble in alcohol, contained no glycerides, and consisted, according to Gregory, of about 25 p.c. of stearic acid, and about 75 p.c. of palmitic and oleic acids (these three acids form the chief constituents of lard). The absence of lime was explained by Gregory as due to the solvent action of water saturated with carbonic acid, which continually ran over the carcase. Gregory fully recognised that the fatty acids had been formed by the hydrolysis of the fat, water having washed away all the glycerol simultaneously produced, and he clearly stated his view that from corpses of animals all nitrogenous and earthy constituents could be washed away, fatty acids only remaining behind. Ebert (Ber. 8, 775) in the main confirmed these results in the examination of a specimen of adipocere. On saponifying with potash, about 1 p.c. ammonia escaped and an insoluble residue (about 6 p.c.), consisting of lime, &c., from tissues, remained. A mixture of potassium salts was obtained, which by fractional precipitation with magnesium acetate yielded mainly palmitic acid. The last fraction, not precipitable by magnesium acetate, but by lead acetate, yielded a hydroxylated acid, the formula of which is given as $C_{17}H_{34}O_3$. This acid, termed by Ebert hydroxymargaric acid, melts at 80°, and is most likely 1 : 10 hydroxystearic acid of the melting-point 81°. The occurrence of this acid in the adipocere examined by Ebert is very likely, as he could not detect any oleic acid; it would thus appear that in the course of time the oleic acid had been oxidised to 1 : 10 hydroxystearic acid. The hard waxy character of adipocere is mainly due to the presence of hydroxystearic acid. Schmelck (Chem. Zeit. 1902, 11) found in the examination of three specimens of adipocere the following results :—

Melting-point . . .	62·5° C.
Insoluble fatty acids .	83 84 p.c.
Ash	1·7 p.c. (containing 83·5 p.c. CaO)
Unsaponifiable matter	16·7 p.c.
Acid value	197
Neutralisation value of the fatty acids . .	203
Iodine value . . .	14

Tarugi (Gazz. chim. ital. 34, ii. 469) also states that adipocere consists chiefly of palmitic acid.

According to Ruttan (Trans. Roy. Soc. Canada, 1917 [iii.] 10, 169) the two isomeric monohydroxystearic acids derived from oleic acid are invariably present, and the disappearance of oleic acid marks the final change in the formation of mature adipocere (*cf.* Ruttan and Marshall, Proc. Amer. Soc. Biol. Chem. 1915).

The formation of adipocere from animal matter had been studied by Kratter in glass vessels filled with water. Kratter's opinion that adipocere originates from the albuminoids must, however, be rejected as erroneous, for there can be no doubt but that the free fatty acids are formed by the hydrolysis of the body fat. All the decomposition products of the albuminoids and the glycerol would be washed away, and the fatty acids would naturally form with the lime of the bones, lime soaps, which may or may not be further hydrolysed by water, to free acid and lime, according to the conditions obtaining in the decomposition of the body. Bacterial and enzymic actions play a quite secondary part in the production of adipocere.

J. L.

ADLUMINE $C_{39}H_{41}O_{12}N$, crystals, m.p. 188°, occurs in *Adlumia cirrhosa* (Rafin.) with *adlumidine* $C_{30}H_{29}O_9N$, plates, m.p. 234°, protopine, and β-homochelidonine (Schlotterbeck and Watkins, Ph. Ar. 1903, 6, 17).

ADONIDIN. A digitalis-like glucoside said to be extracted from the root of *Adonis vernalis* or false hellebore. *v.* DIGITALIS.

ADONITOL. *See* CARBOHYDRATES.

ADORIN. Trade name for a mixture of some powder (infusorial earth, starch, &c.) with paraformaldehyde. Used as a wound dressing.

ADRENALINE. *Adrenalinum B.P.*, *Epinephrine*, *Suprarenin*

$$C_6H_3(OH)_2{\cdot}CH(OH){\cdot}CH_2{\cdot}NH{\cdot}CH_3$$

The U.S.P. has dried suprarenal gland, *Suprarenalum siccum*, but not the active principle. A 'chromogen,' coloured green by ferric chloride and rose-red by iodine, was discovered in the suprarenal medulla by Vulpian (Compt. rend. 1856, 43, 663), but the remarkable rise of blood pressure caused by intravenous injection of suprarenal gland extracts was not observed until 1894 (Oliver and Schäfer, J. Physiol. 1894, 16, i.). After numerous attempts the active principle, which turned out to be also the chromogen, was first obtained crystalline by Takamine (Eng. Pat. 1467, 1901; J. Soc. Chem. Ind. 20, 746), and almost simultaneously by Aldrich (Amer. J. Physiol. 1901, 5, 457). The constitution was next established, mainly by Pauly (Ber. 1903, 36, 2944; 1904, 37, 1388) and by Jowett (Trans. Chem. Soc. 1904, 85, 192). The racemic substance was synthesised by Stolz (Ber. 1904, 37, 4149; and D. R. P. 152814, 157300 of Farbw. Meister, Lucius und Brüning; *cf.* also Dakin, Proc. Roy. Soc., B. 1905, 76, 491). As the racemic substance was found to have little more than half the activity of the natural lævo-variety, its resolution was effected by Flacher (Zeitsch. physiol. Chem. 1908, 58, 581; and D. R. P. 222451 of Farbw. Meister, Lucius und Brüning). The synthetic *l*-base thus obtained is identical with the natural active principle, and is known commercially as *suprarenin.*

The name *epinephrine* was first applied by Abel to *N*-benzoyl adrenaline, but later to the active substance itself, and it is under this name that the substance is referred to in the U.S.P., for instance. The objection to adrenaline is that it is a trade name; close on thirty other trade names have been in use for the substance.

Preparation of natural substance.—The minced glands (generally of oxen) are extracted with acidulated water at 90°–100°; the extract is evaporated to a small bulk, it may then be purified with neutral lead acetate, and it is finally precipitated with several volumes of ethyl or methyl alcohol. The alcoholic filtrate, after concentration to a small bulk, is precipitated with excess of *concentrated* ammonia, when the adrenaline crystallises in sphaerites on standing. Oxidation must be guarded against as far as possible, by boiling with zinc dust, or by extracting with water containing sulphur dioxide; the evaporation is conducted *in vacuo* in a carbon dioxide atmosphere and the precipitation by ammonia takes place under a layer of petrol (Takamine, *l.c.*; Aldrich, *l.c.*; von Fürth, Monatsh. 1903, 24, 261). Abel (Ber. 1903, 36, 1839) extracts at once with a 3·5 p.c. alcoholic solution of trichloracetic acid, which eliminates further purification, and seems to give a good yield. Bertrand (Bull. Soc. chim. 1904, [iii.] 31, 1289) extracts with 95 p.c. alcohol containing oxalic acid, evaporates, shakes with petrol, and purifies with lead acetate.

The crude sandy adrenaline contains inorganic matter, and may be purified by solution in acid and reprecipitation, but better by utilising the solubility of the oxalate in alcohol; the crude base is ground up with a 15 p.c. solution of oxalic acid in 85–90 p.c. alcohol, which leaves inorganic impurities behind (Abel, Pauly).

Syntheses.—Catechol is condensed with monochloracetic acid, by means of phosphorus oxychloride, and the resulting chloracetocatechol (3 : 4-dihydroxy-ω-chloracetophenone)

$$\mathrm{(OH)_2C_6H_3{\cdot}CO{\cdot}CH_2Cl}$$

is suspended in alcohol (50 c.c. for 100 grams. of the ketone); 200 c.c. of a 40 p.c. aqueous methylamine solution are added; on standing methylaminoacetocatechol

$$\mathrm{(OH)_2C_6H_3{\cdot}CO{\cdot}CH_2{\cdot}NH{\cdot}CH_3}$$

separates out, and is washed with water, alcohol, and ether. The ketone is then reduced to the secondary alcohol by aluminium amalgam, or electrolytically. For the resolution the bitartrate is extracted with methyl alcohol; *d*-adrenaline-*d*-tartrate dissolves and *l*-adrenaline-*d*-tartrate remains behind. The *d*-adrenaline so obtained is also utilised, for it may be racemised by heating with dilute hydrochloric acid, and converted into the crystalline racemic hydrochloride (D. R. P. 220355), which can then again be resolved.

The synthesis from chloracetocatechol appears to be the only one of practical importance, but various others have been described. The methylene ether of adrenaline was synthesised by Barger and Jowett (Trans. Chem. Soc. 1905, 87, 967) from piperonal, but could not be hydrolysed to adrenaline, and other attempts in this direction were also unsuccessful (*cf.* Pauly and Neukam, Ber. 1908, 41, 4151; Barger, Trans. Chem. Soc. 1908, 93, 2081; Böttcher, Ber. 1909, 42, 253; Pauly, *ibid.* 1909, 42, 484; Mannich, Arch. Pharm. 1910, 248, 127; D. R. P. 209609, 209610, 212206). Another adrenaline synthesis referred to in the patent literature, consists in methylating the primary base corresponding to adrenaline, namely 3 : 4-dihydroxyphenylethanolamine. This substance, known commercially as *arterenol,* may be obtained (*a*) by the reduction of amino-acetocatechol (D. R. P. 155632); and (*b*) by the reduction of the cyanhydrin of protocatechuic-aldehyde with sodium amalgam (D. R. P. 193634). The latter reaction may be represented thus:

$$\mathrm{(OH)_2C_6H_3{\cdot}CH(OH){\cdot}CN+4H}$$
$$\mathrm{=(OH)_2C_6H_3{\cdot}CH(OH){\cdot}CH_2NH_2}$$

Amino-acetocatechol may be produced (*a*) from chloracetocatechol (above); (*b*) from piperonal or methyl vanillin, *via* ω-nitroacetocatechol, which is reduced (D. R. P. 195814) thus:

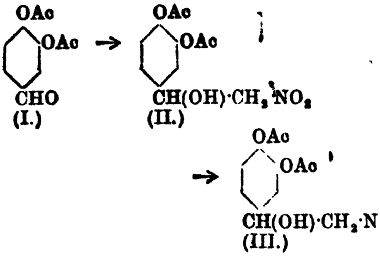
$$\mathrm{(OH)_2C_6H_3{\cdot}CO{\cdot}CH_2{\cdot}NO_2+6H}$$
$$\mathrm{=(OH)_2C_6H_3{\cdot}CO{\cdot}CH_2{\cdot}NH_2}$$

(*c*) by hydrolysis of the condensation products of veratrole with hippuryl chloride (D. R. P. 185598 and 189483)

$$\mathrm{(MeO)_2C_6H_3{\cdot}CO{\cdot}CH_2{\cdot}NH{\cdot}CO{\cdot}C_6H_5}$$
$$\rightarrow \mathrm{(OH)_2C_6H_3{\cdot}CO{\cdot}CH_2{\cdot}NH_2}$$

or by hydrolysis of the similarly constituted phthalimido-acetoveratrole (D. R. P. 209962 and 216640). The last-mentioned four patents are of Farbenfabriken vorm. F. Bayer & Co., all the others of Farbw. vorm. Meister, Lucius und Brüning (*cf.* Friedländer, viii. 1181–1190; ix. 1024–1033). The most recent synthesis is a modification of some earlier ones.

Diacetylprotocatechuic aldehyde I, on condensation with nitromethane in feebly alkaline aqueous solution yields β-hydroxy-β-3 : 4-diacetoxyphenylnitroethane (II.). When this is mixed with the calculated quantity of formaldehyde and reduced by zinc and acetic acid, β-hydroxy-β-3 : 4-diacetoxyphenyl ethyl methylamine (III.) is formed, from which adrenaline is obtained on removal of the acetyl groups :—



(N. Nagai, Jap. Pats. 32440, 32441, 1918).

Properties.—Natural adrenaline, when pure, forms colourless sphaero-crystals, m.p. 211°-212°, $[\alpha]_D - 53°$; the solubility in water at 20° is 0·0268 p.c., and it is also very slight in most organic solvents. Racemic adrenaline decomposes at 230°. Adrenaline dissolves in the calculated quantity of mineral acids, or even in slightly less; it also dissolves in caustic alkalis. Its chief chemical characteristic is the ease with which it undergoes oxidation (*see* colour reactions, below). Solutions with a slight excess of acid are the most stable; traces of iron accelerate oxidation (Gunn and Harrison, Pharm. J. 1908, [iv], 26, 513).

The salts of the optically active adrenalines are mostly amorphous and deliquescent; the *borate* is said to be more stable (D. R. P. 167317). The chief crystalline salt is the *bitartrate* employed in the resolution of the racemic base. The latter yields a crystalline *hydrochloride*, m.p. 157° (D. R. P. 202169), and a crystalline *oxalate*; the corresponding optically active salts are amorphous.

Colour reactions. Colorimetric estimation.—There are three kinds of colour reactions for adrenaline: (1) the general catechol reaction with ferric chloride (limit of green coloration 1 : 30,000); (2) the phosphotungstic reaction of Folin, Cannon and Denis (Journ. biol. Chem. 1913, 13, 477; *cf.* Folin and Denis, *ibid.* 1912, 12, 239), in which the reagent gives a highly coloured blue reduction product; (3) a reaction with a considerable number of mild oxidising reagents, in which the adrenaline is converted into apparently one and the same rose-red oxidation product. For the colorimetric estimation of pure adrenaline solutions the reaction of Folin, Cannon and Denis is the most suitable, and agrees closely with physiological measurements (Seidell, Journ. biol. Chem. 1913, 15, 197; Johannessohn, Biochem. Zeitschr. 1916, 76, 377). The reagent employed is the same as for the estimation of uric acid, but adrenaline is three times as sensitive (Johannessohn gives the ratio 2–98). 100 grams sodium tungstate are dissolved in 750 c.c. of water, and after adding 80 c.c. of 85 p.c. (syrupy) phosphoric acid, the solution is boiled gently for $1\frac{1}{2}$–2 hours, and then made up to 1 litre; $\frac{1}{300}$–$\frac{1}{400}$ mg. adrenaline can be detected; limit 1 : 3,000,000. The blue colour soon fades. Uric acid solutions are used as standards.

For the estimation of adrenaline in extracts of the gland which are always more or less yellow in colour, the phosphotungstate reagent is less suitable (Seidell, *l.c.*), and it is unsuitable for mixtures of adrenaline with cocaine, novocaine, &c., because the latter bases are precipitated by the reagent (Johannessohn, *l.c.*). In these cases a reaction of the third type seems preferable (3). Seidell shakes 10 c.c. of gland extracts containing 1 : 50,000 adrenaline, for one hour with 5 mg. of powdered manganese dioxide, filters, and matches the colour with that of standards, prepared by mixing, in various proportions, a solution of 2 grams $CoCl_2 \cdot 6H_2O + 1$ c.c. concentrated hydrochloric acid in 100 c.c. water, with an auric chloride solution containing 0·1 gram $AuCl_3$ in 100 c.c. water. These mixtures are standardised by comparison with a 1 : 100,000 solution of pure adrenaline, mixed with an extract of desiccated thyroid gland (which has the same yellow colour as a suprarenal extract).

For mixtures containing cocaine, &c., Johannessohn employs the Fränkel-Allers reaction (Biochem. Zeitsch. 1909, 18, 40), which consists in adding an equal volume of 0·001 *N*-potassium *bi*-iodate and a few drops of phosphoric acid, and heating nearly to the boiling-point; a red colour is obtained with adrenaline up to 1 : 100,000 or 1 : 300,000. Other oxidising reagents giving a red colour are auric chloride (Gautier, Compt. rend. Soc. de Biol. 1912, 73, 564; very delicate), potassium persulphate (Ewins, J. Physiol. 1910, 40, 317; 1 : 5,000,000), iodine, mercuric chloride, potassium ferricyanide, bromine, bleaching powder, osmic acid. For a detailed criticism of the quantitative application of these reagents, *see* Borberg (Skand. Arch. Physiol. 1912, 27, 341), also Bayer (Biochem. Zeitsch. 1909, 20, 178) for means of making them more sensitive but less specific.

Physiological methods of estimating adrenaline are more reliable, and may be more accurate than the colorimetric ones. The blood pressure of a cat, with brain and spinal cord destroyed, and without anæsthetic, reacts, according to Elliott (J. Physiol. 1912, 44, 374), 'with mechanical accuracy,' and permits of the estimation of the adrenaline content of a cat's supra-renal with an error of 0·01 mg. (3-4 p.c. of the total amount present). Moderately accurate results may also be obtained with frogs (Läwen, Arch. exp. Path. Pharm. 1904, 51, 415; Trendelenburg, *ibid.* 1910, 63, 161).

Fresh bullock's supra-renals may contain up to 0·25 p.c. adrenaline; the desiccated gland (U.S.P.), corresponding to 6 pts. of the fresh gland, may contain about 1·5 p.c. A fresh bullock's gland dissected free from fat weighs about 10–12 grams. The actual yield in manufacture often does not exceed 0·1 p.c. from bullock's glands; sheep, and especially hogs, contain less. The dried secretion of the parotid gland of *Bufo agua*, a Central American toad, contains as much as 5 p.c. of adrenaline (Abel and Macht, J. Pharm. exp. Ther. 1912, 3, 319).

The most important *physiological action* of adrenaline is that on the arterioles, causing constriction and rise of blood pressure. Intravenously minute doses (0·0003 mg. per kilo in rabbits) produce a distinct effect. Applied to a mucous surface, it causes marked local vaso-constriction and blanching; on this property depends its chief use as a hæmostatic in surgery. It is often used mixed with a local anæsthetic like cocaine. Most commercial solutions and the *Liquor adrenalini hydrochloricus* of the B.P. contain 0·1 p.c. adrenaline dissolved in a slight excess of acid (*e.g.* one-half equivalent) which renders them more stable than solid tablets (according to Johannessohn, *l.c.*; Gunn and Harrison, *l.c.*). Chloroform (B.P.) or other preservative may be added, and salt to make the solution isotonic with the blood. For sterilisation by heat, *see* Rowe (Amer. J. Pharm. 1914, 86, 145). Adrenaline has been recommended (in oral doses of 5–6 mg. per 24 hours) for sea-sickness (Revue Scientifique, 1917). The physiological activity of *d*-adrenaline is about $\frac{1}{15}$ of that of *l*-adrenaline (*e.g.* Cushny, J. Physiol. 1909, 38, 259; Tiffeneau, Compt. rend. 1915, 161, 36), and hence the racemic base is slightly more than half as active as the natural variety.

Adrenaline Substitutes.—Numerous amines have an action more or less resembling that of adrenaline (Barger and Dale, J. Physiol. 1910, 41, 19). Three, all closely related to adrenaline in structure, have been recommended as substitutes, but have not found wide application. Racemic 'arterenol,' 3 : 4-dihydroxyphenylethanolamine $(OH)_2C_6H_3{\cdot}CH(OH){\cdot}CH_2.NH_2$ (*see* above), m.p. 191° (hydrochloride, m.p. 141°), is said to be about half as active as *l*-adrenaline. *Homorenon*, ω-ethylamino-3 : 4 dihydroxyacetophenone $(OH)_2C_6H_3{\cdot}CO{\cdot}CH_2{\cdot}NH{\cdot}C_2H_5$ has a crystalline hydrochloride, m.p. 260°, and a very much weaker action than adrenaline. *Epinine*, 3 : 4-dihydroxyphenylethylmethylamine $(OH)_2C_6H_3{\cdot}CH_2{\cdot}CH_2{\cdot}NH{\cdot}CH_3$, m.p. 188°–189° (Pyman, Trans. Chem. Soc. 1910, 97, 272), is intermediate in action between the two former bases. (For Tyramine, *see* article on ERGOT.)

For a more detailed account of the chemical and physiological properties of adrenaline, *see* Barger, The Simpler Natural Bases, Longmans, 1914, pp. 81–105. G. B.

ADRENCAINE. *See* EUDRENINE.

ADSORPTION *v.* COLLOIDS.

ADUROL. Trade name for a haloid substitution product of hydroquinone, used as a photographic developer.

AËRATED or MINERAL WATERS.

Originally the term 'mineral water' was used to describe natural spring waters containing small quantities of various salts in solution, and frequently saturated with carbon dioxide, hydrogen sulphide, or other gases. When these waters were first imitated by the artificial introduction of carbon dioxide into dilute saline liquids, they were known as 'aërated waters,' to distinguish them from the natural products. At the present time the two terms are employed indiscriminately, and as a rule the whole of the products of the manufacturer of aërated waters are popularly known as 'mineral waters.'

Natural Mineral Waters. In every quarter of the globe natural spring waters containing salts with medicinal properties are common, though fashion has made some more celebrated than others. Some of these waters (*e.g.* Hunyadi Janos) contain magnesium and sodium sulphate, and have an aperient action, whilst others containing iron (*e.g.* Tunbridge Wells water) are valued as tonics. Others, again, like the waters of Harrogate, contain sodium sulphide (0·02 p.c.), and are used as remedies in various complaints.

The most widely consumed natural mineral waters are those which contain only a small proportion of salts and a large amount of carbon dioxide. Typical examples of these are Apollinaris water, Selters water, and St. Gaulmier (French).

The table of analyses (p. 50) show the chief constituents of typical natural mineral waters.

Small quantities of many other compounds are also present in all these waters, but the figures given above represent their main constituents. The composition of all natural mineral waters varies from time to time, but they preserve their general characteristics.

Artificial Mineral Waters. Special mixtures of salts approximately corresponding in composition to those in many of the well-known medicinal waters are now sold, with directions for preparing solutions, which, when aërated, shall produce passable imitations of the natural products.

Among the purely artificial mineral waters mention must be made of ***seltzer water***, which is prepared somewhat upon the lines of the natural Selters water, and contains sodium carbonate, chloride, and sulphate, and sometimes calcium and magnesium chlorides, the proportion of these ingredients being varied to suit the popular taste of the district. It is bottled at a pressure of about 120 lbs., corresponding to about 45–55 lbs. in the bottle.

Other medicinal artificial mineral waters include soda-water, potash-water, lithia-water, and magnesia-water. Soda-water was an official drug in the London Pharmacopœia of 1836, but was not introduced into the British Pharmacopœia until 1867. In the present Pharmacopœia (1898) it is omitted, together with the other alkaline waters. There is thus now no standard for soda-water, and since the old standard of 30 grains of sodium bicarbonate to the pint is sometimes found too alkaline to be palatable, a large proportion of the soda water upon the market contains much less than the old specified proportion of alkali.

Methods of Aërating.—The process of impregnating water with carbon dioxide under pressure dates back to the middle of the 18th century, one of the earliest inventors of apparatus for the purpose being the Duke de Chaulnes in France. In this country the artificial 'aëration' of water was suggested by Bewley in 1767, and in 1772 Priestley constructed an apparatus somewhat on the principle of the modern Kipps' gas generator. A similar apparatus was devised about the same time by Bergman, and was extensively used throughout Sweden.

The earliest processes of bottling aërated waters made use of what is known as the 'Geneva' or ***semi-continuous*** process, in which the carbon dioxide, after being generated from chalk and acid, was forced under pressure with water into a cylinder, whence it could be drawn off into the bottles. This process, which is still employed in modified forms, is useful when a relatively small amount of liquid is to be impregnated, but has the drawbacks of requiring the work to be interrupted to recharge the cylinder, and of bottling the liquid at lower pressures than are often required. Hence in most mineral-water factories the ***continuous process*** is employed. Although numerous patents

in connection with aërating machinery have been taken out, the type of machine which originated with Bramah is still the one in general use.

In Bramah's continuous process the gas is generated in a leaden or lead-lined generator from sulphuric acid and a carbonate, and passes into a gasometer consisting of an inverted copper bell in a tank of water. Thence, after expanding, it is pumped, simultaneously with water, into a condenser or globe, where the water is finely divided and saturated with the gas under a pressure indicated upon a gauge. From this it passes into the bottling part of the machine, where each bottle, placed by hand in position, receives a measured quantity of concentrated sodium carbonate solution or of sweetened syrup and is filled up with the water charged with the gas.

A 'blow-off' valve is provided so that the

air may be completely expelled from the bottle, and in some types of machines there are means for returning the excess of gas to the gasometer, though this is not altogether advantageous

Arrangement of Apparatus—The general mode of arranging the aerating apparatus in the factory is shown in the accompanying figure (p 51) The generator, T, is now frequently replaced by cylinders of liquefied carbon dioxide, which are connected with the gasometer. The soda water machine, properly so called, has one or two pumps for forcing the gas and the water into the condenser, O, the latter being made of gun-metal with a lining of pure tin, and capable of withstanding a pressure three or four times in excess of any normally employed In small installations a gas-engine usually takes the place of a steam-engine

Carbon Dioxide Supply.—The general use of liquefied carbon dioxide instead of that generated from acid and calcium carbonate is the chief improvement on the original method of bottling. The new method is less expensive, more convenient, and obviates the difficulty attending the older process of disposing of the residue of calcium sulphate from the generator

Liquefied carbon dioxide collected from the fermenting tuns in breweries is sometimes employed, but in the writer's experience gas from this source not infrequently contains traces of volatile impurities, which impart an unpleasant flavour to soda-water

Pressures for Aërating—Soda-water and similar unsweetened mineral waters are usually bottled at a pressure of 100–120 lbs to the square inch in bottles, and of 150 lbs in siphons, whilst for lemonade and the like a pressure of 60–80 lbs is employed. In the case of goods intended for export a much lower pressure (usually 40–50 lbs) is generally considered sufficient The figures here given are those indicated upon the pressure gauge of the machine, the actual pressure in the closed bottle being very much less Thus experiments made by the writer have shown that the pressure within bottles of soda water bottled at a machine pressure of 100-120 lbs does not exceed 45-55 lbs An excess of pressure above a certain limit does not result in the liquid containing more gas

During the last few years automatic bottling machines have been introduced into all the leading factories

The principle upon which these machines is based is that of charging an upper cylinder with the carbonated liquid, and filling the bottles automatically in turn, after creating a counter-pressure Under these conditions the liquid flows quietly into the bottles, and there is no unavoidable loss of gas or syrup, through having to remove the air by 'snifting'

The bottles are brought beneath the filling cylinder on a rotating platform, and each in turn fits tightly into a bell mouth, while a valve is provided for the escape of the air expelled by the carbon dioxide This air collects above the liquid in the feeding cylinder, until, when a certain pressure is reached, it is automatically discharged through a valve at the top After filling, the bottles are removed by hand, and either corked by hand or by machinery, without any material loss of pressure

The larger sizes of machines are capable of filling from 100 to 140 dozen bottles per hour, and the saving in gas, as compared with the old type of filling machines, is about 25 p c

Low pressure Bottling—Machines for automatically filling the bottles at a low pressure are also largely used in mineral water factories, and have the advantage of speed over machines in which the filling is effected by the action of counter pressure

An automatic machine of this type is shown below As the machine revolves the empty bottles are successively inserted in the space above the blocks B, which are depressed in turn by the action of the lever C, and are held in position, with an air tight joint round the mouths, by means of a spring The aerated water enters the bottles from air-chambers in a spiral stream, leaving a space in the centre, through which the air escapes, and passing through a small hole in the mouth piece, is compressed in a chamber, until it is released by the removal of the bottle from the machine When the revolution is complete each bottle is removed by hand, and corked or stoppered without material loss of pressure.

By the use of either this system or the counter pressure system there is no waste of gas or liquid, and the bottles are more perfectly charged with carbon dioxide at a pressure of

H, Tappet for opening release valves, I, Air chambers, J, Regulating handles for air chambers

75-80 lbs than was possible on the older types of machines, in which a pressure of 120 lbs or over was commonly used, and the air was expelled from each bottle by means of a 'snifting' valve controlled by hand

An essential of good bottling is that all air should be expelled from the bottle, since otherwise, air being only slightly soluble as compared with carbon dioxide, the liquid will rush with almost explosive violence from the bottle, when opened, but will become flat almost immediately On the other hand, a liquid properly saturated with carbon dioxide and free from air will continue to emit minute bubbles of gas for at least five minutes after it leaves the bottle.

Pressure Gauges—The mode of measuring the pressure of the gas varies in different countries. Thus in England and the United States the zero mark on the dial of the pressure gauge indicates atmospheric pressure, and the succeeding figures represent the number of lbs in *excess* of that pressure In Germany the dial is graduated in atmospheric pressures in excess of the normal pressure, which is represented by zero; whereas in France, which adopts the same mode of expression, the figure 1 represents the normal pressure, and the figure 2 corresponds to 1 on the German scale and to 15 lbs on the British and American scales, and so on

Sweetened Aërated Drinks—Lemonade, ginger ale, and similar sweetened 'mineral waters' are prepared in the same way as soda water A thick syrup is made from sugar and saccharin and water, and this is acidified with citric or tartaric acid and flavoured with an essential oil, which is conveniently added in the form of an alcoholic solution termed a 'soluble essence'

The syrups are filtered through the filter bags shown at C, C, C, in the diagram, into their respective tanks, H, H, H, whence they are drawn off into the bottling machine The use of saccharin to replace part of the sugar in the syrups is almost universal in this country. It has the advantages of reducing the cost and of acting as a preservative, whilst its disadvantages are its cloying taste, which prevents its being used in more than a certain proportion, and the want of fulness on the palate of syrups containing it. The latter drawback is sometimes remedied by the addition of glucose syrup

Methods of detecting and identifying saccharin are described by Boucher and Bourgne, Bull. Soc Chim Belg 1903, 17, 126, Analyst, 1903, 28, 241, von Maler, Farmaz J 1904, 1089; Analyst, 1904, 29, 374, Villiers, Ann Chim. Anal 1904, 9, 418; Analyst, 1905, 30, 21, Chace, J Amer Chem Soc 1904, 26, 1627, Jorgenson, Analyst, 1909, 34, 156.

Addition of Saponin—The popular demand for a liquid which shall retain a frothy head for some time after it has left the bottle has led to the manufacturers frequently adding an extract of quillaia bark or other preparation of saponin, sold under the name of 'foam heading,' &c. Such an addition is more necessary in liquids containing saccharin than in all sugar beverages, which froth more with the carbon dioxide According to the results of experiments made by Lohmann (Zeitsch offentl. Chem. 1903, 9, 320, Analyst, 1903, 28, 361), saponin has no injurious physiological effects On the other hand, according to Bourcet and Chevalier (Pharm. J 1905, 75, 691) commercial saponin contains neutral saponins of a toxic nature

For the detection of saponin, *see* Brunner (Zeit Untersuch Nahr Genussm 1902, 5, 1197), and Ruhle (*ibid* 1908, 16, 165; J Chem Soc Ind 1908, 27, 954), Rosenthaler (Zeit Untersuch Nahr Genussm 1913, 25, 154), and Campos (Ann Chim. anal 1914, 19, 289).

Fermented Beverages—The products of the mineral water factory include one or two beverages in which the aeration is the result of a limited fermentation

Ginger beer, which is the type of this class, is prepared by adding sugar and citric acid to a dilute infusion of ginger root, infecting the liquid with a small quantity of a suitable yeast, bottling it, and allowing the bottles to stand at a proper temperature until sufficient fermentation has taken place

As a rule the fermented liquid contains less than 1 p c of absolute alcohol, but occasionally in very hot weather the fermentation may proceed much further, and the ginger beer may then contain as much as 5 or 6 p c of alcohol. The pressure in the bottle of ginger beer when ready for consumption averages about 15 lbs to the square inch, but in cases of abnormal fermentation it may reach 100 lbs or more, and burst the bottle

Occasionally objectionable flavours are produced by infection of the liquid with wild yeasts or bacteria, just as in the case of ordinary beer

Other drinks of this description are horehound beer and other herb beers. Certain non-alcoholic ales on the market are prepared by partial fermentation of an infusion of malt and hops, which is then used as a syrup, and bottled with aerated water as in the case of lemonade

Stoppers of Bottles—The screw stopper of vulcanite or stoneware with a rubber ring to effect a tight joint is now universally employed, for the glass ball stopper (which had much to recommend it) has fallen into popular disfavour, and is now rarely met with, except in out-of-the-way districts

The chief objection to the rubber-clad stopper is that impurities of various kinds may lodge beneath the rubber, and unless strict cleanliness is observed, may contaminate the contents of the next bottle into which it is introduced.

The Crown corking system has in recent years come into general favour for closing bottles of mineral water

A cap of tinned steel or aluminium, with a corrugated edge, is pressed down by a machine into a special ridge on the neck of the bottle, while a disc of prepared sterilised cork covered with parchment paper, which is fitted into the cap, makes an air tight joint

It is essential that the bottles should be of an exact pattern, since the slightest variation from the standard may lead to faulty bottling and consequent loss of gas

Bacteriological Conditions—It was formerly believed that sterilisation was effected by aerating a liquid with carbon dioxide under a high pressure In 1908, however, bacterioscopic examinations were made, at the instigation of the medical officer for the City of London, of a large number of bottles of soda-water, and it was found that about 25 p.c. could be regarded as pure, and over 33 p.c. as impure, the remainder being 'fairly pure' or 'not pure.' In some of the worst samples the numbers of micro-organisms per 1 c.c. at 20° were uncountable, and some yielded sediment from 50 c.c., which when cultivated at 37°, gave innumerable colonies.

As the result of this investigation a meeting of representative mineral water manufacturers was held, and it was decided to adopt stringent measures to guard against bacterial contamination.

In addition to the obvious precautions of having a pure water supply and observing cleanliness in every stage of the manufacture, it was agreed to discard all wooden tanks and vessels (except for preliminary soaking to remove labels from old bottles), to rinse the bottles with water of assured purity immediately before filling, and to use for this purpose a metal jet of sufficient force. Wherever practicable, rubber rings were to be removed from the stoppers, or, failing that, were to be immersed in a solution of calcium bisulphite, and afterwards rinsed with pure water. The plant was also to be inspected by a competent authority.

There is no doubt that the adoption of such precautions has had the result of raising the standard of purity of soda-water throughout the country.

In considering the bacteriological aspect of the question, several points suggest themselves. Thus an unfavourable bacterioscopic examination of one or two samples taken casually does not necessarily imply faulty manufacture, for it may be the result of accidental contamination of the stopper by the hands of the worker—against which there is no complete safeguard.

Absolute sterility of the contents of the bottle should not be demanded, and it is unreasonable to require a greater degree of purity than that of the average water supply of London. Given a sufficient degree of purity of the original water, which is essential, efficient inspection of the factory at irregular intervals is a better protection than an occasional bacterioscopic examination. When such examinations are made periodically, they should be made under comparable conditions, *i.e.* at the same intervals after bottling; otherwise the product of the cleaner process may show the worse results.

Standards are notoriously difficult to fix, but making allowance for the various chances of contamination, an average sample of soda water, examined one day after bottling, should not yield more than 100 organisms per 1 c.c. at 20°, or contain sufficient *B. coli* to be discoverable in 10 c.c.

Preservatives in Mineral Waters.—The preservatives most likely to be met with in unsweetened mineral waters are sulphites and bisulphites, solutions of which are frequently used, as in breweries, for cleansing the plant.

A small proportion of salicylic acid is often employed to prevent fermentation in the so-called 'fruit syrups' and other sweetened articles, which might otherwise ferment and be the subject of an excise prosecution for containing alcohol.

Fermentations occurring in Mineral Waters.—Excessive fermentation of ginger beer is not uncommon in very hot weather, and the writer has met with samples containing as much as 6 p.c. of absolute alcohol.

Occasionally acetic or lactic fermentation may take place, and spoil a batch of goods, but this seldom happens when thorough cleanliness is observed.

A troublesome form of fermentation, commonly termed the 'mucoid fermentation,' results in the conversion of the contents of the bottle into a thick ropy gelatinous mass. This may be caused by several micro-organisms, such as *B. gelatinosum betæ* or *B. viscosus sacchari*, and is more liable to occur when beet sugar is used for the syrup than when cane sugar is used. When it occurs in an isolated bottle, insufficient cleansing is a chief factor in its production.

Metallic Impurities.—Mineral waters not infrequently contain traces of metallic impurities, especially iron, tin, and lead, derived from the materials used or from some part of the plant.

Iron in soda-water is objectionable from the fact that, when the beverage is added to a light-coloured liquid, such as whiskey, containing a trace of tannin, an unpleasant dark colouration is produced.

Traces of tin find their way into mineral waters through the action of acid syrups upon the tin piping leading to the bottling machines, whilst lead may be derived from solder on the pipes. No such soldering should be permitted, and thorough flushing of tin piping with water night and morning effectually prevents contamination with tin. A still better safeguard, which has been adopted by some factories, is to replace the tin pipe by glass tubes with rubber connections.

Alloys of lead or antimony with tin are more soluble in seltzer water than either metal separately (*see* Barillé, Compt. rend. 1911, 153, 351).

A still more common source of lead is the citric or tartaric acid, in which it is frequently present as a manufacturing impurity.

Copper is not a common impurity, and, when present, is usually due to accidental contact of the acid syrup with the metal.

Arsenic may be derived from glucose used in the preparation of the syrups, or from the use of preparations of phosphoric acid instead of citric or tartaric acid for acidifying the syrups.

It has been asserted that mineral waters take up traces of antimony from the rubber rings of the stopper (which contain a large proportion of antimony sulphide). Experiments made by the writer, however, have shown that even a boiling 5 p.c. solution of hydrochloric acid does not dissolve any antimony from red rubber, and that there is thus no risk of mineral waters being contaminated in this way.

(For the detection of traces of metallic impurities in mineral waters, *see* Budden and Hardy (Detection of Lead, Tin, Copper, and Iron), Analyst, 1894, 19, 169; Tatlock and Thomson (Lead in Citric and Tartaric Acid), Analyst, 1908, 33, 173; Lander and Winter (Poisonous Metals), Analyst, 1908, 33, 450; Report of Conjoint Committee on Arsenic Determination, Analyst, 1902, 27, 48; Report of Royal Commission (Arsenic), Analyst, 1904, 29, 60; Thorpe (Electrolytic Determination of Arsenic), Analyst, 1903, 28, 349); Curtman and Mosher (tin), J. Amer. Chem Soc. 1913, 35, 357). C. A. M.

ÆRGUO. (Verdigris (?) or hydrated basic carbonate of copper.) The name given by the Romans to the green rust produced on copper and bronze by the united action of the oxygen water and carbon dioxide of the air. It was considered by them to enhance the beauty of their bronze statues. The same rust forms on brass, which was, however, not used by the Romans.

ÆSCHYNITE. A rare-earth mineral from Miask in the Ilmen Mountains, southern Urals, described by Berzelius in 1828, and named from *αἰσχύνη*, shame, in allusion to the fact that at that time no means of separating titanium and columbium was known to chemists. It is a titano-columbate (and thorate) of cerium-metals, calcium, and iron, and the composition can be expressed as a combination of a meta-columbate $(Ca,Fe)Cb_2O_6$ with a titanate (and thorate) $Ce_2(Ti,Th)_4O_{11}$. The mineral forms orthorhombic crystals of prismatic habit. It is black or brownish, with a pitchy lustre, and conchoidal fracture; sp.gr. 4·9–5·17; hardness, 5–6. The crystals are found with red felspar, biotite, and zircon in nepheline-syenite at Miask, Urals. The mineral from Hitterö, Norway, referred to this species by W. C. Brogger in 1879, has since been named blomstrandine (*q.v.*). L. J. S.

ÆSCULETIN, ÆSCULIN *v.* GLUCOSIDES and HORSE CHESTNUT.

AETHUSA CYNAPIUM (Linn.). 'Fool's parsley' or the 'lesser hemlock,' a poisonous umbelliferous herb When dried and extracted with alcohol, yields on distillation a small quantity of an essential oil, and the residue contains a resin, a crystalline hydrocarbon *pentatriacontane* $C_{35}H_{72}$ (m.p. 74°) and a crystalline alcohol (m.p. 140°–141°: $[\alpha]_D = -35{\cdot}7°$) either isomeric with phytosterol $C_{26}H_{44}O$, or a lower homologue; *d-mannitol*, together with a small quantity of a *volatile alkaloid* resembling conine, to which the alleged poisonous character of the herb may be due (Power and Tutin, J. Soc. Chem. Ind. 1905, 938).

AFFINITY, CHEMICAL *v.* CHEMICAL AFFINITY.

AFRICAN ELEMI *v.* OLEO-RESINS.

AFRICAN GREEN or **EMERALD GREEN** *v.* PIGMENTS.

AFRICAN INCENSE *v.* OLEO-RESINS.

AFRICAN MARIGOLD. *Tagetes patula.* *Quercetagetin* was isolated from the flowers of the African marigold, *Tagetes patula*, by Latour and Magnier de la Source (Bull. Soc. chim. 1877, [ii.] 28, 337), who state that it also occurs in other varieties of the same plant. In appearance and general properties it is described as resembling quercetin, the colouring matter of quercitron bark, and from this fact, together with its origin, the name *quercetagetin* is evidently derived. On the other hand, according to these authors, its crystalline form, solubility in 60 p.c. alcohol, and the numbers obtained on analysis indicated that it was distinct from quercetin $C_{27}H_{20}O_{12}$, and it was considered to possess the formula $C_{27}H_{22}O_{13}$ (anhydrous) or $C_{27}H_{22}O_{13},4H_2O$ (air-dried). A preliminary re-examination of this colouring matter was made by Perkin in 1902 (Chem. Soc. Proc. 18, 75), and it has more recently been studied in greater detail by the same author (Chem. Soc. Trans. 1913, 103, 209). To isolate the colouring matter, which is largely present in the flowers as glucoside, a concentrated alcoholic extract is diluted with water which precipitates a viscous impurity, and this is removed by means of ether. The clear liquid treated when boiling with addition of a little hydrochloric acid deposits after cooling but a small bulk of the colouring matter, and repeated extraction of the solution with ether is necessary for its economical isolation. The crude product thus obtained can be crystallised from dilute alcohol, but for complete purification it is necessary to prepare the acetyl derivative, and after re-crystallisation to hydrolyse this in the usual manner.

Quercetagetin $C_{15}H_{10}O_8$, or as crystallised from dilute alcohol $C_{15}H_{10}O_8,2H_2O$, forms pale yellow glistening needles or leaflets resembling quercetin in appearance and melts at about 318°. Very dilute alkali dissolves it with a pure yellow colour, which by air oxidation becomes olive, and finally deep brown, but these changes are not so marked when a stronger alkali (10 p.c.) is employed. Alcoholic ferric chloride produces an olive-green colouration, whereas cold alcoholic lead acetate forms an orange-red precipitate which on keeping becomes yellower and finally develops a green tint. On fusion with alkali *protocatechuic acid* is obtained, together with a phenolic product which, however, quickly oxidises, and has not yet been identified.

Quercetagetin readily yields oxonium salts with mineral acids, and of these the *sulphate* $C_{15}H_{10}O_8,H_2SO_4$, fine orange-coloured needles, has been described.

Monopotassium quercetagetin $C_{15}H_9O_8K$ separates as an orange-yellow semi-crystalline precipitate when potassium acetate is added to a solution of quercetagetin in absolute alcohol.

By acetylation *acetylquercetagetin*

$$C_{15}H_4O_8(C_2H_3O)_6$$

colourless needles, melting at 209°–211°, is produced and on alkylation employing alkyl iodide *quercetagetin pentamethyl ether* $C_{15}H_5O_3(OCH_3)_5$, pale yellow needles, m.p. 161°–162°, and *quercetagetin hexamethyl ether* $C_{15}H_4O_2(OCH_3)_6$, colourless needles, m.p. 157°–158°, can be prepared. *Acetylquercetagetin pentamethyl ether*

$$C_{15}H_4O_3(OCH_3)_5C_2H_3O,$$

melts 161°–163°.

Quercetagetin hexaethyl ether $C_{15}H_4O_2(OEt)_6$ m.p. 139°–141°, yields oxonium salts with mineral acids in the presence of acetic acid, the sulphate separating in orange needles, whereas the crystals of the hydrochloride possesses a somewhat more yellow colour. This behaviour is analogous to that of quercetin pentamethyl ether (Watson, Chem. Soc. Proc. 1911, 27, 163).

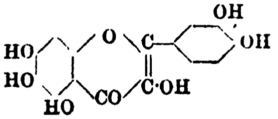
When hydrolysed with alcoholic potassium hydroxide quercetagetin hexaethyl ether gives *protocatechuic acid diethyl ether* and *quercetagetol tetraethyl ether* $C_{18}H_{24}O_6$, which crystallises in prismatic needles, m.p. 46°–48°. The latter yields the oxime $C_{18}H_{25}O_6N$, m.p. 93°–95°, and when oxidised with alkaline permanganate *quercetagetinic acid*, m.p. 100°–102°, is produced.

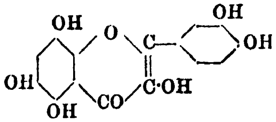
The production of quercetagetol diethyl ether to which the constitution (1) is assigned, and protocatechuic acid diethyl ether (2)

(1) 
$$C_6H(OEt)_4<\begin{matrix}OH\\CO—CH_2·OEt\end{matrix}$$

(2) $CO_2H·C_6H_3(OEt)_2$

from quercetagetin hexaethyl ether, indicate that quercetagetin is a pentahydroxyflavonol isomeric with myricetin and gossypetin. Similarly to this latter colouring matter it appears to contain a tetrahydroxybenzene nucleus, and it is suggested that its constitution may be represented by one of the two following formulæ:





Quercetagetin readily dyes mordanted fabrics shades of a generally similar character to those given by other well-known flavonol colouring matters.

Chromium.	*Aluminium.*	*Tin.*	*Iron.*
Dull olive-yellow.	Yellow-orange.	Brown.	Brownish-black.

A trace of a more sparingly soluble colouring matter is present in the flowers and represents about 1 p.c. of the crude quercetagetin referred to above. It crystallises from alcohol in somewhat indefinite groups of minute needles and dissolves in alkaline solutions with an orange colour passing to green on dilution with water. Though similar in appearance to rhamnetin (quercetin monomethyl ether) it does not contain a methoxy group.

Dyeing Properties of the Flowers.—Employing mordanted woollen cloth, the following shades are produced:—

Chromium.	*Aluminium.*	*Tin.*	*Iron.*
Yellowish-brown.	Pale dull yellow.	Deep yellow-orange.	Brownish-black.

These possess a somewhat redder character than those given by quercitron bark, and are similar to, though not so red as those from patent bark. As quercetagetin mainly occurs in the flowers as glucoside, their tinctorial effect is evidently due to this latter. A. G. P.

AFRIDOL. Trade name for the sodium salt of hydroxymercury-*o*-toluic acid.

AGALITE. A name used in the paper-making trade for a fibrous variety of the mineral talc, a hydrated magnesium silicate, $H_2Mg_3Si_4O_{12}$. It is white with a tinge of green, and is readily reduced to short, fine fibres. It is obtained almost exclusively from the district near Gouverneur, in St. Lawrence Co., New York, about 70,000 tons, valued at $10 per ton, being produced annually, practically all of it being used in the American paper trade. It gives weight and body, and produces a fine gloss on the surface of the paper. L. J. S.

AGALMATOLITE, or Pagodite. A soft stone much used in the East, especially in China, for carving small statues and figures, as signified by these names. At least three mineral species appear to be included under these terms, viz. pyrophyllite, steatite, and pinite; but it is to the compact forms of the first of these that they are perhaps more generally applied. In addition to their compact nature and low degree of hardness, they have in common a greasy or soapy feel: in colour they are white, greyish, greenish, yellowish, &c., often with mottling. Pyrophyllite is a hydrated aluminium silicate, $H_2Al_2Si_4O_{12}$; steatite, a hydrated magnesium silicate, $H_2Mg_3Si_4O_{12}$; and pinite is an alteration-product consisting largely of a finely scaly muscovite-mica, a hydrated potassium aluminium silicate, $H_2KAl_3Si_3O_{12}$. Besides being employed as material for carving, these minerals are used for slate-pencils ('pencil-stone') and for tailor's chalk ('French chalk').

Extensive beds of compact pyrophyllite are quarried in the Deep River region in North Carolina, the material being mainly used for making slate-pencils. At Fukuye, in Goto Island, in the south of Japan, a compact mineral allied to pyrophyllite is mined under the name of 'rōseki' (meaning 'greasy stone' in Japanese); it is crushed, washed, and prepared very much like china-clay, and the product used for making fire-bricks, and to a smaller extent in the manufacture of porcelain and paper. This material contains SiO_2 53–58, Al_2O_3 32–36, H_2O 7–9 p.c. L. J. S.

AGAR-AGAR. Bengal Isinglass. Dried seaweed obtained from Singapore and other places. It is obtained from various red algæ, including *Gelidium corneum*, *G. cartilagineum*, *Eucheuma spinosum*, and *Gracilaria lichenoides*, which grow along the coasts of Eastern Asia and Malaya. The cell-walls of these seaweeds, when placed in boiling water, change into jelly.

It occurs in small transparent strips or as a powder, and dissolves almost entirely in water to a gelatinous, tasteless, and inodorous jelly. It is widely used as a nutritive medium for the cultivation of bacteria and fungi. Analysis of fifteen samples of agar from widely different sources gave the following results: moisture, 14·57–17·84 (average 16·57); protein ($N\times6·25$), 1·53–3·26 (2·34); nitrogen-free extract, 72·72–78·21 (76·15); ether extract, 0·17–0·45 (0·30); crude fibre, 0·39–1·50 (0·80); ash, 3·08–5·68 (3·85); and silica, 0·31–1·11 (average 0·68) p.c. A specially purified commercial agar for bacteriological purposes contained: moisture, 5·72; protein, 1·14; nitrogen-free extract, 89·25; ether extract, 0·32; crude fibre, 0·45; ash, 3·12; silica, 0·29 p.c. High ash or silica content is indicative of an inferior product. An aqueous solution of agar is acid to phenolphthalein. A purified agar for use in bacteriological work where a gelatinising agent containing a minimum of nutrients is desired, may be prepared by washing agar shreds in a dilute solution of acetic acid, washing out the acid, dissolving the agar to a 5 p.c. solution, and pouring the hot solution slowly into a large volume of 95 p.c. alcohol or acetone. The precipitated agar contains considerably less nitrogen than the original material. Part at least of the nitrogen compounds present in agar is available as nutriment for micro-organisms. The setting power of aqueous solutions of agar is not destroyed by acid or alkali between the limiting concentrations of 4·5 p.c. HCl and 5 p.c. NaOH; but if the solution be heated for fifteen minutes under a pressure of 1 atmosphere, the range of concentrations within which solidification occurs is reduced to from 2 p.c. HCl to 4·5 p.c. NaOH. The gelatinising power is increased by addition of peptone and slightly diminished by potassium chloride (Fellers, J. Ind. Eng. Chem. 1916, 8, 1128; J. Soc. Chem. Ind. 1917, 36, 43). *See* also ALGÆ and GUMS.

AGAROBILLA. The seed-pods of *Cæsalpina brevifolia* (Baill.), used in dyeing and tanning.

AGATE. A native form of silica consisting mainly of chalcedony (*q.v.*) and showing a more or less concentric arrangement of differently coloured layers or bands. The layers differ not only in colour, but also in translucency, porosity, and crystalline structure. Some layers show the minutely fibrous structure of typical chalcedony, others are more dense and cryptocrystalline, while some may consist of crystalline quartz, or again of opaline silica. Some of the layers containing larger amounts of impurities and colouring matter may be more of the character of jasper, as in the agate-jaspers or jasp-agates. The material has been deposited layer upon layer from solution in a colloidal form, and subsequently solidified in a partly crystallised condition. The deposition has taken place as a lining in rock cavities, proceeding inwards from the margins of the cavity. In the majority of cases the containing rock is a volcanic rock of basic composition (*i.e.* containing no free primary quartz); the commonest home of the agate being the steam cavities of basaltic rocks. The movement of the molten lava has caused the steam cavities, originally spherical, to be drawn out into almond shapes in the direction of the flow. These almond-shaped, or amygdaloidal, cavities may subsequently become filled with secondary mineral matter of various kinds, derived from the primary minerals of the rock by the action of the hot vapours and solutions which are always present in igneous magmas. Such secondary minerals—calcite and various zeolites—which are commonly associated with agates, have probably been formed while the rock was still hot. The exact conditions of deposition and mode of formation of agates have, however, given rise to much discussion. With the weathering of such an amygdaloidal rock the agate-amygdales, being more resistant, are set free, and may be easily separated from the clayey matrix, or they are washed away and broken up in streams and rivers.

The artificial deposition of gelatinous silica in forms closely resembling those of certain agates has been effected by J. I'Anson and E. A. Pankhurst (Mineralogical Magazine, 1882, v. p. 34). A strong acid is introduced by means of a pipette into a solution of an alkaline silicate containing a certain proportion of alkaline carbonate; the bubbles of carbon dioxide set free become coated as they ascend with gelatinous silica. Agate like structures have also been produced by Liesegang by the diffusion of one saline solution into another in a gelatinous medium (R. E. Liesegang, Geologische Diffusionen, Dresden and Leipzig, 1913; Die Achate, Dresden and Leipzig, 1916).

Many trivial varieties of agate are distinguished, depending on the patterns presented by the several layers of the stone. For example, fortification-agate, eye-agate, ring-agate, riband-agate, brecciated-agate, &c. *Onyx* is an important variety, differing simply in that the layers are plane, thus enabling cameos to be engraved in relief in one layer with a background in another differently coloured layer. A typical onyx with alternately white and black layers is however, of rare occurrence in nature, and has usually been produced by artificial colouring, as explained below. In carnelian-onyx the layers are red and white, and in sardonyx brown and white. Moss-agates, mocha-stones, dendrites, &c., are chalcedonies with enclosures of various kinds.

The artificial colouring of banded chalcedony, or the intensification of the coloration of agates, for the production of ornamental objects was probably known to the ancient Romans, and was practised by the Italian cameo-workers of the Middle Ages. The art was for a time lost, and again came into use at Idar in Germany about the year 1820, where it has been much developed and extensively used. Indeed, practically all the fashioned and polished stones now placed on the market have been artificially treated.

A *black* colour is obtained by soaking the well-dried stones for some weeks in a warm dilute solution of sugar or honey, or in olive-oil, and, after washing, immersing them in warm sulphuric acid. The organic matter absorbed by the more porous layers of the stone is thus carbonised. In case the black colouration is too intense it may be softened by the action of nitric acid. A rich *brown* colour has recently been produced in some translucent stones, giving them somewhat the appearance of garnet, by soaking them in brown sugar-candy and then igniting. A *red* colour is produced by saturating the stone with a solution of an iron salt and igniting. A *yellow* tint inclining to lemon-yellow, is imparted by digesting the stones in warm hydrochloric acid. *Blue*, ranging from the deepest indigo to delicate sky-blue, is produced by soaking the stones first in a solution of ferrous sulphate and afterwards in a solution of potassium ferrocyanide. Such a colour, and also lemon-yellow, is, however, unknown amongst naturally coloured agates. The blue coloured stones have often been passed off as lapis-lazuli, but they are readily distinguished from this by their greater degree of translucency and hardness, and the absence of specks of iron-pyrites. *Green* colours, resembling that of the natural chrysoprase, have been produced by the use of salts of chromium and nickel. Finally, various fancy and quite unnatural colours have been produced by simply dyeing the stones with aniline dyes; these colours fade on exposure to light, and finally disappear. On the history of colouring agates, *see* Nöggerath, Die Kunst, Onyxe . . . zu färben, Karsten's Archiv, 1848, xxii. 262; and on the methods now in use at

Idar, O. Dreher, Das Färben des Achats, Idar, 1913.

The agate-cutting industry has long been centred at Idar and Oberstein on the Nahe, a tributary of the Rhine, and originally the stones were obtained locally from the amygdaloidal melaphyre of the Galgenberg. But since 1827 enormous quantities have been imported from Uruguay and the neighbouring Brazilian state of Rio Grande do Sul. In India, agates and other varieties of chalcedony are abundant in the trap rocks of the Deccan plateau, and have long been worked by the native lapidaries. The well-known 'Scotch pebbles' are prettily coloured agates from Forfarshire, Perthshire, &c. Many localities in America and Australia might also be cited.

Besides being used for a great variety of small ornamental objects, agate finds technical applications in the construction of pestles and mortars, burnishers for gold-workers and bookbinders, smooth stones for paper and card manufacturers, rollers for ribbon makers, and pivot supports for balances, magnetic needles, &c. It may be remarked, however, that an 'agate mortar' need not necessarily show the coloured banding of a true agate, but may just as well be cut from an unbanded chalcedony.

On the agate industry, *see* G. Lange, Die Halbedelsteine . . . und die Geschichte der Achatindustrie (Kreuznach, 1868); Upmann, Beit. z. Gesch. d. Graftsch. Oberstein (Mainz, 1872). On Scotch agates, *see* Guide to the Collection of Scottish Agates, Royal Scottish Museum (Edinburgh, 1899); M. F. Heddle, The Mineralogy of Scotland (Edinburgh, 1901). On agate in general, *see* M. Bauer, Edelsteinkunde, 2nd edit. (Leipzig, 1909), and Engl. transl., Precious Stones, by L. J. Spencer (London, 1904); R. Brauns, transl. by L. J. Spencer, The Mineral Kingdom (Esslingen, 1912).

L. J. S.

AGAVE. An amaryllidaceous genus including several species, the leaves of which provide useful fibres. 'Pite,' or 'pita hemp,' mainly produced in Mexico, is obtained from *A. americana* (Linn.) and *A. mexicana* (Lam.). It is also obtained from several other American species of *Agave*. 'Sisal hemp' is derived from *A. rigida* (Mill.), which grows in Mexico, Central America, and the West Indies.

AGAVOSE. An inactive sugar $C_{12}H_{22}O_{11}$, reducing alkaline copper tartrate, and yielding a lævogyrate sugar on inversion; found in *Agave americana* (Linn.), grown in Mexico. The young flower heads are used in the preparation of a fermented intoxicating drink termed 'pulque' (Michaud and Tristan, J. Amer. Chem. Soc. 14, 548). According to Stone and Lotz, J. Amer. Chem. Soc. 17, 368, this sugar is saccharose.

AGMATINE *v.* Ergot.

AGNIN or **AGNOLIN.** Syn. for *Adeps lanæ*, or purified wool fat.

AGOBILIN. Trade name for a mixture of strontium cholate and salicylate with diacetylphenolphthalein.

AGONIADA BARK. The bark of *Plumiera lancifolia* (Muell.), used in Brazil as a remedy for intermittent fever, contains a bitter crystalline glucoside, *agoniadin* (Peckolt, Arch. Pharm. [2] 142, 40, 1870), identical with the *plumieride* of Boorsma and Merck, obtained from *Plumiera acutifolia* (Poir.); it is probably the *methyl ester of plumieridic acid*, and has the composition $C_{21}H_{26}O_{12}$ (*cf.* Franchimont, Rec. trav. chim. 1898, 18, 334; Proc. K. Akad. Wetensch. Amsterdam, 1900, 3, 35).

AGROPYRUM (B.P.) or **TRITICUM.** The dried rhizome of *Agropyron repens* (Beauv.).

AGROSTEMMA SAPOTOXIN *v.* Glucosides.

AGURIN. Trade name for an addition product of sodium theobromine and sodium acetate.

AGUTTAN. Oxyquinoline salicylic acid.

AICH METAL. An alloy patented by J. Aich in 1860 for use as sheathing for ships. Contains copper, 60 parts; zinc, 38·5 parts; iron, 1·5 parts.

AILANTHUS BARK. The inner bark of *A. excelsa* (Roxb.) and *A. glandulosa* (Desf.); it has the odour and taste of cinnamon; used as a tonic in dyspepsia (Dymock, Pharm. J. [3] 7, 309). An Indian name of the former is *Maharukh*.

AIROFORM. Identical with airol (*q.v.*).

AIROGEN. Identical with airol (*q.v.*).

AIROL. A basic bismuth-oxyiodide gallate, analogous to 'dermatol,' a basic bismuth-gallate. Is a greyish-green powder without smell or taste, soluble in caustic soda or dilute mineral acids. Becomes red on exposure to damp air. Has been used clinically as a substitute for iodoform (*v.* Bismuth and Iodoform).

AJOWAN OIL *v.* Oils, Essential.

AKAZGINE *v.* Nux Vomica.

AK MUDAR, AKANDA, AKRA RUI, or **ERUKKU ERUKKAM.** The bark of *Calotropis gigantea* (Ait.) and *C. procera* (Ait.). An important Indian drug (Dymock, Pharm. J. [3] 10, 122).

AKOLA *v.* Ankool.

AKRA RUI *v.* Ak Mudar.

ALABANDITE. *Manganese sulphide* (MnS) (*v.* Manganese).

ALABASTER. (*Albâtre*, Fr.; *Alabaster*, Ger.) A massive, crystalline, and marble-like variety of the mineral gypsum ($CaSO_4,2H_2O$). It is found in Glamorganshire; at Syston in Leicestershire; at Tutbury, near Burton-on-Trent in Staffordshire, and other places in Britain. A snow-white alabaster much used for small ornamental objects, such as vases, lamps, stands of timepieces, &c., is found at Volterra, in Tuscany. The harder varieties are worked with the same tools as marble, smoothed with pumice stone, polished with a mixture of chalk, soap, and milk, and finished by friction with a flannel.

The softer kinds may be turned or fashioned with rasping tools, fine chisels, or small files, smoothed with dried shave grass, then rubbed with a paste of putty powder or finely divided slaked lime, and polished by washing with soap, water, and lime, and finally with powdered elutriated French chalk or talc.

Alabaster may be stained by heating it to about 90° or 100°, and then dipping it into the colouring solution, which may be either metallic solutions, spirituous tinctures of natural dyes, or coloured oils (Habild, Wagner's Jahr. 28, 669).

A variety of alabaster known as onyx of Tecali, from Mexico, takes a fine polish; its colour varies from milk-white to pale-yellow and pale-green (J. 29, 1264).

ALACREATINE *v.* CREATINE.

ALAITE. Hydrated vanadic oxide $V_2O_5 \cdot H_2O$ found as blood-red, mossy growths with silky lustre at Tyuya-Muyun in the neighbourhood of the Alai Mountains in Fergana, Russian Central Asia. The uranium and vanadium deposits mined at this locality consist of vanadates of uranium, calcium, and copper, occurring as impregnations in a coarse-grained Devonian limestone (K. A. Nenadkevič, 1909).

L. J. S.

ALAMOSITE. A lead silicate $PbSiO_3$, found near Alamos, Sonora, Mexico; analogous to wollastonite $CaSiO_3$ in form, habit, and composition It occurs in radiated aggregates of minute colourless transparent fibres, which give a snow-white appearance to the mass (Palache and Merwin, Amer. J. Sci. 1909, 27, 399; J. Soc. Chem. Ind. 1909, 606).

ALANGIUM LAMARCKII *v.* ANKOOL.

ALANINE, α-Alanine *α-aminopropionic acid* $NH_2 \cdot CHMe \cdot CO_2H$, contains an asymmetric carbon atom, and the dextro, lævo-, and racemic isomerides are known. *d*-Alanine is one of the decomposition products of a large number of proteids; together with a glucoproteid $C_7H_{14}O_4N_2$, it forms 51 p.c. of the product obtained by the hydrolysis of legumin of peas (Bleunard, Ann. Chim. Phys. [5] 26, 47), and is formed to the extent of 21 p.c. from silk fibroin (Weyl, Ber. 21, 1529; Fischer and Skita, Zeitsch. physiol. Chem. 33, 177; Johnson, J. Amer. Chem. Soc. 1916, 38, 1392–1398). It is found in yeast proteid (Neuberg, Woch. Brauerei. 1915, 32, 317–320), and in 'Zurdon's' meat extract (Zeitsch. physiol. Chem. 1913, 83, 458–467). (For the methods of separating alanine from the other hydrolytic products of the proteid, *v.* art. PROTEINS.) *r*-Alanine is prepared synthetically by the action of hydrochloric acid on the aminonitrile $NH_2 \cdot CHMe \cdot CN$, produced by the interaction of aldehyde ammonia and hydrogen cyanide (Strecker, Annalen, 75, 29); or, together with α-aminopropionitrile hydrochloride, when ammonium chloride, potassium cyanide, and acetaldehyde interact in equimolecular quantities in aqueous solution (Zelinsky and Stadnikoff, Ber. 41, 2061); by reducing α-nitrosopropionic acid with tin and hydrochloric acid (Gutknecht, Ber. 13, 1116); or hydrolysis of α-triazopropionic acid (Curtius, J. pr. Chem. [2] 38, 396).

Alanine crystallises in needles or sharp rhombic prisms, dissolves in 4·6 parts of water at 17°, or in 500 parts of 80 p.c. cold alcohol. For solubility and optical activity of *r-alanine*, *see* Pellini and Coppola (Atti R. Accad. Lincei, 1914 [v.] 23, 1, 144–150, from Chem. Zentr. 1914, 1, 124). Its heat of combustion is 389 Cal. and heat of formation 135·2 Cal. (Berthelot and André, Compt. rend. 110, 884). For quantitative estimation of the light absorbed by complex salts of alanine, *see* Ley and Hegge (Ber. 1915, 48, 70), and for the influence of neutral salts on the rotatory power of alanine, *see* Pfeiffer (Ber. 1915, 48, 1938). The resolution of racemic alanine has been effected through the benzoyl derivative, which is separated into *d-benzoylalanine* (m.p. 147°–148° $[\alpha]_D + 37 \cdot 13°$ in alkaline solution), and *l-benzoylalanine* (m.p. 150°–151° (corr.), $[\alpha]_D - 37 \cdot 3°$ in alkaline solution), by crystallisation of the brucine salt, and these yield on hydrolysis the corresponding optically active alanines; *r-alanine* decomposes at 264°–268° (Zelinsky and Stadnikoff, *l.c.*), at 293° (Fischer, Ber. 32, 2451); *d-alanine* has $[\alpha]_D + 9 \cdot 55°$ in hydrochloric acid solution; *d-alanine* is unchanged when heated with strong hydrochloric acid (Abderhalden, Zeitsch. physiol. Chem. 1912, 82, 167–172). Its aqueous solution is decomposed in presence of sunlight (Ganassini, Giorn. Farm. Chim. 61, 439–444); *l-alanine* decomposes at 297° and has $[\alpha]_D - 9 \cdot 68°$ in hydrochloric acid solution. *r-Alanine* is attacked by fermenting yeast (Ehrlich, Biochem. Zeit. 63, 379). A cultivation of *Aspergillus niger* in an aqueous solution of *r*-alanine destroys about 10 p.c. of the dextrorotatory constituent, but *Pencillium glaucum* does not flourish in a 2 p.c. alanine solution. Resolution has been effected also by means of *d*-bromocamphorsulphonic acid (Colombano and Sanna, Att. R. Accad. Lincei, 1913, [v.] 22, 11, 292–298; Gazz. chim. ital. 1914, 44, 1, 97–104).

In its physiological action, *d*-alanine causes a rapid rise in the urinary nitrogen, most of the extra nitrogen being excreted on the same day; *l*-alanine is not decomposed quite so rapidly, but none of it is excreted unchanged (Abderhalden and Schittenhelm, Zeitsch. physiol. Chem. 1907, 51, 323; compare, however, Sevene and Meyer (Amer. J. Physiol. 1909, 25, 214); when given with lactic acid it causes an increase in dextrose elimination almost equal in amount to the theoretical yield (Dakin and Dudley, J. Biol. Chem. 1914, 17, 451). After administering 20 grams of *r*-alanine, 4·7 grams of the β-naphthalenesulphonic derivative of *l*-alanine was recovered from the urine (Schittenhelm and Katzenstein, Chem. Zentr. 1906, i. 1279). When *d*-alanine is injected in the blood-stream it is rapidly absorbed, as very little can be detected in the blood or urine after a lapse of twenty minutes (Abderhalden and others, Zeitsch. physiol. Chem. 1907, 53, 113, 251, 326; 52, 507; 53, 148; 1913, 86, 478; and J. Biol. Chem. 1915, 20, 539–554).

The importance of alanine as a final hydrolytic product of many proteid substances, has led to an extensive examination of its derivatives in order to facilitate its detection (Abderhalden and Schmidt, Zeitsch. physiol. Chem. 1913, 85, 143–147; Dakin and Dudley, J. Biol. Chem. 1913, 15, 127; Chelle, Ann. Chim. anal. 1914, 19, 67) and estimation, and to determine the part it plays in the building up of the proteid molecule. A short account of the more important of these derivatives is appended.

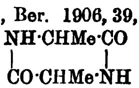
The *copper salt* $(C_3H_6O_2N)_2Cu,H_2O$ forms bluish-violet crystals readily soluble in water. The *nickel salt* $(C_3H_6O_2N)_2Ni,4H_2O$ forms blue crystals, these become anhydrous at 108°–110° and dissolve in 132 parts of water (Orloff, Chem. Zentr. 1897, ii. 192; Bruni and Formara, Atti R. Accad. Lincei, 1904 [v.] 13, ii. 26). Complex salts are formed with heavy metals, *e.g.* $Cr(C_3H_6O_2N)_3Cr(C_3H_6O_2N)_2OH \cdot H_2O$ (Tschugaeff and Serbin, Compt. rend. 1910, 151, 1361; Ley and Winkler, Ber. 1912, 45, 372; Ley and Ficken, Ber. 1912, 45, 377; and *ibid.* 1917, 50, 1123), and with chloride of tin, *e.g.* $SnCl_4 \cdot NH_2 \cdot CHMe \cdot COOH_4$ (Fichter, Färber-Zeit. 1915, 26, 274; Chem. Zeit. 38, 693). Compounds are formed with neutral metallic salts: $LiCl\cdot(NH_2\cdot CHMe\cdot COOH)\cdot H_2O$; $CaCl^2(NH_2\cdot CHMe\cdot COOH)3H_2O$ (Pfeiffer and Modelski, Zeitsch. physiol. Chem. 1912, 85, 1–34; Pfeiffer, Ber. 1915, 48, 1938–1943). The *ethyl ester* has b.p. 48°/11 mm. and sp.gr. 0·9846 at 12·5°; *r-alaninamide*, m.p. 62° (Franchimont and Friedman, Proc. R. Akad. Wetensch. Amsterdam, 1905, 8, 475); *d-alaninamide* has m.p. 72° (corr.) and $[\alpha]_D$ +6° in 5·2 p.c. aqueous solution; *r-alanylchloride hydrochloride* $NH_3Cl\cdot CHMe\cdot COCl$ melts and decomposes at 110°; *d-alanylchloride hydrochloride* has $[\alpha]_D^{20°} +7·32°$ (Fischer, Ber. 1905, 38, 605, 2914); *r-alanineanhydride* (*dimethyldiketopiperazine*

$NH{<}\substack{CHMe\cdot CO\\CO\cdot CHMe}{>}NH$ has m.p. 282°, and *d-alanineanhydride* has m.p. 297° (corr.) and $[\alpha]_D^{20°} -28·8°$ (Fischer, Ber. 1905, 39, 453). *d*-N-*Methylalanine* $CH_3\cdot CH(NH\cdot CH_3)COOH$, m.p. 165°–166° has $[\alpha]_D^{20°} +5·59°$; *l*-N-*methylalanine* $[\alpha]_D^{20°} -5·92°$; N-*benzylalanine*, m.p. about 270° (Fischer and Lipschitz, Ber. 1915, 48, 364; *ibid.* 1916, 49, 1357). *Acetylalanine* $NHAc\cdot CHMe\cdot CO_2H$ crystallises in rhombic plates $a:b:c=0·7792:1:1·0983$; m.p. 137° (de Jong, Rec. trav. chim. 19, 259; Fischer and Otto, Ber. 36, 2106); *chloracetylalanine ester* $CH_2Cl\cdot CO\cdot NH\cdot CHMe\cdot CO_2Et$ has m.p. 48·5°–49·5° (corr.) (Fischer and Otto, *l.c.*); the *benzenesulphonic derivative* $SO_2\cdot Ph\cdot NH\cdot CHMe\cdot CO_2H$ has m.p. 126° (Hedin, Ber. 1890, 23, 3197); *benzylsulphonalanine* $C_6H_5CH_2SO_2NH\cdot CH(CH_3)COOH$ has m.p. 164°–165° (Johnson, J. Amer. Chem. Soc. 1916, 38, 2135); the *β-naphthalenesulphonic derivative* $C_{13}H_{14}O_3NS$ melts and decomposes at 220° (Koenigs and Mylo, Ber. 1908, 41, 4427); the *d-camphorsulphonate* of *alanine* $C_3H_7O_2N,C_{10}H_{15}O\cdot SO_3H,H_2O$ has m.p. 105°–110° $[\alpha]_D^{18°} +14·33°$ (Colombano and Sanna, Atti R. Accad. Lincei, 1913, [v.] 22, ii. 234–237); ethyl *d-alanine-d-bromocamphorsulphonate* $CO_2Et\cdot CHMe\cdot NH_2,C_{10}H_{14}OBr\cdot SO_3H,IH_2O$ becomes anhydrous at 105°, and melts at 192°, $[\alpha]_D^{26°} +67·54°$ (Gazz. chim. ital. 44, 1, 97–104); for *hippurylalanine* $NHBz\cdot CH_2\cdot CO\cdot NH\cdot CHMe\cdot CO_2H$, m.p. 202°, and derivatives, *see* Curtius and Lambotte, J. pr. Chem. 1904, [2] 70, 109; *phthalylalanine* $C_6H_4:(CO)_2:N\cdot CHMe\cdot CO_2H$, m.p. 164°, and *phthaloylalanine* $CO_2H\cdot C_6H_4\cdot CO\cdot NH\cdot CHMe\cdot CO_2H,H_2O$, m.p. 129° (Andreasch, Monatsh. 1904, 25, 774); *palmityl-a-alanine* $CH_3(CH_2)_{14}\cdot CO\cdot NH\cdot CHMe\cdot CO_2H$, m.p. 110°, $[\alpha]_D^{10°} -5·98°$ (Aberhalden and Funk, Zeitsch. physiol. Chem. 1910, 65, 61); *diethyldialaninquinone* $C_6H_2O_2(NH\cdot CHMe\cdot CO_2Et)_2$ forms red prisms, m.p. 140° (corr.) (Fischer and Schrader, Ber. 1910, 43, 525); 2:4-*dinitrophenyl-dl-alanine*, m.p. 178° (Abderhalden and Blumberg, Zeitsch. physiol. Chem. 1910, 65, 318); *d-alanine picrolonate* (Abderhalden and Weil, Zeitsch. physiol. Chem. 1912, 78, 150–155); 2-*d-alanine*-1-*picrolonic acid* has m.p. about 145° (decomposed); 1-*d-alanine*-1-*picrolonic acid*, m.p. 215°, decomposed at 217° $[\alpha]_D^{20°} +11·08°$ (Levene and Slyke, J. Biol. Chem. 1912, 12, 127–139); *d-alaninepicrolonate*, m.p. 214° (decomposes) $[\alpha]_D^{20°} +12·4°$; *dl-alanine-picrolonate*, m.p. 16° (decomposes); *benzylhydrogen-dl-alaninedithiocarboxylate* $CO_2H\cdot CHMe\cdot NHCS_2\cdot CH_2Ph$, m.p. 136° (Siegfried and Weidenhaupt, Zeitsch. physiol. Chem. 1910, 70, 152). For *dimethyl-a-alanineoxalylglycine*

$$CO_2MeCHMeNH\cdot CO\cdot CO\cdot NH\cdot CH_2\cdot CO_2Me$$

m.p. 98·5°, and other derivatives, *see* Meyeringh (Rec. trav. chim. 1913, 32, 140–157).

Among the polypeptides prepared by Fischer, Abderhalden, and others, there are many containing the 'alanyl' group one or more times, *e.g.* *r-alanylalanine* $NH_2\cdot CHMe\cdot CO\cdot NH\cdot CHMe\cdot CO_2H$, m.p. 276° (corr.), the *benzoyl derivative* m.p. 203°–204°, the *ethyl ester* m.p. 114°–116°; *dialanylalanine* $NH[CHMe\cdot CO\cdot NH]_2CHMe\cdot CO_2H$, m.p. 219° (corr.) (Fischer and Kautzsch, Ber. 1905, 38, 2375); *l-alanyl-d-alanine*, m.p. 269°–270° (corr.), $[\alpha]_D^{20°} -68·5°$; *d-alanyl-l-alanine*, m.p. 275°–276° (corr.), $[\alpha]_D^{20°} +68·94°$; (Fischer and Raske, Ber. 1906, 39, 2893, 3981), *cycloalanylalanine*



$\begin{array}{l}NH\cdot CHMe\cdot CO\\ |\qquad\qquad\quad |\\ CO\cdot CHMe\cdot NH\end{array}$ m.p. 282°–282·5° (corr.) (Maillard, Ann. Chim. Phys. 1915, [9] 3, 73); *alanyl glucosamine anhydride* $C_9H_{16}O_5N_2$ turns brown at 245°–250°, and melts at 269°–272° (Weizmann and Hopwood, Proc. Roy. Soc. 1913, A 88, 455–461); *ethylalanyl methylenemalonate* $CO_2Et\cdot CHMe\cdot NH\cdot CH:C(CO_2Et)_2$, m.p. 206°–207°; *alanyl-p-hydroxyphenylethylamine* $C_{11}H_{16}N_2O_2$, m.p. 116° (Guggenheim, Biochem. Zeitsch. 1913, 51, 369); *d-alanyl-d-aminobutyrylglycine* $CH_3CH(NH_2)CO\cdot NH\cdot CH(CO\cdot NH\cdot CH_2COOH)CH_2CH_3$, m.p. 214° (corr.) $[\alpha]_D^{20°} +13·86$ (Abderhalden, Zeitsch. physiol Chem. 1912, 77, 371–478); *d-alanylglycylleucine*

$$(CH_3)_2\cdot CH\cdot CH_2\cdot CH(NH\cdot CO\cdot CH_2NH_2)COOH$$

m.p. 132°–133° $[\alpha]_D^{20°} -13·82°$ (Abderhalden and Fodor, *ibid.* 1912, 81, 21); and the tetrapeptide *glycyltyrosyl-glycyl-d-alanine* decomposing at 225° (corr.) is probably a mixture of stereoisomerides of the tetrapeptide isolated from silk fibroin (Fischer, Ber. 1908, 41, 2860; *cf.* Abderhalden and Hirszowski, Ber. 1908, 41, 2840). For other polypeptides derived from alanine, *see* Fischer (Ber. 37, 2486; 4585; 38, 2375; 2914; Annalen, 340, 128, 152; Ber. 39, 453; 40, 943, 1754, 3717; Annalen, 363, 136), and Abderhalden (Ber. 41, 2840, 2857; 42, 3394; Zeitsch. physiol. Chem. 63, 401; 65, 417; 77, 471; 81, 21; Biochem. Zeitsch. 1913, 51, 369).

β-Alanine, *β-aminopropionic acid* $H_2N\cdot CH_2\cdot CH_2\cdot CO_2H$, prepared by treating β-iodopropionic acid with ammonia (Mulder, Ber. 9, 1902; Abderhalden and Fodor, Zeitsch. physiol. Chem. 1913, 85, 114), or with silver nitrite and reducing the resulting *nitro-* compound with tin and hydrochloric acid (Lewkowitsch, J. pr. Chem. [2] 20, 159); by heating ethyl acrylate with alcoholic ammonia in sealed tubes at 110° (Wender, Gazz. chim. ital. 19, 437); or by the action of potassium hypobromite on an alkaline solution of succinimide—this is the best method, and gives a yield of 60 p.c. of the theoretical (Hoogewerf and van Dorp, Rec. trav. chim. 10, 4; Holm, Arch. Pharm. 242, 590). It can be recognised by conversion into ethyl acrylate (Abderhalden and Fodor, Zeitsch. physiol. Chem. 1913, 85, 117).

β-Alanine forms prisms m.p. 196° (Hoogewerf and van Dorp, *l.c.*), does not melt at 220° (Kursda, Monatsh. 12, 242), m.p. 206°–207° (Lengfeld and Stieglitz, Amer. Chem. J. 15, 504); needles, m.p. 200° (Abderhalden and Fodor, *l.c.*); the hydrochloride of the *methyl ester* has m.p. 94°–95° and of the *ethyl ester* m.p. 65·5°. The *copper salt* $Cu(C_3H_6NO_2)_2,6H_2O$ has the properties of an ordinary copper salt, and not those of a cuprammonium derivative (Callegari, Gazz. chim. ital. 1906, 36, ii. 63).

β-Alanine does not occur naturally in the body; when administered with food it causes an increase in the urinary nitrogen, but it is apparently changed with more difficulty than α-alanine, as the increased nitrogen excretion is not observed until the second day (Abderhalden and Schittenhelm, Zeitsch. physiol. Chem. 1907, 51, 323). M. A. W.

ALANT CAMPHOR *v.* Camphor.

ALANT ROOT. The root of *Inula helenium* is said to contain antiseptic principles, efficacious against tuberculosis bacilli. By distilling the root with water, *helenin*, *alantic acid*, and *alantol* (alant camphor) are obtained. *Alantic acid* $C_{15}H_{22}O_3$ crystallises from alcohol in white crystals, m.p. 91°; and on heating it forms the *anhydride* $C_{15}H_{20}O_2$. Both acid and anhydride are insol. in water, sol. in alcohol or fatty oils; form sol. salts with alkalis. *Alantol* is an aromatic liquid, b.p. 200° (Marpmann, Pharm. Zent. 8, 122; J. Soc. Chem. Ind. 1887, 520).

ALBARGIN. Gelatose-silver: a colloidal preparation of silver.

ALBASPIDIN *v.* Filix mas.

ALBERTITE. A jet-black mineral substance resembling asphalt, discovered in 1849, at Hillsborough, Albert co., New Brunswick. Used in the United States for the production of oil and coke. The yield per ton is said to be 100 gallons of crude oil, and 14,500 cubic feet of illuminating gas, whilst a residue of good coke remains in the retorts. Albertite has been found at Strathpeffer, Ross-shire; it contains 62 p.c. volatile matter, 37 p.c. fixed carbon, and 0·60 p.c. water. Its ultimate composition is 79·75 p.c. carbon, 8·12 p.c. hydrogen, 1·63 nitrogen, and 10·30 oxygen (Morrison, Min. Mag. 6, 101; Chem. Soc. Abstr. 50, 311).

ALBITE *v.* Felspar.

ALBUM GRÆCUM. A term formerly used for the excrement of dogs. It was at one time supposed to have medicinal properties, but is now used only for tanning, as skins treated with it, after the removal of the hair and previous to tanning, preserve their softness. It consists mainly of phosphate of lime. Fowls' dung is said by tanners to answer the purpose better.

ALBUMINOIDS and ALBUMINS *v.* Proteins.

ALCOHOL (Ethylic or Vinous) C_2H_6O, the active principle of ordinary intoxicating liquors. Contrary to the usual statement, alcohol was unknown to the Arabian chemists. The process of distillation was also unknown in Asia. The discovery of alcohol probably took place in Italy. It is first mentioned in an Italian work of the ninth or tenth century (Lippman).

Ethyl alcohol occurs, as esters, in many plants. and in various lichens; and is formed by distilling certain plants and fruits with water, probably by hydrolysis of the esters, or by the action of moulds and bacteria on carbohydrates.

Preparation.—Synthetically from its elements thus:—By passing an electric arc between carbon poles in an atmosphere of hydrogen, acetylene (C_2H_2) is produced, which, in the presence of nascent hydrogen, becomes ethylene (C_2H_4). Ethylene by protracted shaking with sulphuric acid is converted into sulphovinic acid, which, being distilled in presence of water, produces alcohol.

Alcohol is, for practical purposes, usually prepared by dehydrating the products of the distillation of fermented liquids. Up to 1796 the strongest spirit known contained not less than 5 p.c. of water. Lowitz appears to have been the first to prepare it in an approximately anhydrous condition. His process consisted in first increasing the strength of rectified spirit by adding to it potassium carbonate, and after decanting from this, distilling very slowly in presence of a further quantity of dry potassium carbonate. Richter used, instead of potassium carbonate, hot calcium chloride (Crell's Ann. 2, 211). Drinkwater first digested with dry potassium carbonate for twenty-four hours; decanted the strong spirit thus produced, digested with as much fresh-burnt quicklime as was sufficient to absorb the whole of the alcohol, and afterwards distilled in a water-bath at a temperature of 82·2°. The product of this distillation, which was found to have a specific gravity of 0·7946 at 15·6°, was returned to the retort, and a fresh quantity of dry pulverised quicklime added to it, after which it was allowed to digest for a week at a temperature of 15·6°. It was then again slowly distilled and the specific gravity of the product found to be 0·7944 at 15·6°. This was digested at a temperature of 54·4° with hot quicklime, and distilled out of contact with the air at a temperature of 81·1° to 82·2°, and the specific gravity of the product, which was taken as absolute alcohol, found to be 0·793811 at 15·6°/15·6°.

Squibb followed the process of Drinkwater, distilling in a partial vacuum of 380 to 630 mm. The alcohol thus prepared had a specific gravity of 0·79350. The difference between this specific gravity and that found by Drinkwater represents one tenth p.c. of alcohol. Mendeléeff's observations (Pogg. 138, 103, 230) practically confirm those of Drinkwater and Fownes.

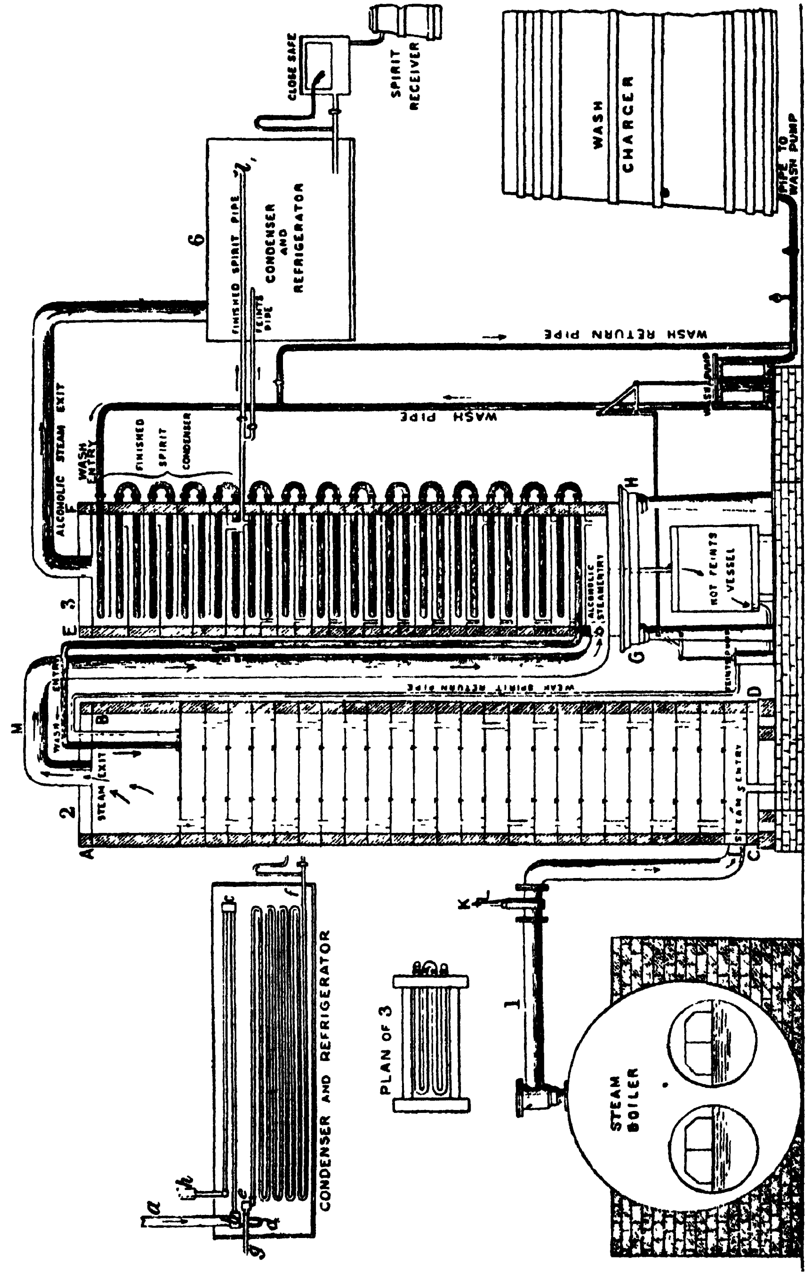
Metallic calcium, free from calcium nitride, may be used to dehydrate alcohol. The calcium should be in shavings, washed with dry carbon tetrachloride to remove traces of petroleum, in the proportion of 20 grams of cleaned and sieved shavings to every litre of alcohol. In order to remove ammonia from the distillate (due to possible traces of calcium nitride) a few centigrams of alizarin are dissolved in a litre of the distilled alcohol together with 0·5 gram of dry tartaric acid dissolved in 10 c.c. of the alcohol. The tartaric acid solution is slowly added to the alcohol coloured by the alizarin until the reddish-blue colour changes to yellow, when the whole is again distilled.

Manufacture.—The first process in the manufacture of spirit is one of brewing, and in general principles it does not differ from that employed in making beer. The brewer, as well as the distiller, endeavours to treat his materials in such a way as to extract from them the greatest amount of fermentable matters. The brewer of beer, however, does not desire to convert all the matter he extracts into spirit, and he brews at such gravities as his customers require. The distiller desires to convert as much as possible of the matter he has extracted from his materials into spirit; he therefore produces a wort containing more maltose and less dextrinous matter than the brewer of beer. He has also an advantage over the brewer in being able to choose the gravities which he knows by experience will produce the best results. It has been found that for distillers' purposes it is advisable to keep the specific gravity of the wort when set for fermentation below 1040. The principle of low temperatures when the diastase is acting in the mash tun appears to be fully recognised, 60° to 63° being generally adopted, and it is understood that the higher the temperature at which the worts are set for fermentation, the greater is the amount of fusel oil in the spirit. The distiller has, therefore, to choose the lowest temperature at which a healthy fermentation can be started, and this is found to range between 23° and 25°. He cannot be too careful as to the purity of the yeast, for not only has he to run the risk of acetic and other ferments being introduced into the wort, involving loss of alcohol, but to provide against the presence of aldehyde, which is objectionable in the spirit. It is found in practice that it is always more prone to appear in hot weather, when the difficulty of keeping the yeast from decomposition is greatest, and as yeast always contains some spirit in a dilute form it is not improbable that the aldehyde is frequently a product of the oxidation of this spirit. Acrolein (probably derived from glycerol) ammonia, and sulphur in organic combination are occasionally found in small quantities in crude spirit.

The materials used in the manufacture of alcohol in the United Kingdom are chiefly malt, maize, rice, sago, tapioca, barley, rye, oats, sugar, and molasses, but occasionally dates and locust beans have been employed. At the present time *maize* constitutes fully 75 p.c. of the grain used. In Scotland the smaller distillers use malt only, and the spirit they produce under the name of Highland, Campbeltown, or Islay Whiskey, Glenlivet, Lochnagar, &c., has imparted to it a flavour derived partly from the peat used in drying the malt. The process of manufacture consists in distilling the fermented wort—then called wash—in a common still, collecting the distillate, which is weak spirit contaminated with fusel oil, and is called 'low wines,' and redistilling. The spirit which passes over in the middle of the redistillation is that which is used for consumption. It contains from 60·8 to 76·7 p.c. of alcohol by weight (20 overproof to 45 overproof), but is generally diluted by the addition of water to 55·4 p.c. of alcohol by weight (11 overproof) before being sent into consumption or placed in bond. Irish whiskey differs from Scotch chiefly in the absence of peat flavour. The materials used in its manufacture are, with one or two exceptions, a mixture of malt and grain, the proportion of malt being, however, greater than in English distilleries. It is generally bonded at 25 overproof (64 p.c. of alcohol by weight).

We have hitherto dealt with the spirit manufactured in 'Common' or 'Pot' stills, or in other words by boiling the wash, condensing the steam thus produced, reboiling the product and recondensing. But by far the greater quantity of the alcohol of commerce is produced by the Coffey still, in which the alcoholic vapour produced is deprived of water as the process continues until a spirit is formed of much greater purity than that manufactured by the old method. The annexed illustration represents a Coffey's distilling apparatus, the left-hand column being called the *analyser*, the right hand one the *rectifier*. The first operation is to fill both columns with steam. This is accomplished by introducing it under pressure from the boiler at C, whence it ascends within the analyser, passing by the pipe M into the bottom of the rectifier. When a proper temperature has been attained, the wash is pumped from the wash charger by a pipe which enters the top of the rectifier. This pipe is only shown sectionally in the sketch after entering the column, but it is continuous, and the wash passes slowly through it, becoming warmer, owing to the pipe being in contact with the steam. When it has reached the bottom of the rectifier it is not far from the boiling-point. It will be seen that the pipe then ascends, and finally delivers the wash into the top of the analyser. The lines across the analyser represent plates of perforated copper, and in connection with each is a tube which projects about an inch and a half above the plate, and dips into a shallow vessel placed on that next beneath. The wash on entering falls on the first plate, but on reaching a depth of an inch and a half passes through the tube to the second one. In the mean time the steam produces ebullition in the contents of the plates, and carries away with it the alcoholic vapour through the steam exit pipe, so that by the time the wash has reached the bottom of the column it has been deprived of its alcohol. The alcoholic vapour passes by the pipe M into the bottom of the rectifier, which like the analyser contains plates and metal tubes, and where a process of gradual cooling takes place by the action of the pipe carrying the cold wash. Fusel oil vapour, condensing at a higher temperature than alcohol, is the first to assume the liquid form, and contaminated with spirit passes into the hot 'feints' receiver. The vapour containing alcohol continues to ascend, meeting with portions that have condensed, and are undergoing the process of rectification. It will be seen that the upper part of the apparatus is marked off in the sketch as finished-spirit condenser. It is so called because all that condenses within its area, instead of returning towards the bottom of the apparatus to be rectified, passes by the finished-spirit pipe or feints pipe into the receivers. At the top of the apparatus is a pipe marked 'alcoholic steam exit,' which carries away most of the aldehyde as well as spirit vapour which under special circumstances may not have been condensed before reaching that point.

The English distillers confine themselves almost exclusively to this apparatus, brewing for the most part from a mixture of grain and malt. In addition to Coffey's still, various forms of rectifying stills are in use to meet special requirements, *e.g.* the production of a purer though not stronger spirit than that obtainable from the Coffey still for the purpose of compounders and certain manufacturing processes, and apparatus having for their object (in consequence of the increasing demand for fusel oil) the recovery of the maximum amount of this by-product, which indeed is now considerably more valuable than the spirit itself. The spirit produced does not to any large extent go into consumption as whiskey, the want of flavour being an objection in regard to the better qualities. Large quantities are transferred to the rectifiers, who redistil them with various



flavouring ingredients, producing gin, British brandy, British rum, and the various cordials, A portion, after being redistilled from potassium carbonate, or filtered through charcoal, is used in the arts and in medicine under the names of rectified spirit and spirits of wine. The British Pharmacopœia (1914) requires rectified spirit to be of a specific gravity of 0·8337 at 15·6°/15·6°, equal to 85·68 p.c. of alcohol by weight. The Pharmacopœia of the United States fixes it at 0·820, equal to 91 p.c., which is about the strength it comes from Coffey's apparatus. The four official (B.P.) diluted alcohols obtained by mixing 90 p.c. alcohol (*Spiritus rectificatus*) with distilled water contain, respectively, 70, 60, 45, and 20 p.c. of alcohol by volume.

They are prepared as follows:—

1. *Seventy per cent. Spirit.*—Sp.gr. 0·8899. Mix 310·5 c.c. of distilled water with 1 litre of 90 p.c. alcohol. Or dilute 777·8 c.c. of 90 p.c. alcohol with water so as to make 1 litre at 15·5°.

2. *Sixty per cent. Spirit.*—Sp.gr. 0·9134. Mix 536·5 c.c. of distilled water with 1 litre of 90 p.c. alcohol. Or dilute 666·7 c.c. of 90 p.c. alcohol with water so as to make 1 litre at 15·5°.

3. *Forty-five per cent. Spirit.*—Sp.gr. 0·9435. Mix 1053·4 c.c. of distilled water with 1 litre of 90 p.c. alcohol. Or dilute 500·0 c.c. of 90 p.c. alcohol with water to the bulk of 1 litre at 15·5°.

4. *Twenty per cent. Spirit.*—Sp.gr. 0·9760. Mix 3558·0 c.c. of distilled water with 1 litre of 90 p.c. alcohol. Or dilute 222·2 c.c. of 90 p.c. alcohol with water to the bulk of 1 litre at 15°.

Attempts have been made, especially in America, to produce alcohol from wood, by the Classen process, or by some modification of it. This process consists in converting the cellulose of the wood or some portion of it into dextrose and other sugars by treatment with dilute acid under pressure, and, after neutralising the acid, fermenting the sugar with yeast, and separating the alcohol by distillation. The yield is about 21 gallons of 95 p.c. alcohol per ton of wood, sawdust or pine wood waste being usually employed, the output being upwards of 2000–2500 gallons *per diem*. The method has not been commercially successful in this country, and is carried on only to a limited extent, and under exceptional conditions, in the United States (J. Ind. Eng. Chem. 1911, 3, 439; 1915, 7, 920; J. Soc. Chem. Ind. 1912, 31, 513; 1917, 36, 532; 1918, 37, 131; Chem. Tr. J. 1918, 63, 103; Zeitsch. angew. Chem. 1913, 26, 786; J. pr. Chem. 1915, 91, 358; Chem. and Metall. Eng. 1918, 19, 552).

Some considerable quantity of alcohol is, however, obtained from the waste liquors formed in the manufacture of wood pulp by the sulphite process. This liquor contains from 1 to 2 p.c. of sugars, which, after neutralisation, or removal of the sulphur dioxide, can be fermented and the alcohol recovered by distillation. The industry is established in Norway, Sweden, Germany, Switzerland, and on the American continent. The yield of alcohol is said to be about 1 p.c. or rather more, of the sulphite waste liquor. The spirit obtained contains methyl alcohol, and is therefore unsuitable for potable purposes; but it can, of course, be employed as motor fuel, and for other uses where a denatured spirit is applicable (Johnsen, J. Soc. Chem. Ind. 1918, 37, 131T).

The synthetic production of alcohol from acetylene, produced from calcium carbide, was largely developed in Germany during the war. The methods employed consist either in transforming the acetylene into ethylene and thence into alcohol by treatment with oil of vitriol and water by a process first discovered by Hennell in 1828; or by converting the acetylene into aldehyde in presence of a catalyst, such as a mercury salt, and then reducing the aldehyde to alcohol by passing its vapour, mixed with hydrogen, over finely divided nickel, at a particular temperature.

For descriptions of the various forms of potable spirit—brandy, rum, whisky, gin, &c.—*see* the special articles on these subjects.

Properties.—In the dehydrated condition ethyl alcohol is a colourless liquid, having a specific gravity of 0·791 at 20°/20° (Lowitz, Crell's Ann. 1796, 1, 1), 0·7938 at 15·6°/15·6° (Fownes, Phil. Trans. 1847, 249), 0·793811 at 15·6°/15·6° (Drinkwater, Phil. Mag. Feby. 1848), 0·79350 at 15·6°/15·6°, 0·79367 at 15°/4° (Mendeléeff, Pogg. 138, 230), (Squibb, Ephemeris, 1884–5, and Pharm. J. [3] 16, 147–148), 0·7851 at 25°/4° (Winkler, Kailan, Osborne, McKelvy, and Bearce, J. Washington Acad. Sci. 1912, 2, 95), 0·7936 at 15°/4° (Schoorl and Regenbogen, Proc. K. Akad. Wetensch. Amsterdam, 1918, 20, 831), 0·80627 at 0°/4° (Young, Klason, and Norlin, Merriman). It boils at 78·4° under a pressure of 760 mm. (Kopp, Annalen, 92, 9), 78·3° (Young and Merriman), and solidifies at −130·5° (Wroblewski and Olsewski, Compt. rend. 96, 1140 and 1125), –112·3° (Ladenburg and Krugel, Ber. 1899, 32, 1818). It is inflammable, the combustion evolving great heat but little light, and producing carbon dioxide and water. It acts as a caustic irritant in contact with the tissues of the body, owing probably to the energy with which it draws moisture from the surface. It possesses a specific heat of 0·6120 at temperatures between 16° and 40·5° (Schüller, P. Erg. 5, 116–192). Its index of refraction for $H\beta$=1·3667 (Brühl), and its critical temperature 243·6° at 48·9 m. At this point 1 gram occupies 3·5 c.c. (Ramsay and Young, Proc. Roy. Soc. 38, 329).

VAPOUR PRESSURE OF ETHYL ALCOHOL.
(Merriman, Trans. Chem. Soc. 1913, 103, 632.)

°	Pressure in mm.	°	Pressure in mm.
0	12·0	18	38·7
1	12·9	19	41·2
2	13·9	20	43·8
3	14·9	21	46·5
4	15·9	22	49·4
5	17·0	23	52·4
6	18·2	24	55·6
7	19·4	25	59·0
8	20·7	30	78·6
9	22·1	40	134·9
10	23·5	50	222·2
11	25·1	60	352·7
12	26·7	70	542·5
13	28·4	80	812·7
14	30·3	90	1187·0
15	32·2	100	1694·0
16	34·3	105	2007·0
17	36·4		

The viscosity of ethyl alcohol at various temperatures has been measured by Thorpe and Rodger (Phil. Trans. 1894, 185, II, 533), with the results shown in the annexed table:—

Temperatures. °	η	Temperatures. °	η
7·16	0·015328	42·34	0·007875
13·23	0·013573	49·37	0·007047
19·22	0·012094	55·57	0·006354
25·24	0·010792	61·07	0·005815
31·89	0·009560	67·55	0·005253
37·51	0·008644	73·57	0·004764

The electric conductivity of alcohol and of its aqueous solutions has been determined at 15°, by Doroschewsky and Roschdestvensky (J. Russ. Phys. Chem. Soc. 1908, 40, 887; J. Soc. Chem. Ind. 1909, 28, 853).

Ethyl alcohol is hygroscopic and is miscible with water in all proportions. On adding water to anhydrous alcohol a considerable development of heat occurs owing to the contraction in the resultant volume. The maximum contraction is found by mixing 48 vols. of water with 52 vols. of anhydrous alcohol, measured at 15·56°.

H. T. Brown (Analyst, 1915, 40, 379) has shown from the alcoholometric tables published by Thorpe that in the case of mixtures of very dilute alcohol and water there is a slight expansion instead of contraction.

Commercial 'absolute' alcohol usually contains about 1 p.c. to 1·5 p.c. of water. In the B.P. (1914) 'absolute' alcohol is defined as 'ethyl hydroxide C_2H_5OH, with not more than 1 p.c. by weight of water; sp.gr. from 0·794 (equivalent to 99·95 p.c. of ethyl hydroxide by volume and by weight) to 0·7969 (equivalent to 99·4 p.c. of ethyl hydroxide by volume or 99 p.c. by weight). Anhydrous copper sulphate shaken occasionally during two or three hours in a well-closed vessel with about fifty times its weight of absolute alcohol does not assume a decidedly blue colour (absence of excess of water).'

Absolutely anhydrous alcohol should give no cloudiness when mixed with benzene, and no pink colouration when shaken with a crystal of potassium permanganate, and no turbidity or evolution of gas (acetylene) in contact with calcium carbide. Anhydrous alcohol added to a fragment of anthraquinone and sodium amalgam acquires a green colour; if a trace of water be present the colour becomes red (Claus, Ber. 10, 927).

Ethyl alcohol is readily detected by the formation of *ethyl acetate* on adding sodium acetate and a few drops of acetic acid to the liquid to be tested, together with an equal volume of strong sulphuric acid, and heating the mixture, when the characteristic smell of ethyl acetate is produced. A less characteristic reaction is the formation of *iodoform* when the liquid is mixed with a few drops of a solution of iodine and warmed and the colour of the iodine destroyed by a solution of sodium carbonate or hydroxide. If *benzoyl chloride* be shaken with the liquid, it forms ethyl benzoate; on warming the decanted solution with a solution of caustic potash the ethyl benzoate is recognised by its odour. Other tests are the formation of *aldehyde* by the action of a mixture of potassium dichromate and sulphuric acid, recognised by its smell and its behaviour with Schiff's reagent; the formation of *dinitrophenetole* (Blanksma, Chem. Weebklad, 1914, 11, 26); *phthalic ester* (Reid, J. Amer. Chem. Soc. 1917, 39, 1249).

According to Pasteur very small traces of ethyl alcohol, especially in fermented liquids, may be detected on distilling the aqueous liquid suspected to contain it by observing the formation of the striæ, or 'tears' produced by the condensation of the first few drops of the distillate. A few c.c. of the liquid to be tested are placed in a wide test tube fitted with a cork and a long glass tube. The liquid, which should contain a spiral of copper or platinum wire, or a few fragments of pumice, to ensure regular ebullition, is heated by a small flame and the formation of the 'tears' in the long tube noticed. With care as little as 0·001 p.c. of alcohol can in this way be detected.

Alcohol forms ethoxides with sodium and potassium, and unstable compounds with certain crystalline salts, *e.g.* zinc chloride, the latter called alcoholates. Subjected to the action of a limited supply of oxygen, it is converted into aldehyde (C_2H_4O), which, by further oxidation, becomes acetic acid ($C_2H_4O_2$). Distilled with chloride of lime, it forms chloroform ($CHCl_3$). With sulphuric acid at a temperature not exceeding 145° it yields ether ($C_4H_{10}O$). With twice its bulk of sulphuric acid it gives ethylene (C_2H_4). With excess of dry chlorine gas it produces chloral (C_2HCl_3O).

Uses.—In addition to its use as a beverage, spirit is employed as a solvent for many of the drugs required in medicine, and diluted to the standard of British proof—that is, to the specific gravity of 0·91976 at 15·6°, representing 49·28 p.c. by weight of Drinkwater and Fownes alcohol—it forms part of a large proportion of the tinctures of the Materia Medica. It is also used largely as a solvent for essential oils, in preparing perfumes and essences, and ether and other ethyl derivatives are manufactured from it.

Methylated spirit. In 1853 a strong representation was made to the Government to allow the use of alcohol duty free in the arts and manufacturing processes in which it was required, and after careful inquiry the Board of Inland Revenue in 1855 decided to sanction, under certain restrictions, a mixture of nine parts of spirits of wine and one part of methyl alcohol (wood naphtha) free of duty under the name of *methylated spirits.* In 1861 the permission was extended to all other purposes except consumption as a beverage or as a medicine. The reasons for selecting wood naphtha were that whilst it would be least likely to interfere in any of the processes for which alcohol was required—especially as a solvent—it would be very difficult to separate from the alcohol when once mixed. The principal restriction on the use of methylated spirit is that it shall only be kept by authorised persons and in authorised premises.

In 1891 it was found necessary (owing to the possibility of methylated spirit being sufficiently purified to render it fit for potable purposes, and the growing practice of drinking even the unpurified methylated spirit by the poorer classes in some of the larger cities) to again restrict the use of methylated spirit made as above described (*i.e.* 'ordinary methylated spirit') to manufacturers only, and, even then, subject to revenue restrictions, and to prescribe the addition of a further denaturant to methylated spirit intended for general purposes. This denaturant consists of mineral naphtha (petroleum), and the mixture, known as '*mineralised*' methylated spirit, may be sold by licensed retailers to the general public for any purpose to which it is applicable, as lighting, heating, cleansing, or mixing with paints, varnishes, &c.

It was found, however, that 'ordinary' methylated spirit was not universally applicable to manufacturing processes requiring the use of alcohol, and accordingly, in 1902, the Commissioners of Inland Revenue, under powers conferred upon them by the Spirits Act of 1880 and the Finance Act of 1902, authorised the use of duty-free alcohol denatured with substances other than wood-naphtha in certain manufacturing operations and subject to special conditions.

As the result of an inquiry by a Departmental Committee, in 1904–5, the amount of wood-naphtha to be used as a denaturant for 'ordinary' methylated spirit used for industrial purposes was reduced from 10 to 5 p.c. of the mixture. This is described as '*industrial*' *methylated spirit.*

At the present time (1920), there are, therefore, two descriptions of methylated spirit officially recognised in the United Kingdom, viz.:

(*a*) *Mineralised methylated spirit* as sold by licensed retailers for general use (except for the preparation of beverages or medicine), and containing not less than 10 p.c. by volume of approved wood-naphtha, and, in addition, not less than 0·375 p.c. of approved mineral naphtha (petroleum of specific gravity not less than 0·800).

(*b*) *Industrial methylated spirit,* intended for use in manufacturing processes, and sold only by methylators to persons authorised to receive this kind of spirit. This must contain not less than 5 p.c. of approved wood-naphtha or other substance or combination of substances approved by the Commissioners of Customs and Excise.

The wood-naphtha must be sufficiently impure to make the methylated spirits so nauseous as to render them incapable of being used as a beverage or of being mixed with potable spirits without rendering them unfit for human consumption. It must contain not less than 72 p.c. by volume of methyl alcohol, and not more than 12 grams per 100 c.c. of aldehydes, acetone, and higher ketones, estimated as acetone by Messinger's iodoform process, nor more than 3 grams of esters estimated as methyl acetate by hydrolysis; not more than 30 c.c. of naphtha shall be required to decolourise an aqueous solution containing 0·5 gram of bromine, and 5 c.c. at least of deci-normal acid shall be required to neutralise 25 c.c. of the spirit when methyl orange is used as indicator.

The wood-naphtha which is now used by methylators is fairly uniform in character as regards its content of methyl alcohol, and it is by the recognition of this alcohol that the presence of methylated spirits is usually detected. Acetone is present in much more varying quantities, whilst unsaturated alcohols, compound ethers, and nitrogenous basic substances are present in too small and varying proportions to afford suitable means for detecting methylated spirits in mixtures.

The most satisfactory methods for detecting methyl alcohol in presence of ethyl alcohol depend either on differences in the physical properties of the alcohols themselves, or on differences in the chemical behaviour of their derivatives or products of oxidation, but of these, few are capable of indicating with certainty the presence of less than 1 p.c. of methyl alcohol.

Of the methods which have hitherto been devised for this purpose, none can compare, as regards the certainty of the conclusions which may be drawn from the results, with that of Riche and Bardy, which depends on the ultimate formation of methylaniline violet and its deposition on wool (Compt. rend. 1875, 1976). As a preliminary test, and one which may with advantage be incorporated in the Riche and Bardy process, the following will be found to be useful. About 10 c.c. of the strong spirit—freed, if necessary, from essential oils, &c., by the salt-petroleum method and fractionated from potassium carbonate (*v.* ALCOHOLMETRY)—are placed with 30 grains of powdered iodine in a small round-bottomed flask which can be readily connected with a condenser. Two grams of amorphous phosphorus are added and the resulting alkyl iodides distilled and collected under water in a small separator. When from 10 to 12 c.c. have been collected, the iodides are washed with water, decolourised with dilute potash, and drawn off from the aqueous layer into a flask containing a little freshly heated potassium carbonate. After remaining an hour or so with occasional shaking, the potassium carbonate is removed by filtration, and the boiling-point of the iodides carefully determined. Ordinary ethyl alcohol yields an iodide which has a constant boiling-point of 72°. When methyl alcohol is present in the spirit, the initial boiling-point of the iodides is lower and a portion distils below this temperature. By noting the temperature at which the first drop of distilled iodides falls into the condenser and receiver respectively, the presence of relatively small quantities of methyl alcohol can be detected. The results (see table in next col.) obtained with synthetic mixtures indicate the delicacy of the method.

In doubtful cases, or when the initial boiling-point is below 70°, the first fraction of 3 c.c. of distilled iodides is digested with an equal volume of aniline at a moderate temperature, and the Riche and Bardy method proceeded with. After standing one hour, hot water is added to the crystalline mass, and the mixture boiled for some minutes, 25 c.c. of strong potash solution are then added, and the liberated aniline oil washed with water; 1 c.c. of this oil is intimately mixed with 10 grams of a mixture consisting of 100 grams of dry quartz sand, 3 grams of cupric nitrate, and 2 grams of common salt, and the mixture introduced into a wide tube and heated for some hours at 90°–100°. The product is exhausted with warm alcohol and the extract filtered and made up to a volume of 100 c.c.

If the sample of spirit contained ethyl alcohol only, the colour of the liquid will be red, but in the presence of 1 p.c. of methyl alcohol it has a distinct violet shade, whilst in the presence of 2 p.c. the violet is very decided, and becomes more so as the proportion of methyl alcohol increases. 5 c.c. of the alcoholic extract are then mixed with water to a volume of 100 c.c., and 2 c.c. of this dye diluted with water to about 400 c.c. The mixture is now heated to a temperature not exceeding 75°, and from two to three feet of Berlin wool, previously freed from grease by treatment with hot dilute potash, immersed in it for 30 minutes.

Percentage of methyl alcohol by volume in the mixture of alcohols	Temperature at which the first drop of iodides falls into the condenser	Volume of distillate obtained below 72° from 10 c.c. of iodides
		c.c.
Nil	70°	Nil
0·38	69°	0·2
0·94	65°	0·8
1·86	63°	2·2
2·77	62°	4·0
3·66	60°	5·0
4·55	58°	6·0
5·42	57°	6·2
6·26	56°	6·4
7·10	55°	6·5
10·00	52°	7·5

Pure ethyl alcohol under these conditions will not produce a dye, and the wool after washing and drying remains practically white. If, however, methyl alcohol was originally present, the fibre will be violet, the tint becoming more intense and increasing in depth according to the quantity present. Riche and Bardy recommend that 5 c.c. of the above diluted dye should be taken instead of 2 c.c. as here described, but although by this means a more intense dye is obtained when methyl alcohol is present, it is found that an appreciable dye, although not of the same colour, is deposited when pure ethyl alcohol has been operated with, and this may lead to confusion. For purposes of comparison it is therefore advisable to operate concurrently with a sample of rectified spirits.

If it be desired to estimate the proportion of methyl alcohol or methylated spirits in a sample, the method of Thorpe and Holmes may be employed. This method depends on the complete oxidation of methyl alcohol to carbon dioxide by means of chromic acid mixture, rectified spirits under the same conditions yielding only a small quantity of carbon dioxide equivalent to 0·01 gram for each gram of ethyl alcohol present (Chem. Soc. Trans. 1904, 1).

As a result of many experiments it has been proved that unless the boiling-point of the iodides is abnormal, no dye is obtained by the Riche and Bardy method, nor does the yield of carbon dioxide on oxidation exceed the limits given above for rectified spirits, but in all cases in which a dye is obtained a proportional excess of carbon dioxide is also obtained.

In other countries there are, as a rule, classes of denatured alcohol corresponding more or less with those authorised in the United Kingdom, *i.e.* spirit for general use so completely denatured as to be deemed undrinkable, and spirit not absolutely denatured and intended for use by responsible manufacturers subject to a more or less strict revenue control.

Wood-naphtha is the denaturant most in favour for spirit intended for general use, the nauseous character of the methylated spirit being sometimes intensified by the addition of such substances as pyridine bases, benzine, &c.

In *France*, spirit for general use contains one-eleventh of its volume of officially approved wood-naphtha, with an addition (when used for lighting and heating purposes) of 0·5 p.c. of heavy benzine distilling between 150° and 200° and 4 p.c. of gum resin for 'finish.'

In *Germany*, the official formula is 2 p.c. of wood naphtha, 0·5 p.c. of pyridine bases, and (optionally) 0·125 p.c. of rosemary oil. Spirit intended for motor cars, and internal combustion engines is denatured by adding 1 p.c. of wood-naphtha, 0·25 p.c. of pyridine bases, 0·25 p.c. of a solution of methyl violet dye, and from 2 to 20 p.c. of benzol to the pure spirit.

In the *United States of America*, 10 p.c. of approved methyl alcohol and 0·5 p.c. of benzene is prescribed to be added to spirit denatured for general use.

In *Belgium*, specific denaturants are prescribed for each of the principal manufacturers, and this practice obtains in certain other countries, as Germany, France, Switzerland, America, and the United Kingdom, when it can be shown that ordinary methylated spirit is unsuitable. In such cases the denaturants are naturally very varied in character, being specially adapted to the particular necessities of each manufacturer.

(Minutes of Evidence and Report of the Department Committee on Industrial Alcohol, 1905; Herrick, Denatured or Industrial Alcohol.)

ALCOHOLOMETRY is the term applied to any process for estimating the amount of alcohol in a spirituous liquid. In simple mixtures of alcohol and water a determination of specific gravity at a standard temperature affords an accurate index of alcoholic content, and it is by taking advantage of this fact that the assay of spirit for revenue and commercial purposes is usually carried out.

When alcohol and water are mixed together the volume of the mixture is invariably less than the sum of the initial volumes, and the degree of contraction varies with the proportion of alcohol present. In countries in which the revenue from spirit is of great importance it has therefore been found necessary to ascertain by experiment the specific gravities of mixtures of alcohol and water in all proportions and at various temperatures. These experiments have in general been carried out at the request of the Governments interested, and the results are embodied in tables associated with the names of those entrusted with the investigations.

In 1794 Sir Charles Blagden and Mr. Gilpin completed an extensive series of experiments, undertaken at the request of the British Government (Phil. Trans. 1790–1794), the results of which have since served as the basis of systems of alcoholometry in this and other countries. At that time anhydrous alcohol had not been prepared, Blagden and Gilpin's tables having reference to spirit of a sp. gr. 0·825 at 15·6°/15·6° (60°/60°F.). Tralles, in 1811, conducted a like investigation for the Prussian Government (Gilb. Ann. 1811), and adopted 0·7946 as the specific gravity of alcohol at 15·6°/15·6°. He incidentally confirmed the general accuracy of the results of Blagden and Gilpin, and constructed tablet of spirit-strengths which for upwards of sixty years formed the basis of German alcoholometry. Similar researches were undertaken by Gay-Lussac (Paris, 1824), McCulloch (Washington, 1848), Baumhauer (Amsterdam, 1860), Mendeléeff (St. Petersburg, 1865), and more recently by the Kaiserliche Normal Eichungs Kommission (Berlin, 1889), the several results of which have from time to time been incorporated in the systems of alcoholometry adopted by the respective Governments. The unofficial investigations, of Fownes (Phil. Trans. 1847), Drinkwater (Chem. Soc. Mem. 848), and Squibb (Ephemeris, 1884), are likewise entitled to consideration.

Drinkwater prepared alcohol of a specific gravity 0·79381 at 15·6°/15·6° (in air), whilst Squibb obtained it as low as 0·7935, but this result lacks confirmation.

The work of Mendeléeff for the Russian Government admittedly constitutes the most

comprehensive and exact of the researches hitherto made in the field of alcoholometry. Mendeléeff obtained alcohol of a specific gravity 0·79425 at 15°/15°, which at 15·6°/15·6° is equivalent to 0·79384 in a vacuum, or to 0·79359 in air, and he assigned to Drinkwater's alcohol an alcoholic content of 99·95 p.c., and to the strong spirit of Blagden and Gilpin 89·06 p.c. by weight. The results of Tralles' and Gay-Lussac's experiments, being based on alcohol less dehydrated than that of Drinkwater, compare less favourably with those of Mendeléeff.

Mendeléeff was so well satisfied with the work of Blagden and Gilpin, and Drinkwater, that, for spirituous mixtures of low strength, he included many of their results in his tables of spirit-densities, and after a critical investigation and subsequent verification by the Kaiserliche Normal Eichungs Kommission, his results have been substantially adopted as the basis of the present system of German alcoholometry in place of the relatively less accurate data of Tralles.

The results of the work of these four authorities have been incorporated in the accompanying table of spirit-densities, which may serve for the pyknometrical determination of the true strength of spirits. In the assessment of duty and in commercial transactions, the standard of strength is termed 'proof.' Spirit of proof strength is defined as 'that which at the temperature of 51°F. (10·6°C.) weighs exactly $\frac{12}{13}$ths of an equal measure of distilled water' also at 10·6°. According to the best available data this mixture of alcohol and water has a specific gravity of 0·91976 at 15·6°/15·6°, and contains 49·28 p.c. by weight and 57·10 p.c. by volume of anhydrous alcohol. Spirits which contain a greater proportion of alcohol than is contained in proof spirit are said to be of overproof strength (o.p.), and those which contain a smaller proportion are said to be of underproof strength (u.p.). Variations of temperature are deemed not to affect the fiscal strength of spirits. Spirits which are of proof strength at 10·6° are consequently deemed to be of proof strength at other temperatures, and the same applies to spirits of any other strength, provided that no change in composition has occurred. In computing the strength of a spirit mixture reference is made to the volume of proof spirit it contains, if underproof, or will produce if overproof, at the dominant temperature, which for revenue purposes in this country is fixed at 10° (50°F.). Mendeléeff's alcohol is thus found to be 75·35 overproof, or 100 volumes at 10°, when diluted with water to proof strength, yield 175·35 volumes at that temperature.

In the annexed table specific gravities of aqueous alcoholic mixtures are correlated with percentages of alcohol by weight and by volume, and fiscal proof spirit. The specific gravities are reduced to air values and represent the ratio of the weight of a given volume of spirit to the weight of the same volume of water at 15·6° under the same atmospheric conditions; they may be converted to specific gravities in vacuum by means of the expression—

$$\frac{s + 0{\cdot}0012}{1{\cdot}0012}$$

Although it is probable that the density of a spirituous liquid can be determined more accurately by the use of a pyknometer than by other means, in practical operations where regard must be had to convenience, it is preferable to employ one of the many hydrometers or alcoholometers, the stems of which are variously graduated to show densities, percentages of alcohol by weight or by volume, or again arbitrary indications which can be interpreted by suitable tables.

Since the year 1816, Sikes' hydrometer has been the legal instrument for ascertaining the strength of spirits for revenue purposes in Great Britain and Ireland, as well as in most of the British Colonies. It is made of brass, gilded, and consists of a hollow sphere provided at one pole with a graduated rectangular stem uniform in section, and at the other with a conical spindle terminating in an oval counterpoise to give stability to the instrument when floating in a liquid, and also to serve as an attachment for various poises. The graduated portion of the stem contains ten principal divisions, which are equal in length, and marked '0' at the upper, and '10' at the lower end, and between these points the stem is again subdivided to 2 tenths of a division. When the instrument is floating at the '0' mark in spirit at a temperature of 15·6°, it indicates a strength of 66·7 overproof, or 92·50 p.c. of alcohol, whilst the '10' mark corresponds to a strength of 58 overproof, or 86·11 p.c. of alcohol (by weight). For strengths weaker than these a series of nine poises or weights are used, numbered consecutively from 10 to 90. The poises are made of hammered brass, gilded, and can be attached by means of a slot in the poise to the spindle of the hydrometer. The series of principal divisions can thus be repeated ten times, reading from '0' to '100,' which latter indication represents distilled water. Sikes' hydrometer indications refer to readings on the stem at the surface of the liquid in which it is floating, the capillary meniscus being disregarded, and are interpreted into proof-strengths by means of tables which are arranged so as to identify a sample of spirits at any temperature between −1·1° (30°F.) and +37·8° (100°F.).

The hydrometer which is used for strong spirits beyond the range of the ordinary Sikes' instrument is known as the 'A' or 'Light hydrometer,' and tables proper to this instrument are also issued. It is made of brass, gilded, and graduated on the stem similarly to Sikes' hydrometer. When floating at the '0' mark in spirit at a temperature of 15·6°, it indicates a strength of 73·5 overproof, or 98·24 p.c. of alcohol, whilst the '10' mark corresponds to 66·7 overproof, or 92·50 p.c. of alcohol by weight, the strength proper to the '0' mark on Sikes' hydrometer.

In the United States of America Tralles' tables are legalised, and, as in England, revenue is raised with reference to a mixture of alcohol and water termed 'proof.' American proof spirit is defined as containing one-half of its volume of Tralles' alcohol at 15·6°. For Excise purposes a series of alcoholometers are employed, each having a limited range, and indicating percentages of proof spirit—'0' representing water, '100' proof spirit and '200' alcohol—and readings at temperatures other than 15·6° are corrected by means of tables to what they

would be in the same spirit at that temperature. In comparing American with British proof it is necessary to remember that the American gallon is smaller than the British Imperial gallon, 100 British being equivalent to 120 American gallons. Consequently, 100 British proof gallons are equal to 137 American proof gallons.

Similarly, in Holland a proof standard is recognised. Dutch proof contains 50 p.c. by volume of anhydrous alcohol at 15°. As in the United States, a series of alcoholometers are employed, differing only in regard to the range of their strength indications. The alcoholometer scale is divided into 28 principal divisions or degrees, which are equal in length, and again subdivided, each principal division representing $\frac{1}{100}$ of the volume of the instrument below the zero mark. Spirit tables based on the results of Baumhauer's investigations accompany the instruments and translate degrees on the scale into percentages of alcohol at 15° on which the revenue charge is based.

In Italy Tralles' alcoholometer is used officially. This instrument is made of glass, and at the standard temperature of 15·6° directly indicates the volume of alcohol contained in 100 volumes of spirit when measured at the same temperature. Indications at other temperatures are corrected by means of tables to true percentages by volume at 15·6°.

In Austria-Hungary an alcoholometer closely resembling Tralles', and indicating percentages of alcohol by volume at 15° is used. Its indications are uniformly higher than those of Tralles' to the extent of from one or two tenths per cent. Readings on this instrument are taken at the highest point of the capillary meniscus, which extends 1–2 mm. on the stem above the normal surface of the liquid.

Tralles' alcoholometer and tables are used commercially in Russia, but for Revenue purposes a metal hydrometer with nine poises similar in character to Sikes' hydrometer is official. On this instrument, however, Sikes' indications are reversed, so that '100' is made to represent strong spirit, and '0' distilled water. The hydrometer scale is arbitrary, and indications are interpreted into percentages by volume of Tralles' alcohol at the standard temperature of 15·6°.

Previous to the year 1887, Tralles' instrument was also used in Germany. It has now been replaced by a system of weight alcoholometry, based on Mendeléeff's data, whereby the proportion by weight of alcohol is determined. The official alcoholometers are made of glass, and graduated to show percentages of alcohol by weight at 15°—apparent percentages at other temperatures being converted into true percentages by means of tables. Duty is, however, charged on the volume of anhydrous alcohol present in a spirit when measured at 15·6°. This system is therefore analogous to the British, with the exception that the dominant temperature at which British proof-strengths are computed is 10°.

In France Gay-Lussac's original volume alcoholometer and tables have been corrected to the new values for densities of mixtures of alcohol and water determined by the 'Bureau national des poids et mesures' (1884). The density of anhydrous alcohol at 15°/15° is given as 0·79433 in vacuum, as against 0·7947 assumed by Gay-Lussac, and the difference between the graduations of the old and new official instruments reaches a maximum of 0·4 p.c. for spirits containing from 20 to 21 p.c. of alcohol by volume. Thus 20° at a temperature of 15° on the new legal centesimal alcoholometer indicates spirit containing 20 p.c. by volume of alcohol, and corresponds to 20·4° on Gay-Lussac's original instrument. The French spirit tables indicate, at temperatures extending from 0° to 30°, the percentage by volume of alcohol which a liquid contains at 15°.

Previous to the adoption of Gay-Lussac's alcoholometer and tables by the French Government, Cartier's areometer was used as the Revenue instrument. Its stem is graduated from 10 to 45 in divisions of equal length, and indicates the concentration of a spirituous liquid by arbitrary degrees, which serve as spirit-strengths for charging duty. Cartier's areometer is still used in Spain and South America.

In Switzerland, Beck's hydrometer is used for spirit assaying, and, like Cartier's instrument, of which it is a modification, floats at the lowest indication in distilled water at 12·5° (10°R.).

By means of the above table the indications of any one of these instruments at 15·6° can be converted into degrees of any other, and British fiscal strengths compared with those of other countries.

An indispensable step to a correct assay of spirit is the removal of any foreign matter which may be in solution in the alcoholic mixture. In the case of potable spirits, wines, liqueurs, &c., the spirit is freed from saccharine and other dissolved matter by distillation. The distillation of a strong spirituous liquid into its own volume so as to obtain an accurate determination of the amount of alcohol present is impracticable with the apparatus and the methods of distillation commonly used, so that although it is possible to distil without loss spirits of underproof strength into the same volume, it is necessary to dilute overproof spirits and distil into two, three, or four times the original volume. The amount by which the true alcoholic strength of brandy or rum differs from the apparent strength, as indicated by the hydrometer or a density determination, is termed the 'obscuration.'

In the case of medicinal preparations, flavouring essences, &c., which yield distillates containing essential oils and volatile substances, special treatment is necessary before a pyknometrical determination of spirit is possible. In these circumstances the sample or distillate is mixed with water in a separator so that the mixture shall contain not more than 20–25 p.c. by volume of alcohol, and common salt is added in quantity sufficient to saturate the liquid. The mixture is then shaken vigorously with 50–100 c.c. of light petroleum, and after remaining a short time, the aqueous layer is extracted, if necessary, a second time with petroleum (for instance when chloroform or ether is present), and finally drawn off into a flask and distilled. In the case of soap liniments and similar preparations, dilute sulphuric acid is used instead of salt, and the aliphatic acids and volatile matters removed by petroleum before distilling (Chem. Soc. Trans. 1903, 314). Preparations containing iodine are decolourised with sodium thiosulphate, and excess of caustic soda added to prevent decomposition of the tetrathionate during distillation. Similarly, volatile acids must be neutralised, and ammoniacal liquids distilled from dilute sulphuric acid solution.

For the estimation of ethyl alcohol in fusel oil, or liquids containing fusel oil, the salt-petroleum process may be employed, but as the higher alcohols cannot be wholly eliminated by this method, the specific refraction of the distillate is determined by the Zeiss Immersion Refractometer. The refractions of mixtures of ethyl alcohol and water have been determined at various temperatures by Wagner and Schultze (Zeitsch. anal. Chem. 1907, 508) and others, and a near approximation to the true alcoholic content of a fusel oil mixture, treated as above described, can be obtained by applying to the apparent percentage by volume of alcohol, as indicated by the density of the distillate, a subtractive correction of 0·5 p.c. for each degree of difference between the refractometer reading as found at 15·6°, and that required for a mixture of ethyl alcohol and water corresponding to the ascertained density. This method of eliminating foreign matters in spirit assaying, from a knowledge of their influence on the specific refractions of aqueous alcoholic mixtures, is capable of wide application, and has been utilised, for instance, by Leach and Lythgoe (Amer. Chem. J. 1905, 964) for determining the proportion of methylated spirits in a spirituous liquid (v. REFRACTOMETER). J. H.

ALCORNIN or **ALCORNOL.** An alcohol, $C_{22}H_{24}O$, of the nature of phytosterol, found in Alcornoco bark (Hartwich and Dünnenberger, Arch. Pharm. 1900, 341).

ALCOVINOMETER. An instrument for determining the alcoholic content of a wine by observing its ascent in a capillary tube.

ALDEHYDE, *Acetaldehyde* C_2H_4O or $CH_3{\cdot}CHO$. A product of the oxidation of ordinary (ethylic) alcohol. Aldehyde occurs, together with its polymerides metaldehyde and paraldehyde, in the 'first runnings' from the stills in the rectification of alcohol which has been filtered through charcoal (Kramer and Pinner, Ber. 2, 403; 4, 787; Johnson, J. Soc. Chem. Ind. 8, 57; Hewitt, *ibid.* 21, 97); the best yield is obtained from the alcohol manufactured from potatoes and from the sugar beet. It is also present in crude wood spirit (Krämer and Grodzki, Ber. 9, 1921); in crude petroleum (Robinson, J. Soc. Chem. Ind. 18, 232); in wine during the process of ageing (Trillat, Compt. rend. 136, 171; *idem.* Ann. Inst. Pasteur, 22, 704, 753, 876; *idem.* Bull. Soc. chim. 5, 546, 550; 7, 71); and in certain circumstances in the fermentation products of alcohol (Trillat, Compt. rend. 146, 645; Trillat and Souton, 146, 996; Kayser and Demolon, 146, 783; Trillat and Souton, Bull. Soc. chim. 7, 244; Ann. Inst. Pasteur, 24, 302; Kostychev, Zeitsch. physiol. Chem. 79, 130; 83, 93; 89, 367; 92, 402; Biochem. Zeitsch. 64, 237; Kostychev and Hübbenet, Zeitsch. physiol. Chem. 79, 359; 85, 408; Neubey and Kerb, Biochem. Zeitsch. 43, 494; 64, 251; Ber. 47, 2730; Grey, Biochem. J. 7, 359; Buchner, Langheld, and Skraup, Ber. 47, 2550; Muller-Thurgan and Osterwald, Am. Chem. Abstr. 1916, 2274, 2474). According to Battelli and Stern (Compt. rend. soc. biol. 68, 5) it is produced in animal tissues by oxidation of alcohol through the action of alcoholase. It occurs in poplar blossoms (Kostychev, Hübbenet, and Sheloumov, Zeitsch. physiol. Chem. 83, 105), and by oxidation of certain substances, such as rhamnose (Rosenthaler, Arch. Pharm. 251, 587). Kerbosch (Rec. trav. chim. 34, 235) showed the presence of traces of acetaldehyde in the latex of *Hevea braziliensis*. It is possibly also a degradation product of glucose in the animal body, and may be reduced to alcohol by the liver (*cf.* Embden and Baldes, Biochem. Zeitsch. 45, 157).

Aldehyde is also formed when calcium formate is heated with calcium acetate (Limpricht, Annalen, 97, 369), and when lactic acid and the lactates are distilled with manganese dioxide and sulphuric acid (Stadeler, Annalen, 79, 333); or by the action of dilute sulphuric acid alone on lactic acid.

$$CH_3CH(OH){\cdot}COOH = CH_3{\cdot}CHO+HCOOH$$

(Erlenmeyer, Zeitsch. f. Chemie, 1868, 343), a process used commercially at one time for the production of aldehyde for the preparation of Aldehyde Green. It is also one of the products of the dry distillation of sugar (Völckel, Annalen, 87, 303).

Preparation.—Aldehyde is formed by the oxidation of alcohol by means of platinum black (Döbereiner, Gm. 8, 274), of manganese dioxide and sulphuric acid (Liebig, Annalen, 14, 133), of potassium dichromate and sulphuric acid (Stadeler, J. 1859, 329), of metallic catalysers (Bouveault, Bull. Soc. chim. 1908, 3, 117; Sabatier and Senderens, Compt. rend. 136, 738); or when alcohol is passed through an iron tube heated to 710°–750° (Ipatieff, Ber. 34, 596).

According to Lang (J. Soc. Chem. Ind. 22, 571), the most useful oxidising agents for converting alcohol to aldehyde are the manganic salts. When prepared by Liebig's method, 2 parts of 80 p.c. alcohol are heated with 3 parts of manganese dioxide, 3 parts of sulphuric acid, and 2 parts of water, and the distillation carried on until the distillate begins to show an acid reaction; this point is reached when about three parts have collected in the well-cooled receiver. The distillate containing alcohol, acetal and ethereal salts is then distilled with an equal weight of calcium chloride, and 1½ parts collected; this is again rectified with an equal weight of calcium chloride and ¾ part distilled over. The product so obtained is nearly anhydrous, but still contains alcohol and small quantities of ethereal salts; to free it from these, it is dissolved in 2 vols. of ether, saturated with ammonia in the cold, and the aldehyde-ammonia which separates is collected, dissolved in water, distilled with dilute sulphuric acid in a water-bath, and the distillate rendered anhydrous by rectification over calcium chloride at as low a temperature as possible.

Improved methods and apparatus for oxidising alcohol into aldehyde are described by Boult, Eng. Pat. 3998, 1896; J. Soc. Chem. Ind. 15, 668; Fournier, Eng. Pat. 7887, 1897; J. Soc. Chem. Ind. 16, 695.

Ethylene oxide $(CH_2)_2O$ (the anhydride of glycol) yields acetaldehyde on heating (Nef, Annalen, 335, 201), particularly in presence of aluminium oxide at 200° C. (Ipatieff and Leontowitsch, Ber. 36, 2017).

It is also produced by treating ethylene glycol with Fenton's reagent, or by treating ethylene diamine with nitrous acid (Neuberg and Rewald, Biochem. Zeitsch. 67, 127), and from pyruvic acid by heating to 150° C. with dilute sulphuric acid (Beilstein and Wiegand, Ber. 17, 841)

$$CH_3{\cdot}CO{\cdot}COOH = CH_3{\cdot}CHO+CO_2$$

A process claimed by the Fabrique de Produits de Chimie Org. de Laire (Eng. Pat. 5533, 1913) consists in heating ethyl halide with hexamethylenetetramine or formaldehyde and ammonia.

Various aliphatic acids, such as succinic, glyceric, maleic, fumaric, tartaric, crotonic, &c., yield acetaldehyde on treatment with Fenton's reagent in sunlight (Neuberg, Biochem. Zeitsch. 67, 50). Behrens (D. R. P. 276764) describes the production of acetaldehyde by mixing the gases obtained by distilling coal, wood, turf, &c., with 5–6 p.c. of carbon dioxide and heating the mixture for some time. Snelling (U. S. Pat. 1124347) claims the production of aldehyde by passing the vapour of ethyl alcohol into a porous earthenware tube, which may be lined with platinum or palladium, heated to about 800°, and drawing off the hydrogen produced in the reaction which diffuses through the walls of the tube; the emoval of the hydrogen allows the reaction to proceed more nearly to completion.

The most convenient laboratory method is that of Sabatier and Senderens (*l.c.*), by passing alcohol vapour over metallic copper heated to about 300° C. (*cf.* also Eng. Pat. 17259, 1911). Aldehyde *is also formed to some* extent by heating charcoal, saturated with acetylene, to 350° C. with water (Degrèz, Ann. Chim. Phys. [7] 3, 216).

Commercially, aldehyde can be obtained from the 'first runnings' of the alcohol stills. A special form of still in which the separation of aldehyde from alcohol is brought about during the rectification of the latter is figured and described by Galland (Dingl. poly. J. 259, 225).

Production from Acetylene.—Within the last few years the commercial production of acetaldehyde from acetylene has become increasingly important, thereby offering new routes for the production of ethyl alcohol, acetic acid, acetone, and so on.

This process depends on the discovery of Kutscherow (Ber. 14, 1540; 17, 13), that in the presence of mercury salts, such as mercuric chloride, acting as catalysts, acetylene reacts with water to give acetaldehyde:

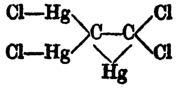
$$CH \vdots CH + H_2O = CH_3{\cdot}CHO$$

This result appears to be due to the intermediate formation of a compound

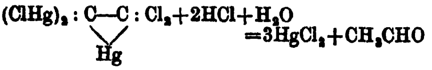
$$(ClHg)_3 \vdots C{\cdot}CHO$$

(trichlormercuriacetaldehyde), which is split up by water to form mercuric chloride and acetaldehyde (Kutscherow, *l.c.*; 42, 2759; Keiser, Amer. Chem. J. 15, 537; Biginelli, Chem. Zentr. 1898, i. 926; Hofmann, Ber. 31, 2212, 2783; 32, 874; 37, 4459; 38, 663; Hofmann and Kirmreuther, Ber. 41, 314; 42, 4232; Biltz and Mumm, Ber. 37, 4417; 38, 133; Annalen, 404, 219; Brame, Trans. Chem. Soc. 87, 427; Erdmann and Köthner, Zeitsch. anorg. Chem. 18, 48; Béhal, Ann. Chim. Phys. [6] 15, 267).

According to Hofmann (*l.c.*) the compound formed has the structure:



and is formed by the addition of two molecules of mercuric chloride to one of mercuric carbide HgC_2, which is then split up by water:



$$(ClHg)_2 : C{-}C : Cl_2 + 2HCl + H_2O = 3HgCl_2 + CH_3CHO$$

(*cf.* Soc. Anon. nouvelle l'Oyonnith, Fr. Pat. 420436). (For further details see ACETYLENE.)

The first English patent dealing with the matter is by the Chem. Fab. Griesheim Elektron (Eng. Pat. 29073, 1910), according to which aldehyde and its polymerisation products, such as paraldehyde and crotonic aldehyde, are produced by the reaction of acetylene with a solution of a mercury salt in an organic or inorganic acid at a temperature below 70° C. Such suitable acids are sulphuric, phosphoric, acetic, chloracetic, &c., the use of 45 p.c. sulphuric acid mixed with mercuric oxide is also recommended at temperatures below 70°. The Consortium f. Elektrochemische Industrie (Eng. Pat. 6000, 1913) describe a modification consisting in passing acetylene through sulphuric acid solutions of mercury oxides containing not more than 60 parts SO_4 in 1000 parts of water, and working at temperatures over 70° C. The aldehyde formed distils off, and mercury is deposited at the bottom of the liquid; the patent also describes an electrolytic process for reoxidising the mercury which is gradually deposited by reduction during the process. The same firm later (Eng. Pat. 16848, 1913) claim a process in which an excess of acetylene is passed through the catalytic solution, the aldehyde formed is carried away in the gas stream, from which it is then removed, and the acetylene passed back to the catalyst.

Bayer & Co. (Eng. Pat. 6527, 1914), (void) claim a process similar to the foregoing, but in which the sulphuric acid is replaced by an organic sulphonic acid, such as the sulphonic acids of benzene, *o*-chlorphenol, naphthalene, or the corresponding di- or tri- sulphonic acids, &c. The chief purpose of using such acids is to avoid the condensation and polymerisation of the acetaldehyde caused by prolonged action of stronger acids such as sulphuric.

Chem. Fab. Griesheim Elektron (Eng. Pat. 15669, 1914) describe the use of a 20–35 p.c. acid mixed with a mercury salt, the temperature being kept below the boiling-point of the acid; sulphuric, phosphoric, or organic sulphonic acids are specified as suitable.

G. Boiteau (Eng. Pat. 15919, 1914), in dealing with the production of a catalytic liquid, produced by dissolving a mercuric salt in a suitable solvent and then forming the sulphate *in situ* by the addition of sulphuric acid, is chiefly concerned with the production of ethylidene diacetate.

A further improvement claimed by the Consortium (Eng. Pat. 16957, 1914) consists in passing an excess of acetylene through a hot solution containing mercury compounds and so adjusting the conditions that a state of thermal equilibrium is approximately attained. This is carried out by adjusting the rate of flow of the gas and the temperature of the reaction vessel, so that the heat evolved by the reaction is balanced by the heat lost by evaporation of water and by addition of fresh water to keep the volume of liquid constant; the reaction may be carried out in thermally insulated vessels surrounded by a water jacket; a temperature of 80° is said to be suitable, using sulphuric acid of 6–35 p.c. strength.

H. W. Matheson, of the Canadian Electro-products Company, describes a process which consists in passing acetylene in excess into sulphuric acid of 6 p.c. strength containing mercuric oxide in suspension, at 40–65° C. and at pressures varying from atmospheric to 3–4 lbs. above: the process is made continuous by the periodic addition of the necessary amounts of water, acid and mercuric oxide. (Eng. Pat. 132557.)

To overcome the difficulty caused by the gradual separation of mercury as a heavy sludge, which is difficult to deal with, Meister, Lucius,

and Brüning (Eng. Pat. 24153, 1914) suggest the introduction of suitable oxidising agents to the reaction liquid, such as ferric salts, chromic acid, or chromates, to prevent the separation of metallic mercury (*cf.* U.S. Pat. 1151928, 1151929; D. R. P. 293070).

A method for overcoming this trouble is given by T. P. Hilditch and J. Crosfield and Sons consisting in the periodic addition of small amounts of suitable oxidising agents such as manganates, permanganates or hydrogen peroxide to reoxidise the sludge to mercuric oxide. (Eng. Pats. 124702, 125926.) Lead peroxide, ceric oxide and manganese dioxide are also claimed (Eng. Pat. 131086).

The Consortium (Eng. Pat. 5132, 1915) state that satisfactory results are obtained by the use of solvents, such as glacial acetic acid, mixed or not with vinyl acetate, ethylidene diacetate, &c., in the presence of mercuric oxide and strong acids; water is added in the theoretical proportions and the temperature kept at 80°–90°. The use of iron or nickel apparatus is also suggested.

The difficulty caused by the formation of the mercury sludge is also discussed by the Chem. Fab. Griesheim Elektron (Eng. Pat. 10140, 1915), who claim the recovery of the mercury by carbonising the residue by heat, or by mixing the sludge with caustic soda and electrolysing.

The Soc. Chem. Ind. in Basle regenerate the catalyst by electrolysis in presence of a suitable oxygen-carrier such as an iron salt (Eng. Pat. 130138).

H. Dreyfus (Eng. Pat. 105064), in a somewhat lengthy claim, states that the production of acetaldehyde is conveniently carried out by observing one or more of the following conditions:—

(1) Sulphuric acid is employed of 5–20 p.c. (2) Less than 20 p.c. of mercury compounds are used. (3) The temperature is kept below 60° C. (4) The acetylene is rapidly introduced in such quantity that it is all absorbed. (5) The acetylene is at first introduced slowly until all the mercury compound becomes grey or greyish-black. (6) After a quantity of aldehyde has been formed the introduction of acetylene is stopped and the temperature raised to distil off the aldehyde, after which the temperature is again lowered and more acetylene introduced. (7) The acetylene is previously purified from sulphuretted hydrogen, phosphine, ammonia, &c. (8) Water is added throughout the reaction to keep the percentage of acid constant. (9) The absorbing solution is first heated up to dissolve all the mercury compounds and then cooled to the temperature suitable for the reaction. (10) The mixture of gas and liquid is strongly agitated, and the acetylene is introduced under slight pressure; in place of sulphuric acid other acids, such as benzene sulphonic acid or phosphoric acid, may be used. The aldehyde may be removed from the solution by evacuation or by solvents such as acetylene or ethylene chlorides or benzene, instead of by distillation. The mercury residue may be regenerated by treatment with suitable oxidising agents; the process may be carried out in lead-lined apparatus, the surface of which is previously coated with a layer of lead sulphate, or iron apparatus lined with acid resisting plates or earthenware may be used. The use of suitable heating and cooling pipes is also described. The same inventor, in a patent of addition to the above (Eng. Pat. 106483), claims a modification of the principal process, using sulphuric acid of over 20 p.c. strength and extracting the aldehyde by means of a solvent such as derivatives of acetylene, ethylene, or benzene.

Dreyfus also claims the use of iron-silicon alloy vessels for the process, which are resistant to hot dilute sulphuric acid and to the action of mercury (Eng. Pat. 115899).

In Eng. Pat. 107584, the Deutsche Gold and Silber Scheide Anstalt describe a distinctly different process, consisting in passing a mixture of acetylene and steam over contact agents, such as molybdic acid on asbestos, at high temperatures; somewhat similar is the proposal of Chemische Fabrik Rhenania (Eng. Pat. 109983), to pass acetylene and steam over bog-iron ore at 400°–420°; in place of bog-iron ore, hydrated iron oxide, bauxite, hydrated aluminium silicates, or compounds of copper, nickel, cobalt, manganese, chromium, cerium, or vanadium may be used. (*Cf.* also Eng. Pat. 107585.)

Of later developments we may note that Hibbert and Morton (U.S. Pats. 1213486; 1213487; 1247270; Can. Pats. 181655; 181656; 181657) recommend the introduction into the catalytic mercury solution of a salt of a weak acid, specifically a borate; the absorption of the acetylene and the distillation of the acetaldehyde is said to be more rapid and complete, and the tendency to the formation of undesirable by-products is said to be greatly reduced. They also claim the use of several catalytic baths arranged in series so that the vapours pass through them all in succession.

The Comp. des Produits chim. d'Alais, in Eng. Pat. 130650, describe the production of acetaldehyde from acetylene in an apparatus in which the reaction liquid is subjected continuously to a vacuum so as to remove the aldehyde as formed.

As actually carried out on the large scale at the Shawinigan works of the Canadian Electro products Co., acetylene gas is led into dilute sulphuric acid containing mercuric oxide in suspension, the oxide being led in continuously and the acetaldehyde removed by the large excess of acetylene used: the requisite oxide is prepared by electrolysing mercury in large cast iron pots 6 ft. in diameter and 15 ins. high using the mercury as the anode and dilute caustic soda as the electrolyte. (Can. Chem J. III. 260 (1919).)

Substituted acetaldehydes applicable to perfumery can be obtained by condensing a ketone with a halogen or amino substituted acetic ester in the presence of sodium. The α-hydroxy acrylic ester thus obtained is saponified and decomposed by heat or distillation under reduced pressure (J. Soc. Chem. Ind. 23, 455).

Properties.—Aldehyde is a colourless liquid b.p. 20·8°, m.p. −120·7°, and sp.gr. 0·80092 at 0° (Kopp, Annalen, 64, 214); 0·79509 at 10° 0·79138 at 13°, 0·78761 at 16° (Perkin, Chem Soc. Trans. 45, 475). It has an extremely pungent suffocating odour; it is very inflammable, and burns with a feebly luminous flame.

It is soluble in all proportions in alcohol, ether, and water, and is separated from the aqueous solution as an ethereal layer on addition of calcium chloride. It possibly forms an addition compound with water

$$CH_3·CHO+H_2O = CH_3·CH(OH)_2$$

(*aldehydrol; ethylidene glycol*) (Ramsay and Young, Trans. Roy. Soc. 1886, i. 117; Perkin, Trans. Chem. Soc. 51, 815; Binot and Pickering, *ibid.* 71, 774; Homfray, *ibid.* 87, 913; Colles, *ibid.* 89, 1249). When heated with aqueous soda, potash, or barium hydroxide, so-called aldehyde resin is obtained as a brown mass (Liebig, *l.c.*; Weidenbusch, Annalen, 66, 153; Lederer, Monatsh. 22, 536). Sodium amalgam converts aldehyde into ethyl alcohol, a small quantity of β-butyleneglycol, which is also formed by the action of magnesium amalgam (Meunier, Compt. rend. 134, 473; Tistschenko and Grigoreeff, J. Russ. Phys. Chem. Soc. 38, 540; Voronkoff, *ibid.* 38, 547), being formed simultaneously (Kekulé, Annalen, 162, 310). With sodium, acetaldehyde reacts violently, producing the compound $CH_2 : CH·ONa$, which rapidly polymerises to a brown substance, whilst if the reaction takes place in presence of benzoyl chloride in ethereal solution aldehydoaldolbenzoate $C_{13}H_{16}O_4$, m.p. 86°-87°, is formed (Freer, Amer. Chem. J. 18, 552; Annalen, 293, 326). Phosphorus pentachloride reacts with it, yielding ethylidene dichloride (Geuther, Annalen, 105, 323). With potassium cyanide alanine and α-imino dipropionic acid are formed (Franzen and Ryser, J. pr. Chem. 88, 293).

Reduction of Aldehyde.—In presence of reduced nickel hydrogen reduces aldehyde to ethyl alcohol, a good yield and pure product being obtained (Sabatier and Senderens, Compt. rend. 137, 301). Modifications of this process have been worked out and patented. Thus, H. Dreyfus (Eng. Pat. 108856) describes the production of ethyl alcohol by the action of hydrogen on acetaldehyde in the presence of suitable catalysts such as platinum, platinised asbestos, copper, iron, chromium, nickel, cerium, uranium, vanadium, and their oxides, &c. The reaction is carried out by passing the mixture of hydrogen and aldehyde vapour through reaction vessels or tubes at temperatures ranging from the boiling-point of aldehyde to 400° C., and condensing the product. The Elektrizitäts Werke Lonza (Swiss Pat. 74129, 1917) claim the production of alcohol by passing aldehyde vapour and a large excess of hydrogen over a heated catalyst (Eng. Pat. 120163; *cf.* also 128929). It is understood that the last-named firm has been granted a concession from the Swiss Government to manufacture 7000 tons of alcohol a year from calcium carbide at their works at Visp in the Rhone Valley, and are to supply not less than 2500 tons alcohol to the Government J. Ind. and Eng. Chem. 1917, 903). An acetic acid factory is also being constructed at Wallis.

For the production of one ton of alcohol by this process about one ton calcium carbide is necessary, and 500 cubic metres of hydrogen; the former requires some 8000 kw. hours and the latter about 3000 kw. hours. In addition each ton alcohol requires 2500 kg. of coal and 4000 kg. limestone (Chem. Ind. 1917, 335).

Oxidation of Aldehyde.—With potassium permanganate, acetic acid is formed, but in presence of excess of potash, oxalic and carbonic acids are also formed (Denis, Amer. Chem. J. 38, 561).

It has been found possible to oxidise acetaldehyde on a commercial scale by means of oxygen or air in the presence of a suitable catalyst. The various patented processes may be divided into two classes:—

(1) Where air or oxygen is passed into the liquid aldehyde containing a dissolved catalyst.

(2) Where the two substances are passed over a heated catalyst.

(1) The Consortium f. Elektrochemische Industrie (Eng. Pat. 16849, 1913) claim the production of per-acetic acid by treating acetaldehyde with oxygen at a low temperature, preferably with the exclusion of injurious impurities, such as water and manganese compounds. The reaction is said to be facilitated by the use of chemically active rays. On allowing per-acetic acid obtained from acetaldehyde to attain the room temperature it is decomposed by the remaining aldehyde into acetic acid.

(From this it would seem possible that in the various processes next to be described, the first stage in the production of acetic acid is the addition of oxygen to form per-acetic acid $CH_3·CHO+O_2=CH_3·CHO·O_2$, which then reacts with acetaldehyde, yielding acetic acid:

$$CH_3·CHO·O_2+CH_3·CHO=2CH_3·COOH.)$$

The same patentees next described (Eng. Pat. 17016, 1913) the production of acetic acid by oxidising aldehyde by means of air or oxygen in the presence of a manganese compound acting as a catalyst. The catalyst is preferably employed in the dissolved or colloidal condition which may be prepared by introducing permanganates into the aldehyde when reduction takes place to a catalytically active brown liquid.

In Eng. Pat. 17018, 1913, the Consortium describe a modification of Eng. Pat. 16849, 1913, consisting in obtaining per-acids by adding certain metal salts, other than manganese compounds, such as compounds of chromium, cobalt, iron, uranium, and vanadium. The use of ferric acetate is claimed by Th. Dreyfus in Eng. Pat. 130035.

A further modification of Eng Pat. 17016, 1913, is claimed by the Consortium (Eng. Pat 7418, 1914), consisting in substituting for permanganates the formate, acetate, butyrate, benzoate, lactate, or other organic salt of manganese.

Meister Lucius and Brüning (Eng. Pat. 10377, 1914) assert that greatly improved results are obtained by passing in the air or oxygen under pressure; thus, for instance, oxygen at a pressure of two atmospheres is passed into acetaldehyde containing 1 p.c. by weight of ceric oxide; the temperature rises to 50°-60°, and cooling is necessary. Yields up to 95 p.c. are claimed; as catalysts are mentioned also ferric oxide, vanadium pentoxide, chromium oxide, and platinum black. A table is given, showing the influence of pressure:—

Acetic Acid obtained p.c. of Theoretical Yield.

	With catalyst.	With pressure.	With pressure and catalyst.
After 1 hour,	4 p.c.	5 p.c.	35 p.c.
After 5 hours,	16 p.c.	20 p.c.	95 p.c.

A somewhat different process is given in Eng. Pat. 14113, 1914, by the Chemische Fabrik Griesheim Elektron, consisting in manufacturing acetic acid by passing acetylene and oxygen alternately or simultaneously into acetic, chloracetic, lactic, or other organic acid containing water, to which has been added a mercury compound with or without the addition of bisulphate, sulphuric acid, &c. Aldehyde is first formed when passing in acetylene, and is then oxidised to acetic acid by the oxygen subsequently introduced. This proceeding sounds, however, somewhat dangerous, and is probably less easily controlled than the others. The B.A.S.F. claim a process for carrying out the oxidation by means of air or oxygen in presence of iron compounds and organic salts of alkalis and alkaline earths, including magnesium and aluminium (D. R. P. 294724).

(2) The second method is described by the Chem. Fab. Griesheim Elektron (Eng. Pat. 17424, 1911), and consists in adding acetic acid, chloracetic acid, or acetic anhydride to the aldehyde before the commencement of the oxidation. A catalyst such as vanadium pentoxide, uranium oxide, or roasted ferrosoferric oxide, Fe_3O_4, facilitates the reaction. The process may be conducted in tubes or towers, &c., packed with glass or clay. In an addition to this patent (8076, 1912) an improvement is claimed consisting in treating small quantities of aldehyde with oxygen in vessels, tubes, towers, &c., until the greater part is oxidised to acetic acid, and then adding further quantities of aldehyde and passing a stronger current of oxygen, whereby oxidation proceeds rapidly. The process may be accelerated by the addition of a catalyst, such as those already mentioned.

H. Dreyfus (Eng. Pat. 105065) claims the production of acetic acid by passing a mixture of aldehyde vapour with air or oxygen through vessels or tubes containing contact substances, such as platinised asbestos, preferably at a temperature above the boiling-point of acetic acid; the mixture of aldehyde vapour and air or oxygen may be preheated to a suitable temperature before entering the contact apparatus; the heat of the gases issuing from the contact apparatus may be utilised for this purpose, the process being carried out in apparatus similar to that employed in the manufacture of sulphuric anhydride by the contact process.

The same inventor in a later patent (Eng. Pat. 108459) describes a further modification of the previous process consisting in oxidising acetaldehyde by means of air or oxygen at temperatures of 150°-250° C. either in presence or absence of a catalyst. Suitable catalysts are stated to be: platinum, copper, copper oxide, chromium oxide, uranium oxide, vanadium oxide, cerium oxide, iron, pumice, &c. The gases are preferably caused to travel through a long path in the reaction apparatus, and the air employed is preferably in excess of the theoretical amount. Further improvements given in Eng. Pat. 110545, by the same patentee, are chiefly concerned with minor details; thus the mixture of aldehyde vapour and air may be obtained by passing air through liquid aldehyde and passing the mixture into the reaction chamber; or liquid aldehyde may be vaporised by a current of air in the bottom of the reaction chamber itself, the latter being provided with suitable agitators. The temperature of the liquid aldehyde or of the air may be regulated so as to control the composition of the mixture of vapour and gas, or the liquid aldehyde may be suitably diluted, say, with acetic acid for the same purpose. The liquid acetic acid formed collects in a suitable part of the apparatus and flows away, while the issuing gas containing aldehyde may be treated again, or the contained aldehyde may be recovered and re-used (*cf.* Fr. Pat. 479656, and additions 20201, 20202).

In Eng. Pat. 116279, S. Utheim claims the production of acetic acid from aldehyde by the action of oxygen under pressure, the aldehyde being supplied to the oxygen in a confined space in limited quantities, *e.g.* in a number of narrow tubes with suitable cooling. Whilst the Comp. des Prod. chim. d'Alais describe the oxidation as taking place in suitable towers by means of air or oxygen in absence of a catalyst, the product being heated continuously to destroy any peracetic acid formed (Eng. Pat. 130651).

The process described in Eng. Pat. 109983 by the Chemische Fabrik Rhenania falls into a somewhat different category, as it deals with the direct production of acetic acid from acetylene by passing the latter, mixed with steam, over partially reduced bog iron-ore; the process does not, however, appear to be of much importance owing to the poor yield.

Hibbert (U.S. Pat. 1230899; Can. Pat. 178237) recommends the use of wood charcoal previously saturated with strong acetic acid to promote the reaction between acetaldehyde and oxygen, using it as a packing for towers through which the mixture is passed. A 90 p.c. yield of 70 p.c. acid is obtained, working at 45° C.

W. H. Matheson, of the Canadian Electro-products Co., Shawinigan Fall, Quebec, states that the oxidation process carried out at these works is done in aluminium vessels, as copper, iron, etc, are unsuitable and have led to violent explosions (Can. Chem. Jour. III. 260 (1919). These works manufactured synthetic acetone and acetic acid for the British Government during the war, and from Nov., 1917, to Nov., 1919, about 10,000 tons glacial acetic acid were shipped to England, chiefly for the manufacture of acetylcellulose for aeroplane dope; at the time of the Armistice (Nov. 11, 1919), the plant had been enlarged to produce about 1600 tons per month at a total capital cost of about £800,000. According to A. F. Cadenhead (Can. Chem. Jour. III., 268 (1919)), one ton of carbide produces on an average about half a ton of acetic acid.

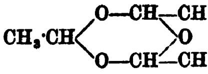
When subjected to electrolysis in faintly alkaline or neutral solution it is decomposed into alcohol and acetic acids (Slaboszewicz, Chem. Zentr. 1903, i. 279; Law, Chem. Soc. Trans. 1905, 198; Jackson and Laurie, *ibid.* 1906, 156), whilst when heated alone to high temperatures carbon monoxide and methane are the chief products (Bone and Smith, Chem. Soc. Trans. 1905, 910; Ipatieff, Chem. Zentr. 1906, i. 87; Nef, Ann. 318, 198). Action of silent electric discharge (*cf.* Besson and Fournier, Compt. rend. 150, 1238). Action of ultra-violet rays (Berthelot and Gaudechon, Compt. rend. 56, 233).

Acetaldehyde and its dimethyl derivative have antiseptic properties (Coblenz, J. Soc. Chem. Ind. 17, 728; Pasqualis, Chem. Zentr. 897, ii. 10, 12). It is also useful in photographic developing (Seyewetz, Bull. Soc. chim. 9, (3) 134), and the vapour or solution in alcohol or benzene slowly hardens dry gelatine films (Beckmann, Chem. Zentr. 1896, ii. 930; D. R. P. 116446; 116800).

Production of synthetic rubber indirectly rom aldehyde, *see* Dubosc (Caoutchouc et Gutta Percha, 9, 6608, 6713). In presence of alumina at 400° isopropyl alcohol condenses with aldehyde to give a good yield of piperylene Ostromisslensky, J. Russ. Phys. Chem. Soc. 47, 1507). By passing aldehyde and alcohol vapours over heated catalysts, such as alumina, phosphoric acid, &c., butadiene is formed Ostromisslensky, J. Russ. Phys. Chem Soc. 7, 1494, 1509). Precipitated alumina is pecially noted as, heated to 369°–460°, a 6–18 p.c. yield of pure erythrene is obtained.

Aldehyde readily polymerises in the presence of small quantities of various substances, such as sulphuric acid, phosgene, zinc chloride, hydrogen chloride, sulphur dioxide, the halogens, particularly iodine, &c., and two compounds are obtained the relative quantities of which depend upon the temperature; the chief pro-uct being *metaldehyde* $(C_2H_4O)_3$ (Hanriot and Oeconomides, Ann. Chem. Phys. [5] 25, 227; McIntosh, Chem. Soc. Trans. 1905, 790; Vecchini, Gazz. chim. ital. 22, ii. 586), when he action takes place in a freezing mixture; nd the isomeric *paraldehyde* (elaldehyde) when t occurs at the ordinary temperature.

Paraldehyde $(C_2H_4O)_3$ is prepared from cetaldehyde by the addition of a drop of con-entrated sulphuric acid, the liquid boiling up t once with almost explosive violence; the product can be purified either by freezing out below 0° and removing the liquid portion, or y washing with a little dilute sodium carbonate solution, drying over calcium chloride and rectifying (Fehling, Annalen, 27, 319; Werden-usch, *ibid.* 66, 155; Geuther and Cartmell, *ibid.* 112, 17; Geuther, Zeitsch. f. Chemie, 865, 32; Lieben, Annalen, Suppl. 1, 114 861–2; Kekulé & Zincke, Annalen, 162, 143; Brühl, *ibid.* 203, 26, 43; Franchimont, Rec. rav. chim. 1, 239; Desgrez, Bull. Soc. chim. 1, [3], 362; Wachhausen, Chem. Zentr. 1897, 493; Ciamician and Silber, Ber. 35, 1080). Polymerisation is also caused by halogen ydracids (MacIntosh, J. Amer. Chem. Soc. 3, 588). In the latter case addition products re formed, *e.g.* $(C_2H_4O)_3\cdot 3HCl$, m.p. −18°; $(C_2H_4O)_3\cdot 3HBr$, m.p. −15°; $(C_2H_4O)_3\cdot 3HI$, quid below −32°. Paraldehyde is a clear mobile colourless liquid of pleasant odour and harp taste, b.p. 124°, D_{20} 0·994, m.p. 12·5°. t possesses the same molecular weight also in he vapour phase, and in solution (Patern and asini, Ber. 19, 2529; Carrara and Terrari, azz. chim. ital. 36, i. 426). It is sparingly 12 parts paraldehyde, the solubility diminishing on warming; it does not show the characteristic aldehyde reaction; thus it does not reduce ammoniacal silver nitrate, does not resinify on heating with aqueous potash, and does not unite with ammonia or bisulphites; its formula is therefore assumed to be:



On warming with a little sulphuric acid it is readily depolymerised completely into ordinary aldehyde; many other reagents also produce the same effect; it may also occur on very long standing (Troeger, Ber. 25, 3317). Owing to the ease of depolymerisation paraldehyde is frequently made use of in place of aldehyde for many reactions where the monomolecular form is inconvenient to use owing to its low boiling-point.

Thus it condenses with diacetoneamine to form vinyldiacetoneamine (E. Fischer, Ber. 17, 1793; C. Harries, Ber. 29, 522); with aniline to form quinaldine (D. R. P. 24317; 28217; 35133; Eng. Pat. 956, 1883; 4207, 1883), and with hydroxyquinol to form yellow dyes (Liebermann and Lendenbaum, Ber. 37, 1171, 2728).

Paraldehyde sets free iodine from alkali iodides (Wachhausen, Chem. Zentr. 1897, i. 493). It is not attacked by pure nitric acid, but is readily oxidised if nitrous acid be present (Behrens and Schmitz, Annalen, 277, 313, 335).

Smits and de Leeuw assume the existence of an equilibrium of a pseudo-ternary system of aldehyde-metaldehyde-paraldehyde, the values for the different components varying according to the catalyst (Smits and de Leeuw, K. Akad. Wetenschapen, 1910, 318; Amer. Chem. Abstr. 1911, 1862; Zeitsch. physiol. Chem. 77, 268). Paraldehyde is used to some extent as a soporific.

Metaldehyde crystallises in needles or tetragonal prisms, sublimes without previous fusion at 112°–115°, and when heated in sealed tubes at 120° is entirely reconverted into ordinary aldehyde (Friedel, Bull. Soc. chim. 9, (3) 384). According to Troeger (Ber. 25, 3316), after standing for ten years a sample was converted into aldehyde and paraldehyde, but according to Hantzsch and Oechslin (Ber. 40, 4341), metacetaldehyde is not isomeric with paracetaldehyde, and is quite stable when pure. Orndorff and White (Amer. Chem. J. 16, 43) state that when it is allowed to stand for some time the metaldehyde is converted into tetraldehyde $(C_2H_4O)_4$.

Neither polymeride is resinised by aqueous soda or potash, but in other reactions they behave generally as ordinary aldehyde and yield similar products (Kekulé and Zincke).

Formation of Acetic Ester.—Another important change of the nature of polymerisation takes place under certain conditions, causing the formation of acetic ester in excellent yield.

Tischtschenko (J. Russ. Phys. Chem. Soc. 38, 398–418; Chem. Zentr. 1906, ii. 1309, 1552) proposes the following method of working: Acetaldehyde is cooled down to −20° C., uncrushed aluminium ethylate is added, and the mixture allowed to stand for several days decided that the yield of acetic ester increases with the amount of alcoholate added but only to a certain maximum limit namely 69·1 p.c. of ester (using 15 p.c. of aluminium ethylate), and that it is necessary to use the alcoholate in lumps; he also concluded that by using small quantities of the catalyst the yield of ester is lessened, with increased formation of by-products, and when only about 4 p.c. alcoholate is used the formation of by-products predominates over the ester condensation.

The Consortium f. Elektrochemische Industrie found later (Eng. Pat. 26825, 1913) that the various drawbacks could be overcome by adding to the aluminium alcoholate certain catalytic substances, such as tin chlor-ethylate, which are without catalytic activity themselves but increase the power of the alcoholate very greatly; thus, in an example, 150 parts anhydrous aldehyde were cooled down to 0° C., and 9 parts of aluminium ethylate previously fused with 10 p.c. of tin chlorethylate (from 20 parts tin tetrachloride and 14 parts absolute alcohol) were added during half an hour, with vigorous stirring and efficient cooling. After ten hours the odour of aldehyde had disappeared and the product was distilled, 96 p.c. of almost pure acetic ester coming over between 74° C. and 80° C. A comparative experiment in which the stannic chlorethylate was omitted gave only a 19 p.c. yield. In Eng. Pat. 26826, 1913, by the same firm, a further improvement is claimed, using instead of anhydrous aluminium ethylate, the same body treated with a small quantity of water or with substances containing water, in particular aluminium hydroxide. In an example the following figures are given:—

Kind of alcoholate.	Al. content.	Yield of ester.
Untreated	17·7 p.c.	21 p.c.
Fused with a little water	21·0 p.c.	87 p.c.
Untreated	17·7 p.c.	23 p.c.
Fused with $Al(OH)_3$.	24·8 p.c.	85 p.c.

The further improvements claimed in Eng. Pat. 4887, 1915 (*idem.*) consist in increasing the activity of the catalyst by dissolving in the melted alcoholate suitable substances such as dehydrated potash alum, dehydrated copper sulphate or camphor, or by supercooling the alcoholate, *e.g.* by melting and cooling rapidly by pouring into a solvent or on to a metal plate. Ethyl acetate is of special use as a solvent; the mixture of melted alcoholate and added substances mentioned above may also be dissolved in ethyl acetate; the solutions may be employed hot, or may be allowed to cool with partial separation of the alcoholate from solution.

Meister, Lucius and Brüning describe (Eng. Pat. 1288, 1915) the production of acetic ester from aldehyde by means of aluminium alcoholate, the latter being dissolved in a suitable organic solvent such as dry solvent naphtha.

(*Aluminium Alcoholate.*—The production of this catalyst is described by Farbw. v. Meister, Lucius, and Brüning in D. R. P. 286596, and addition 293613, and in 289157. According to those specifications aluminium ethoxide is obtained in good yield from aluminium and anhydrous alcohol if, in presence or absence of halogen alkyls or iodine, small amounts of mercuric chloride are added as a catalyst; other alcohols may be substituted for ethyl alcohol, yielding the corresponding alcoholates.

Upon subsequent vacuum distillation for the purpose of purifying the crude product, the aluminium ethylate goes over readily without bumping, solidifying to a snow-white mass, while mercury is not carried over with it. Or the ethylate may be distilled under atmospheric pressure without decomposition if the vapours are rapidly withdrawn from further super-heating. This may be effected by employing a low form of distilling vessel whereby condensation in the upper part of the vessel is prevented.)

Reactions.—Aldehyde in aqueous solution very readily reduces an ammoniacal solution of silver nitrate giving a bright metallic mirror. Acetaldehyde (and all aldehydes which are stable in aqueous soda solution) can be detected by adding to a solution of the suspected substance in dilute alkali a fresh solution of 1 part of paradiazobenzenesulphonic acid in 60 parts of water rendered alkaline with a little soda, and then some sodium amalgam; if an aldehyde is present, a reddish-brown colour is developed after the mixture has stood for 10-20 minutes (Penzoldt and Fischer, Ber. 16, 657).

A solution of rosaniline decolourised by sulphurous acid (Villiers and Fovolle, Compt. rend. 119, 75), or magenta bleached by sunlight (Blaser, Chem. Zentr. 1899, ii. 848), regains its original colour on addition of an aldehyde (Denigès, Compt. rend. 150, 529). This reaction is due to the formation of coloured compounds by the condensation of the aldehyde and magenta (Urbain, Bull. Soc. chim. 1896, iii. 15, 455). With salts of *m*-diamines aldehydes give coloured solutions with intense greenish fluorescence (Bitto, Frdl. 36, 369). With sodium nitroprusside and alkali, acetaldehyde gives a cherry-red colouration, whilst if tri-methylamine is first added a blue colour is produced (Bittoi Annalen, 267, 372; 269, 377; Denigès, Bull. Soc. chim. 17, (3) 381; Simon, Compt. rend. 125, 1105; Bull. Soc. chim. 19, (3) 297). Thiosemicarbazide mixed with an aldehyde in acetic, alcoholic, or aqueous solution yields characteristic thiosemicarbazones. Acetaldehydethiosemicarbazone has m.p. 146° (Freund and Schander, Ber. 35, 2602). Phenylhydrazone α-form, m.p. 98°-101°; β-form, m.p. 57° (Lockemann and Liesche, Annalen. 342, 14; Laws and Sidgwick, Trans. Chem. Soc. 99, 2085). Toschi and Angiolani (Gazz. chim. ital. 45, i. 205) recommend the use of 4-4′-diphenylsemicarbazide, the acetaldehyde derivative having m.p. 133°-134°.

Other tests for aldehydes are described by Ihl, Chem. Zeit. 14, 1571; Doebner, Ber. 27, 352, 2020; Lumière and Seyewetz, Bull. Soc. chim. 19, (3) 134; Rimini, Atti Real. Acad. Lincei, 1901, 10, 355; Murco, Compt. rend. 31, 943; Riegler Frdl. 42, 168; Behrens, Chem. Zeit. 26, 1125; Sadtler, J. Soc. Chem. Ind. 23, 387; Prud'homme, Bl. Soc. Ind. Mulhouse, 1904, 74, 169; Leys, J. Pharm. Chim. 1905, 22, 107; Auld and Hantzsch, Ber. 38, 2677.

Quantitative Estimation.—*Cf.* Rieter, Chem. Zentr. 1896, ii. 368; Rocques, Compt. rend. 127, 526, 764; Seyewetz and Bardin, Bull. Soc. chim. [3] 33, 1000; Colles, Trans. Chem. Soc. 89, 1249. Colorimetric estimation, Paul, Zeitsch. f. anal. Chem. 35, 649; Tolman, J. Amer. Chem. Soc. 28, 1624; by means of pyrrole, Sobolev and Saleski, Zeitsch. physiol. Chem. 69, 441. Estimation in presence of paraldehyde, Richter, Pharm. Zeit. 57, 125; Heyl, *ibid.* 28, 165, 720. In presence of acetone, Hagglund, Zeitsch. anal. Chem. 53, 433.

Condensation Products.—Aldehyde readily yields condensation compounds; thus when allowed to remain in the cold with dilute hydrochloric acid, or with aqueous solutions of zinc chloride or of salts having an alkaline reaction, such as potassium carbonate, aldol is obtained.

The Dupont de Nemours Powder Co. describe (Eng. Pat. 17259, 1911) the production of acetaldol by means of a solution of alkali or alkaline carbonate, borate, phosphate, or cyanide; the acetaldol so produced may be extracted with ether; or the solution may be reduced by aluminium amalgam to yield butylene glycol. A further patent by the same firm (Eng. Pat. 22621, 1912) claims the production of aldol by treating aldehyde with an alkaline substance, such as an alkali hydroxide or salt, sodium ethylate &c., dissolved in a solvent containing little or no water. Ethyl alcohol is mentioned as a suitable solvent (*cf.* also Swiss Pat. 64932; U.S. Pat. 1151113).

The Consortium f. Eletrochemische Industrie in Eng. Pat. 19463, 1913, claim the production of aldol by treating aldehyde in the absence of water with a small quantity of an alkali or alkaline earth metal, or alloy or amalgam thereof, or with their compounds with aldehyde or with other compounds of these metals that are soluble in aldehyde, such as the alcoholates or cyanides. By slow distillation *in vacuo* aldol is obtained, and by slow distillation at ordinary pressure crotonic aldehyde is formed. Organo-metallic compounds are formed by adding alkali and alkaline-earth metals to aldehyde in the absence of water (*cf.* also D. R. P. 269996).

According to N. Grünstein (Eng. Pat. 101636) aldol and other condensation products are obtained from acetaldehyde by treating the latter with quicklime or strontia; the reaction is facilitated by the addition of a trace of water. The condensation can also be effected by means of other condensing agents, such as alkaline earth metals or their carbides, such as calcium carbide, mixed or not with the oxides; the aldehyde is preferably introduced during the process. The aldol produced can be distilled *in vacuo.* Hibbert describes the production of aldol by dissolving aldehyde in gasoline and treating the solution, after cooling to −10°, with potash or caustic soda (U.S. Pat. 1086048).

Crotonaldehyde is formed when it is heated with concentrated hydrochloric acid (Kekulé, Annalen, 162, 92; Kling and Roy, Compt. rend. 144, 1111; Zeisel and v. Bitto, Monatsh. 29, 591), or with concentrated sulphuric acid (Delépine, Compt. rend. 133, 876; 147, 1316; Bull. Soc. chim. 27 [3] 7).

Aldehyde has also been condensed with other aldehydes and ketones (Wallach, Chem. Zentr. 899, ii. 1024; Schmalzhoffer, Monatsh. 211, 671; Wogrinz, *ibid.* 22, 1; Weiss, *ibid.* 25, 1065; Schachner, *ibid.* 26, 65; Salkind, J. Russ. Phys. Chem. Soc. 37, 484; Rainer, Monatsh. 25, 1035; Ehrenfreund, *ibid.* 26, 1003); with amines (Eibner and Peltzer, Ber. 33, 3460; Eibner, Annalen, 328, 121; Knoevenagel, Ber. 37, 4461); with rhodanic and substituted rhodanic acids forming stable dyeing compounds (Andreasch and Zipser, Monatsh. 24, 499; 26, 1191; Zipser, *ibid.* 23, 592; Stachetz, *ibid.* 26, 1209; Bergellini, Atti Real. Acad. Lincei, 15, 35, 181; Andreasch, Monatsh. 27, 1211; 29, 399; Wagner, *ibid.* 27, 1233); with methyl ketole forming leuco- bases of the dyes of rosaniline type (Freund and Lebach, Ber. 36, 308; Freund, Ber. 37, 322); with indole dyes, also forming leuco- bases (Loew, Ber. 36, 4326); with cyanides and cyanacetic esters (Claisen, Ber. 25, 3164; Barbier and Bouveault, Compt. rend. 120, 1269; Kohn, Monatsh. 19, 519; Wade, Chem. Soc. Proc. 1900, 156; Bertini, Gazz. chim. ital. 31, i. 265; Fiquet, Bull. Soc. chim. 7, (3) 767); with phenyl hydrazones (Fischer, Ber. 29, 793; 30, 1240; Pechman, Ber. 31, 2123; Bamberger and Pemsel, Ber. 36, 85; Lockmann and Liesche, Annalen, 342, 14; Medvedeff, Ber. 38, 16646, 2283; Maurenbrecher, Ber. 39, 3583; Laws and Sidgwick, Trans. Chem. Soc. 99, 2085); with *o*-hydroxy nitroso compounds pyrazine derivatives are formed (Lange, Ber. 42, 574). Substances capable of use in perfumery can be obtained by condensing aldehydes with negatively mono- substituted acetic acids in presence of ammonia or a primary or secondary amine (J. Soc. Chem. Ind. 24, 689, 1323). (For compounds of other substances with aldehydes, *see* Hooker and Carnell, Chem. Soc. Proc. 1893, Fischer, Ber. 27, 165; Claisen, Annalen, 237, 261; Conneler, Chem. Zeit. 20, 585; Kietreiber, Monatsh. 19, 735; Bamberger and Müller, Ber. 27, 147; Rassow, J. pr. Chem. 172, 136, 129; Betti, Gazz. chim. ital. 30, ii. 310; 33, i. 27; Koenigs, Ber. 34, 4336; Moureu and Desmots, Compt. rend. 134, 355; Knoevenagel, Ber. 36, 2136; Hann and Lapworth, Chem. Soc. Trans. 1904, 46; Simon and Conduché, Compt. rend. 138, 977; Darzens, Compt. rend. 142, 214; Eissler and Pollock, Monatsh. 27, 1129; Rolla, Gazz. chim. ital. 37, 623; Senier and Austin, Chem. Soc. Trans. 1907, 1233; Wohl, Ber. 40, 4679; Braun, Ber. 41, 2169; Zeisel and Bitto, Monatsh. 29, 591.)

Additive compounds.—Aldehyde not only shows a strong tendency to yield polymerides and condensation compounds, but unites directly with a large number of substances.

(1) Compounds with alcohols (*v.* ACETALS).

(2) Compounds with acids:—Geuther, Annalen, 106, 249; Lieben, *ibid.* 106, 336; 178, 43; Rübencamp, *ibid.* 225, 279; Schiff, Ber. 9, 304; Ponzio, J. pr. Chem. 161, 431; Schroeter, Ber. 31, 2189; Annalen, 303, 114; Delépine, Compt. rend. 133, 876; McIntosh, Amer. Chem. J. 28, 588; Wegscheider and Späth, Chem. Zentr. 1910, i. 1421 (*v.* ACETALS).

(3) Compounds with alkaline sulphites:—Aldehyde forms definite crystalline compounds when dissolved in concentrated aqueous solutions of the acid sulphites (bisulphites) of the alkali metals. The *potassium* salt $C_2H_4O,KHSO_3$ crystallises in indistinct needles; the *sodium* salt $C_2H_4O,NaHSO_3+\frac{1}{2}H_2O$, in fine needles or nacreous plates. The *ammonium* compound has the formula $C_2H_4(OH)SO_2{\cdot}NH_2$. These salts are almost insoluble in excess of the sulphite, and separate in the crystalline state; from them aldehyde can be obtained by distillation with a

stronger acid, an alkaline carbonate, or by alkali nitrites (Bunte, Annalen, 170, 305; Freundler and Bunel, Compt. rend. 132, 1338; Seyewetz and Burdin, Compt. rend. 141, 259; Rosenheim, Ber. 38, 2005; Coppock, Chem. News, 1907, 225). With hyposulphites in neutral or acid solutions aldehyde hyposulphites are obtained; $2RCHO,M_2S_2O_4$ (J. Soc. Chem. Ind. 25, 475); by varying the condition sulphoxylates of type $RCH_2{\cdot}SO_3M$ can be formed (D. R. P. 180529). Crystalline thioaldehydes are obtained by the action of hydrogen sulphide on an acidified alcoholic solution of aldehyde (Baumann and Fromm, Ber. 22, 2600; Ber. 24, 1419, 1457; Klinger, Ber. 32, 2194; Drugman and Stockings, Chem. Soc. Proc. 1904, 116; Vanino, J. pr. Chem. 185, 367).

(4) Compound with ammonia:—*Aldehyde-ammonia* $C_2H_4O{\cdot}NH_3$, obtained by leading dry ammonia into aldehyde in ethereal solution (Liebig, Annalen, 14, 144; Jean, Bull. Soc. chim. 13, (3) 474; Trillat, *ibid.* 13, (3) 689; Delépine, Compt. rend. 125, 951; 128, 105; 137, 984; 144, 853; Coninck, Compt. rend. 126, 1042; Tschitschibabin, J. Russ. Phys. Chem. Soc. 37, 1229; Duden, Bock and Reid, Ber. 38, 2036; Ciamician and Silber, Ber. 38, 1671; 39, 3942), crystallises in large rhombohedra, melts at 70°–80°, boils at 100° without decomposition, and is decomposed into its constituents on distillation with dilute acids. When hydrogen sulphide is passed through a mixture of aldehyde ammonia and ether a crystalline substance $SH{\cdot}CHMe{\cdot}NH{\cdot}CHMeOH$, m.p. 60°–63°, is obtained (Chabrié, C. R. Soc. Biol. 1896, 3, 72).

(5) Compounds with hydrocyanic acid:—(Tiemann, Ber. 14, 1965; Strecker, Annalen, 91, 349; Erlenmeyer and Passavant, *ibid.* 200, 120).

(6) Compounds with metallic salts:—With mercuric sulphate it forms the compound $SO_4:(HgO)_2:HgC_2H_4O$ (Denigès, Compt. rend. 128, 429); with mercuric nitrate, $C_2Hg_2NO_4H$ (Hofmann, Ber. 31, 2212); and with mercuric acetate alkaline solution at 0°, $CMe{\cdot}HO{\cdot}HgO$ (Lasserre, J. Pharm. 1905, 22, 246). With gold chloride it forms a coloured colloidal solution (Garbowski, Ber. 36, 1215); and with magnesium bromide, the compound $MgBr_2,3CH_3CHO$ (Menschutkin, Zeitsch. anorg. Chem. 53, 26); with calcium cyanide it forms $C_6H_{10}O_6N_2Ca_3$ (Franzen and Ryser, J. pr. Chem. 88, 293); compound with KCN (*cf.* Eng. Pat. 19463, 1913).

Substitution Products.—The action of chlorine on aldehyde has been studied by Wurtz (Annalen, 102, 93), Wurtz and Voigt (Bull. Soc. chim. 17, 402), and by Pinner (Annalen, 179, 21; Coblenz, *l.c.*; Freundler, Bull. Soc. chim. 1, (4) 66; Freundler, Compt. rend. 143, 682). Pinner finds that when chlorine is passed into ordinary aldehyde at 10°, metaldehyde and paraldehyde are first formed, and these subsequently yield substitution-derivatives, of which chloral is the chief product, butyric chloral and dichloraldehyde being formed in smaller quantity. The following derivatives have been prepared:—*Chloraldehyde* $CH_2Cl{\cdot}CHO+\frac{1}{2}H_2O$ (Natterer, Monatsh. 3, 446); with potassium cyanide and ammonium chloride, *β*-chloro-*a*-hydroxy propionic acid is formed (Raske, Ber. 45, 725); *dichloraldehyde*, $CHCl_2{\cdot}CHO$ (Grimaux and Adams, Bull. Soc. chim. 34, 29 Wohl and Roth, Ber. 40, 212); *trichloraldehyde* (*v.* Chloral).

According to S. Utheim chloroform is readily formed by acting upon aldehyde with bleaching powder in the presence of water (Eng. Pat. 116094).

The bromine derivatives, and the action of bromine on aldehyde, have been examined by Pinner (Ber. 7, 1499, and *l.c.*; Bugarsky, Zeitsch. physikal. Chem. 48, 63; Freundler, Compt. rend. 140, 1693; Mauguin, Compt. rend. 147, 747). Reactions of dibromoacetaldehyde (*cf.* Mylo, Ber. 45, 645).

Aldehyde blue is obtained by treating pararosaniline with aldehyde or, better, paraldehyde in aqueous acid solution, and precipitating the dye with sodium chloride. It is soluble in alcohol and ether, and when treated with strong hydrochloric acid is converted into a reddish yellow base which shows all the properties of a rosaniline dye (Gattermann and Wichmann, Ber. 22, 227). By slightly varying the conditions in the preparation of aldehyde blue, *aldehyde green* can also be obtained (Miller and Plöchl, Ber. 24, 1700).

ALDEHYDE GREEN *v.* Triphenylmethane colouring matters.

ALDEHYDINE *v.* Bone oil.

ALDEHYDINES. Compounds formed by the condensation of ortho-diamines with aldehydes (Ladenburg, Ber. 10, 1126) (*v.* Amines).

ALDER BARK. (*Aune*, Fr.; *Erle*, Ger.) *Alnus glutinosa* (Gaert.). Used for tanning and dyeing. The percentage of tannin varies from 16 to 18 (Eitner, Zeit. f. d. Chem. Grossgew. 3, 668; 4, 279).

The tannin appears to be a methyl tannin like that of the oak; it gives a reddish-blue precipitate with ferrous acetate, an olive-green precipitate with ferrous sulphate, and is precipitated by a gum solution.

A solution of the bark is employed for obtaining black, greys, and browns on linen; in Germany for reds; and in Kamchatka for colouring skins a red tint.

ALDOFORM. A formaldehyde preparation.

ALDOL (*β-hydroxybutyric aldehyde; butanol-3-al*) $CH_3CHOH{\cdot}CH_2{\cdot}CHO$ was first obtained by Wurtz in 1872. It is produced by the action of cold dilute hydrochloric acid or other condensing agents, such as alkali acetates, carbonates or bicarbonates, or zinc chloride in aqueous solution, on acetaldehyde.

200 grams acetaldehyde at 0° C. are dropped into 200 grams water at 0° C. and 10 grams potassium carbonate are gradually added. The mixture is allowed to stand for 12–18 hours at 10° C., then shaken, first with an equal volume of ether, and again with half its volume of ether. The aqueous solution is exactly neutralised with hydrochloric acid and again extracted with half its volume of ether. The ether extracts are then united, the ether distilled off, and the residue distilled *in vacuo.* (*Cf.* art. Aldehyde.)

Aldol is a colourless liquid which boils at 83° (20 mm.), and has a specific gravity of 1·121 at 0°. It is miscible with water and alcohol. When distilled under atmospheric pressure it loses water and passes into *crotonaldehyde* $CH_3{\cdot}CH:CH{\cdot}CHO$; a similar result being obtained by heating it to 100° C. with water containing a small amount of sodium hydroxide.

As an aldehyde, it reduces an ammoniacal solution of silver nitrate.

On standing for some time aldol becomes viscous, and after some days solidifies, passing into the solid polymeric form known as *paraldol.* This form melts at 82°C., and on reduction with aluminium amalgam yields β-butylene glycol $CH_3·CHOH·CH_2·CH_2OH$.

The above compound furnishes an example of the so-called 'aldol condensation,' which has been studied at length by von Lieben and his pupils (Monatsh. 1901, 22, 289), and the requisite condition for such a reaction is that the carbon atom adjacent to the carbonyl group of the aldehyde should be united to at least one hydrogen atom, although this need not be the case when the condensation occurs between two different aldehydes, *e.g.*

$$(CH_3)_3C·CHO+R_2CH·CHO$$
$$=(CH_3)_3C·CHOH·C(R_2)CHO$$

A similar type of reaction is also possible between aldehydes and ketones, which fulfil the suitable conditions.

As a class, the aldols are colourless liquids which readily polymerise on standing. These polymerides show the same chemical reactions as the liquid forms, and are partially reconverted into such forms on distillation *in vacuo.* When distilled under atmospheric pressure the aldols decompose, partly into the constituent aldehydes from which they were produced, and partly into the corresponding unsaturated aldehyde (by loss of water).

ALDOSES *v.* CARBOHYDRATES.

ALE *v.* BREWING.

ALEMBROTH, SALT OF. A compound of mercuric chloride and sal ammoniac

$$2NH_4Cl,HgCl_2,H_2O$$

formed by mixing the two salts in suitable proportions. Also called by the alchemists Salt of Wisdom.

ALEUDRIN. Trade name for carbamic acid ester of αα-dichloro*iso*propyl alcohol.

ALEURITES CORDATA (Steud.). The seeds of this euphorbiaceous plant, which is found largely in Japan, yield Japanese wood-oil (*q.v.*).

ALEURITIC ACID *v.* LAC, Art. RESINS.

ALEURONE GRAINS. Organised granules deposited in the cells of many seeds of plants, generally near the exterior, in which the proteins are mainly concentrated. They were so named by Hartig, who first described them. In many plants, the aleurone grains possess the shape of crystals. Botanists, indeed, regard them as consisting of two parts: (1) a *crystalloid,* crystal-like protein body, and (2) one or more rounded *globoids* mainly composed of mineral matter, in which phosphoric acid, lime, and magnesia are usually the largest constituents.

When the aleurone grains exhibit the form of crystals, it is generally found that they are soft and swell up if treated with weak acids or alkalis. The term 'crystalloid,' as used by botanists in this connection, has reference to the appearance of the aleurone grains, and not to their property of diffusion when dissolved through membranes. According to Tschirch and Kritzler (Chem. Zentr. 1900, ii. 585), the aleurone grains of a variety of plants consist mainly of globulins. The crystalloids consist of at least two globulins, which are soluble in dilute, but insoluble in concentrated saline solutions (*e.g.* ammonium sulphate, sodium chloride with trace of acetic acid, potassium dihydrogen phosphate). A small amount of an albumose is also probably present. The globoids contain a globulin and mineral matter, especially calcium, magnesium, and phosphoric acid; they are soluble in concentrated solutions of ammonium sulphate, acidified sodium chloride, or potassium dihydrogen phosphate. The grains with their enclosures are reserve-food materials which are consumed when the seed germinates. They originate as liquid 'vacuoles,' in which an increasing amount of protein material is gradually deposited. The germinating power of seeds probably depends upon the solubility of the crystalloids in dilute sodium chloride solution.

According to Posternak (Compt. rend. 1905, 140, 322), aleurone grains often contain anhydro-oxymethylene diphosphoric acid, or inositol phosphoric acid $C_6H_6(PO_4H_2)_6$ (phytin). He found the following amounts of nitrogen and mineral substances in the aleurone grains of (1) spruce fir, (2) sunflower, (3) hemp, (4) white lupin:—

	N	K	Ca	Mg	Fe	Mn	P	S	Si
1.	12·97	2·50	0·37	1·25	0·09	0·25	2·67	0·64	0·35

Sodium and chlorine were not found. H. I.

ALFA *v.* HALFA.

ALFALFA. The Spanish name for lucerne, *Medicago sativa* (Linn.).

ALFORMIN. A 16 p.c. solution of basic aluminium formate.

ALGÆ. (*Varech* or *Algues*, Fr.; *Algen*, Ger.). A class of cryptogamous plants including the green, brown, and red seaweeds and vegetable plankton growing in sea-water, and allied mainly green fresh-water plants, including diatoms, desmids, and 'conferva'-like forms. Many of the salt-water species are edible; none of them is poisonous.

Rhodymenia palmata (Linn.) (dulse, dylish, or dellish) and *Alaria esculenta* (murlins) are used as food by the peasantry of the Highlands and of Ireland. *Porphyra laciniata* (Lightf.) (laciniated purple laver), very abundant on the British coasts, is sold in England as laver, in Ireland as sloke, and in Scotland as slaak. *Chondrus crispus* (Linn.) (carrageen, Irish or pearl moss) is collected on the west coast of Ireland, and is frequently used there by painters and plasterers as a substitute for size. It is also used in making jellies, &c., in medicine;

and a thick mucilage scented with some prepared spirit is sold as 'bandolin,' 'fixature,' or 'clysphitique,' and is employed for stiffening silks.

Amongst other algæ having an economic value are Ceylon moss or edible moss (*Gracilaria lichenoides*), found in the Indian archipelago; the agar-agar of Malacca, or agal-agal of China, which is derived from *Gracilaria lichenoides*, *Eucheuma spinosum* (Linn.) and other algæ (*see* AGAR). The substance is now much used in bacteriological research as a nutrient jelly; for gumming silks, paper, &c., and for making a paste not liable to be eaten by insects.

Manna, or mannite, can be obtained from *Laminaria saccharina* (Lamx.) or sugar wrack, found on sandy shores, attached to pebbles.

In Yezo (Japan) different species of *Laminaria* and *Arthrothamnus* are collected for use as edibles, and in large quantities as raw material for iodine manufacture and potassium salts. Other varieties commonly used as a source of iodine are *Ecklonia cava* and *E. bicyclis*.

Alginic acid (Algin) is prepared from *Macrocystis pyrifera*, found on the Pacific coast of America, by treating a sodium carbonate extract with hydrochloric acid, redissolving in sodium carbonate and reprecipitating with acid several times, then dissolving again in sodium carbonate, purifying the sodium alginate by dialysis, decomposing it with hydrochloric acid, and purifying the alginic acid by dialysis. Alginic acid dried at 100° will absorb 200 to 300 times its weight of water. Its optical activity is $[\alpha]_D^{15\cdot5°} = 169\cdot2°$. The sugars produced by hydrolysis with 2 p.c. hydrochloric acid gave a yellow osazone, m.p. 154°-155°, closely resembling *l*-xylosazone, and also a red amorphous osazone.

Algin probably consists of a complex composed of compounds of the pentosan type and cellulose. It has weakly acid properties, and the sodium salt precipitates many metals from solution (Hoagland, J. Agric. Research, 1915, 4, 39; J. Biol. Chem. 1915, 23, 287. *See* IODINE.

The following table shows the composition of various species of algæ; the quantity of nitrogen in some of them is remarkably large:—

Alga	Water	Dry matter	Per cent. nitrogen in dry matter	Protein contained in dry matter
Chondrus crispus, bleached from Bewlay Evans .	17·92	82·08	1·534	9·587
Chondrus crispus bleached second experiment . .	19·79	80·21	1·485	9·281

Laminaria digitata, or dulse tangle . .	21·38	78·62	1·588	9·925
Rhodymenia palmata .	16·56	83·44	3·465	21·656
Porphyra laciniata . .	17·41	82·59	4·650	29·062
(*Sarcophyllis*) *edulis* .	19·61	80·39	3·088	19·300
Alaria esculenta . .	17·91	80·09	2·424	15·150

Certain of the *Laminaria*, after washing to remove salts, are found to be suitable as fodder, and when mixed with hay and straw in lieu of oats are readily eaten by horses. Although poorer in carbohydrates than oats the seaweed is much richer in protein.

In addition to the large amount of chlorine in marine algæ (up to 38 p.c. of the ash) there are often not inconsiderable quantities of iodine, the presence of which is responsible for the employment of seaweeds in the composition of certain 'anti-fat' specifics.

Certain algæ are characteristic of water containing sewage and putrefactive substances in quantity, and some algæ play an important *rôle* in the disinfection of polluted rivers.

ALGAROBILLA. Algarobilla consists of the pods of *Cæsalpina brevifolia*. The tannin, which appears to be a mixture of allagetannin and gallotannin, lies in semi-resinous particles adhering loosely to the somewhat open framework of the fibre. It is one of the strongest tannin matters known, and contains on the average 45 p.c. In character it resembles dividivi, and its extract is somewhat prone to fermentation. It is very suitable for tanning and also for dyeing purposes.

ALGAROTH, POWDER OF. *Pulvis Algarothi, English Powder.* A crystalline oxychloride of antimony, obtained by pouring antimony chloride into hot water. Used in the preparation of tartar emetic (*v.* ANTIMONY).

ALGARROBIN. A natural dye product, obtained from the wood of the carob tree, *Ceratonia siliqua*, found in the Argentine. According to a report of the United States Consul-General at Buenos Ayres, it is largely employed in the Argentine for dyeing khaki cloth for military purposes, and some quantity is also imported to the Continent of Europe. It is said to dye the textile fibres a light brown colour, though if these be previously mordanted, more varied shades may be obtained. As it acts also as a mordant for the coal tar colours, it would appear to be a tannin, and may be allied to ellagitannin, as its name suggests (*cf.* ALGAROBILLA, *l.c.*). A. G. P.

ALGIN. A nitrogenous body obtained from seaweed, somewhat resembling albumen (*v.* ALGÆ). Used in the sizing and finishing of certain textile fabrics as a substitute for Irish moss (carrageen); should contain from 4 to 6 p.c. of alginic anhydride (*v.* IODINE).

ALGIRON (*Alginoid iron*). Trade name for an iron compound of alginic acid (from seaweed); contains 11 p.c. iron.

ALGODONITE. A copper arsenide of a steel-grey colour. Found in the Lake Superior copper-mining district.

ALGOL COLOURS *v.* ALIZARIN AND ALLIED COLOURING MATTERS; VAT DYES.

ALGOLAVE. Trade name for the salicylic ester of propyl oxy*iso*butyric acid.

ALHAGI CAMELORUM (Fischer), **JAWASA, or JAWANI.** A leguminous thorny shrub, widely spread from Greece to dry parts of India, where a drug extracted from it is used for rheumatism, and also as a laxative and diuretic (Pharm. J. [3] 9, 145).

ALIVAL. Iodo hydroxypropane.

ALIZARIN AND ALLIED COLOURING MATTERS. *See* also articles on ANTHRACENE, ANTHRAQUINONE, CHAY ROOT MADDER, METHYL ANTHRACENE, VAT DYES. Madder, *Rubia tinctoria*, which was for a long time used on a large scale in the 'Turkey-red' industry, contains two colouring matters, alizarin and purpurin, of which the former is by far the more important.

Alizarin is not found ready-formed in the madder-root, but exists there as a glucoside called 'ruberythric acid,' which when allowed to ferment, or when boiled with dilute acid, splits up readily into alizarin and glucose.

The colouring matter itself was first isolated from the madder-root in 1827 by Colin and Robiquet, who obtained it by extracting ground madder with hot water and subliming the purified extract carefully in a glass tube.

This method of sublimation was not considered sufficient proof of the existence of alizarin in madder, and it was not till Schunck succeeded in isolating this substance by chemical means from the madder extracts used by dyers that this important point was definitely settled.

In assigning the correct formula to alizarin, considerable difference of opinion existed at first, owing no doubt to some extent to the difficulty experienced in obtaining alizarin in a condition pure enough for accurate analysis.

Schunck proposed the formula $C_{14}H_{10}O_4$, whilst Strecker believed it to be $C_{10}H_6O_3$ and related to 'chloroxynaphthalic acid' (chlorohydroxynaphthaquinone), a derivative of naphthalene, since both these substances on oxidation yield phthalic acid.

Strecker's formula was the more generally accepted by chemists, and chloroxynaphthalic acid was looked upon as being simply chlorinated alizarin, the two bodies being thus related:

$C_{10}H_6O_3$	$C_{10}H_5ClO_3$
Alizarin.	Chlorinated alizarin or Chloroxynaphthalic acid.

In order to prove the relation supposed to exist between these two substances, it was only necessary to replace the chlorine atom in chloroxynaphthalic acid by hydrogen, when alizarin should result.

This operation was eventually accomplished by Martius and Griess, who obtained thus a substance of the formula $C_{10}H_6O_3$, which was, however, not identical with alizarin, and was therefore supposed to be isomeric with it.

Following these experiments of Martius and Griess, Graebe, in 1868, commenced his research on quinones, the working out of which led not only to results which proved beyond a doubt what the chemical nature of alizarin really was, but also eventually resulted in the artificial production of this important colouring matter. In pursuing this investigation Graebe succeeded in preparing chloranil $C_6Cl_4O_2$, by treating phenol with potassium chlorate and hydrochloric acid, and in acting on this with caustic potash he found that two of the atoms of chlorine in this compound became replaced by (OK), producing the potash salt of chloranilic acid $C_6Cl_2(OK)_2O_2$, a change the knowledge of which proved to be of the utmost importance in his subsequent experiments on the artificial production of alizarin.

Chloroxynaphthalic acid was now considered by Graebe to be related to naphthalin in much the same way as chloranil was to benzene, *i.e.* to be a derivative of naphthaquinone.

Soon after this the attention of Graebe and Liebermann was turned to alizarin, which they also thought might belong to the quinone series.

In determining the constitution of this substance, the first step was to obtain some information as to the nature of the hydrocarbon from which alizarin was derived, and this was done in the following way: Alizarin prepared from madder was mixed with zinc-dust and heated strongly in a furnace, according to Baeyer's method of reducing benzenoid compounds, and in this way a crystalline hydrocarbon was obtained having the composition $C_{14}H_{10}$, which on examination was found to be identical with anthracene, a hydrocarbon previously obtained by Dumas and Laurent from coal tar. Using the information already obtained in the research on quinone, Graebe and Liebermann now assumed that alizarin must be a dihydroxyquinone of anthracene, the relation of these substances to one another being seen from the following formulæ:—

$C_{14}H_{10}$	$C_{14}H_8O_2$	$C_{14}H_6O_2(OH)_2$
Anthracene.	Anthraquinone.	Alizarin.

Having thus obtained anthracene from alizarin, it was now only necessary to reverse the operation and convert anthracene into alizarin, and the problem of the artificial production of a vegetable colouring matter would be solved for the first time.

In 1862 Anderson, while investigating anthracene, obtained from it by oxidation a substance of the formula $C_{14}H_8O_2$, which he named oxanthracene.

In this substance Graebe and Liebermann recognised the quinone of anthracene (anthraquinone), the first step in the synthesis of alizarin from anthracene, and in order to convert this quinone into alizarin all that was necessary was to replace two atoms of hydrogen in it by hydroxyl, an operation which is easily done in the following way:—

Anthraquinone when heated with two molecules of bromine in sealed tubes is converted into dibromanthraquinone, thus:

$$C_{14}H_8O_2+2Br_2=C_{14}H_6Br_2O_2+2HBr.$$

This substance when heated with potash exchanges each of its bromine atoms for (OK), yielding the potash salt of alizarin, $C_{14}H_6(OK)_2O_2$, a reaction which is precisely similar to the formation of chloranilate of potash from chloranil as described above. The potassium alizarate thus obtained, when decomposed with hydrochloric acid, yielded alizarin, and thus the problem of the artificial production of alizarin was solved.

In considering this synthesis, perhaps the most remarkable fact, from a chemical point of view, is that, in consideration of the number of possible isomers of alizarin, just that dibromanthraquinone prepared by Graebe and Liebermann should on treatment with potash have yielded alizarin. Had this not been so, the artificial production of alizarin would no doubt have been very much delayed.

The great importance of alizarin as a dyeing agent induced Graebe and Liebermann to patent this process, which proved, however, to be of no commercial value, owing to the great expense attending the use of bromine, and it was therefore desirable to find some new method which would render their discovery important from a manufacturing point of view.

This was first achieved by W. H. Perkin[1] in the following way:—Sulphuric acid, as is well known, forms with many organic bodies compounds called sulphonic acids, which in composition simply correspond to the substance acted on *plus* sulphuric anhydride.

Thus benzene C_6H_6 when treated with sulphuric acid yields benzenesulphonic acid $C_6H_5SO_3H$; naphthalene $C_{10}H_8$, naphthalenesulphonic acid $C_{10}H_7SO_3H$. When fused with caustic potash these sulphonic acids are split up into the potassium salt of the corresponding phenol and potassium sulphite, thus:

$$C_6H_5SO_3H + 3KOH = C_6H_5OK + K_2SO_3 + 2H_2O.$$

Similarly disulphonic acids when fused with potash are converted into dihydric phenols, thus:

$$C_6H_4(SO_3H)_2 + 6KOH = C_6H_4\begin{matrix}OK\\OK\end{matrix} + K_2SO_3 + 4H_2O.$$

In this second example it will be seen that a body is formed which bears the same relation to benzene as alizarin does to anthraquinone, and it was therefore probable that if anthraquinone were subjected to a similar series of reactions, alizarin would result.

The great obstacle to carrying out this synthesis, in the first instance, was the remarkable stability of anthraquinone in general and particularly towards sulphuric acid, which is so great that it dissolves in moderately hot sulphuric acid without change, and crystallises out again in needles on cooling.

When, however, a mixture of anthraquinone and sulphuric acid was heated very strongly, reaction did eventually take place, the product becoming perfectly soluble in water, the solution now containing mono- and disulphonic acids of anthraquinone.

After removing the excess of sulphuric acid from the new product, it was mixed with caustic potash, and heated to about 180°.

During the heating the melt became darker and darker in colour, and eventually almost black, and on dissolving this in water a rich purple solution was obtained which when acidified with dilute sulphuric acid gave a copious precipitate of alizarin.

The great obstacle to the preparation of alizarin—viz. the use of bromine—was thus removed, and, as the future has proved, a process had been obtained by which this colouring matter could be manufactured in quantity and at a price so cheap as entirely to supersede the old method of dyeing with the madder root.

Another process for the manufacture of artificial alizarin shortly afterwards discovered by W. H. Perkin, and largely used by him on a manufacturing scale, is the following:—

Anthracene is treated with chlorine and thus converted into a beautifully crystalline compound called dichloranthracene $C_{14}H_8Cl_2$.

This substance combines with Nordhausen sulphuric acid, forming a bright-green solution, which contains a sulphonic acid of dichloranthracene. When heated with sulphuric acid this substance undergoes a remarkable change, hydrochloric acid and sulphurous acid are evolved, and a disulphonic acid of anthraquinone formed, thus

$$\underset{\text{Dichloranthracene-disulphonic acid.}}{C_{14}H_6Cl_2(SO_3H)_2} + H_2SO_4 = \underset{\text{Anthraquinone disulphonic acid.}}{C_{14}H_6O_2(SO_3H)_2} + 2HCl + SO_2$$

This anthraquinone disulphonic acid when fused with potash yields alizarin.

Although other methods for the production of alizarin have since been devised, there is little doubt that the bulk of the alizarin of commerce is still obtained from 'silver salt,' the name given in the works to sodium anthraquinone-2-sulphonate.

Alizarin, purpurin and similar dyes will not dye unprepared fabrics; these must first of all be mordanted.

The mordants used in this case consist of metallic hydroxides—*e.g.* of aluminium, iron, and chromium. Chloride of tin (tin crystals) is also extensively employed.

With alumina mordants alizarin produces shades of red and pink; with iron mordants, shades of black and purple; with chromium mordants, a dull purple; and with tin crystals a bright yellowish orange. These mordants may also be mixed and thus a large variety of different shades produced. A description of the method of application of these various mordants and the processes employed in dyeing with alizarin will be found in the article DYEING.

Since the first production of artificial alizarin on the large scale, the study of this substance and of the various colouring matters related to it has received a large amount of attention at the hands of chemists, the result being that a considerable number of derivatives of anthraquinone have been prepared and examined.

Most of these are either colouring matters themselves, or easily converted into such, several of them being obtained on the large scale in the manufacture of alizarin.

These derivatives may be divided under the following heads:—

(1) Sulphonic acids of anthraquinone.
(2) Monohydroxyanthraquinones.
(3) Dihydroxyanthraquinones.
(4) Trihydroxyanthraquinones.
(5) Higher hydroxylated anthraquinones.

In this article are included the two dyeing matters, Gallein and Cœrulein, which are very closely allied to alizarin in tinctorial properties, and also a brief description of some acid wool dyes derived from hydroxyanthraquinones.

Sulphonic acids of anthraquinone.

Anthraquinone-1- (or α-) sulphonic acid

$$C_6H_4<\begin{matrix}CO\\CO\end{matrix}>C_6H_3{\cdot}SO_3H \quad (1)$$

It is a remarkable instance of the influence of a catalyst that whilst anthraquinone ordinarily sulphonates in the 2- position, yet in the presence of quite small amounts of mercury the 1- position is almost exclusively attacked.

In preparing anthraquinone-1-sulphonic acid 100 parts of anthraquinone are heated for three hours at 130° with 110 parts of sulphuric acid, containing 29 p.c. sulphuric anhydride, and 0·5 part of mercury.

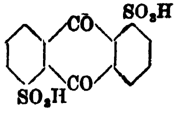
The free acid is easily soluble in alcohol and

---

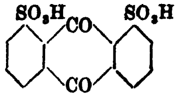
[1] It should be mentioned here that while these experiments were in progress, Caro, Graebe and Liebermann were investigating the same reaction in Germany.

water, its lead, barium, and strontium salts are very insoluble in hot water. The calcium salt is fairly soluble, but crystallises on heating the solution. The potassium salt occurs in glistening yellow leaflets.

Anthraquinone-1 : 5- and -1 : 8-disulphonic acids



and



The further sulphonation of the α acid in presence of mercury leads to the formation of 1 : 5- anthraquinone disulphonic acid, mixed with 1 : 8- and 1 : 7- acids. The same mixture is produced by the direct sulphonation of anthraquinone (100 parts) with 200 parts of sulphuric acid containing 40 p.c. sulphur trioxide, in the presence of mercury (1 part) at 160° for one hour. The mixture of acids is converted into calcium salt and fractionally crystallised. The calcium salt of the 1 : 8- acid is least soluble, the middle fraction is the largest and consists of 1 : 5-, whilst the calcium salt of 1 : 7- is easily soluble.

Alternatively and preferably the acids may be separated by taking advantage of their different solubilities in sulphuric acid. The reaction mixture obtained in the above described preparation would be mixed with 100-200 parts of sulphuric acid (60° Be.), and the 1 : 5- acid is then obtained in the crystalline condition and collected on asbestos. The 1 : 8-isomeride is precipitated from the filtrate on the addition of half its volume of water. Both acids are converted into potassium salts by adding potassium chloride to their hot aqueous solutions. The success of these sulphonations depends very largely on the even distribution of the mercury catalyst throughout the mass, and to attain this end the mercury may be introduced in the form of yellow mercuric oxide, or a mercurous or mercuric salt, and intimately mixed with the anthraquinone employed in the operation. The discovery of a simple method of manufacture of these α-sulphonic acids of anthraquinone led to a great development in the anthracene series of dyes, especially in connection with the production of acid wool dyes of the type of Alizarin Saphirol, and a whole series of vat dyes, for example, the Algol colours (*see* VAT DYES).

The α-sulphonic acids may also be obtained by the oxidation of the sulpho-derivatives of anthracene. Thus anthracene α- and θ-disulphonic acids yield anthraquinone-1 : 8- and 1 : 5-disulphonic acids respectively on treatment with nitric acid. Chlorine or bromine atoms in the alpha position in the anthraquinone nucleus may be displaced in favour of the sulpho-group by treatment of these halogen derivatives with aqueous sodium sulphite. Neither of these methods possesses technical importance.

Literature.—Liebermann and Dehnst (Ber. 12, 1288), Iljinsky (Ber. 36, 4194), Schmidt (Ber. 1904, 37, 66; Eng. Pat. 10242 and 13808, 1903; D. R. P. 157123, 164292, and 167169), Cain (Intermediate Products for Dyes, Macmillan, 1918, 243).

Anthraquinone-2- (or β-) sulphonic acid

$$C_6H_4{<}\begin{matrix}CO\\CO\end{matrix}{>}C_6H_3(SO_3H).$$

This acid is formed together with a certain amount of anthraquinone disulphonic acid by heating anthraquinone with fuming sulphuric acid to 170° or with ordinary sulphuric acid to 250°-260°.

In preparing it a mixture of one part of fuming sulphuric acid (containing 40–50 p.c. anhydride) and 1–1½ parts of anthraquinone is gradually heated to about 160° and kept at this temperature for eight or ten hours, the whole being well stirred during the operation.

The product thus formed consists chiefly of the monosulphonic acid together with a little disulphonic acid and unchanged anthraquinone. On diluting with water the anthraquinone separates out, and can easily be filtered off, leaving the sulphonic acids in solution. In order to separate the mono- from the disulphonic acid the clear filtrate is neutralised with carbonate of soda (or caustic soda). This causes the difficultly soluble sodium salt of anthraquinone monosulphonic acid to separate out, leaving the easily soluble salt of the disulphonic acid in solution.

The pasty mass obtained on neutralising with soda is thoroughly pressed, washed with a little water, and then if required pure recrystallised from this solvent. In this way a beautiful brilliant white scaly crystalline mass is obtained, which consists of pure sodium anthraquinone monosulphonate, the so-called 'silver salt' of the alizarin manufacturer. This salt crystallises with $1H_2O$, and 100 parts of water dissolve 5·59 parts at 18°, and 18·88 parts at 100°.

The free acid obtained by the addition of an acid to the soda salt crystallises in plates. It is very easily soluble in cold water and alcohol, but almost insoluble in ether.

Dünschmann has pointed out that acids other than the β-acid are obtained in this process and that, after the greater part of the 'silver salt' has separated, further concentration gives a product containing the two monosulphonic acids of anthraquinone mixed with the 2 : 6-disulphonic acid. The final mother liquor contains the 2 : 7-disulphonic acid. A hot saturated solution of the mixed acids is treated with one-tenth of its volume of a 45 p.c. solution of sodium hydroxide and cooled to 55°–60°, whereupon most of the 2 : 6-acid separates as sodium salt, whilst on cooling the mother-liquor sodium anthraquinone-1-sulphonate crystallises. To avoid the formation of these by-products Grandmougin employs as sulphonating agent an acid containing only 15 p.c. SO_3 at 150°, and under these conditions it is stated that only the β-acid is produced.

When fused with caustic soda, this acid (or rather its sodium salt) gives first hydroxyanthraquinone $C_6H_4{<}\begin{matrix}CO\\CO\end{matrix}{>}C_6H_3OH$, and then alizarin; and, as will be shown later on, alizarin, when prepared on a manufacturing scale, is invariably formed from the monosulphonic acid of anthraquinone, not from the disulphonic acid as might be expected. The reason for this is that on fusing hydroxyanthraquinone with caustic soda, a continuous process of oxidation and reduction is carried on, the change being represented by the following equation:—

$$C_{14}H_7(ONa)O_2+NaOH+O$$

Sodium monohydroxyanthraquinonate.

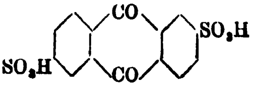
$$=C_{14}H_6\begin{pmatrix}ONa\\ONa\end{pmatrix}O_2+OH_2$$

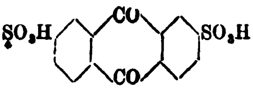
Sodium alizarate.

the oxygen being supplied at the expense of a part of the hydroxyanthraquinone which is thereby reduced to anthraquinone. On the large scale this reduction is prevented by the use of chlorate of potash in the fusion.

Literature.—Graebe and Liebermann (Annalen, 160, 131; 212, 44; Ber. 7, 805); Grandmougin (Lehrbuch der Farben Chemie, 4th ed. 1913, 260); Dünschmann (Ber. 37, 321).

Anthraquinone-2 : 6- and 2 : 7-disulphonic acids (α- and β-disulphonic acids respectively),





In the presence of the mercury catalyst anthraquinone-2-sulphonic acid is attacked in the positions 5 and 8, yielding anthraquinone-1 : 6- and 1 : 7-disulphonic acids, the constitutions of which have been proved by conversion into the corresponding hydroxyanthraquinones by heating under pressure with milk of lime. On the other hand, sulphonation, in the absence of mercury, of either anthraquinone or its β-sulphonic acid, yields a mixture of the 2 : 6- and 2 : 7-acids. The higher the temperature the greater the proportion of the α- or 2 : 6-acid which is formed.

(1) A mixture of 10 kilos of anthraquinone and 20 to 30 kilos of fuming sulphuric acid, containing 45–50 p.c. SO_3, is heated to a temperature of 160°–170° until a sample taken out is found to dissolve completely in water. The product is then heated another hour to convert any mono- into disulphonic acid, poured into water, neutralised with caustic soda, and evaporated.—(2) 10 kilos of anthraquinone, 12 kilos of hydrogen sodium sulphate, and 40 kilos of ordinary concentrated sulphuric acid are heated under pressure for five or six hours to 260°, the product treated with water, and the acids converted into sodium salts as above.

In concentrating the solution of the sodium salt obtained by either of the above methods, the sodium salt of the α-acid crystallises out first, the more readily soluble salt of the β-acid remaining in the mother-liquors, and thus by repeated recrystallisation, the two acids are easily separated from one another.

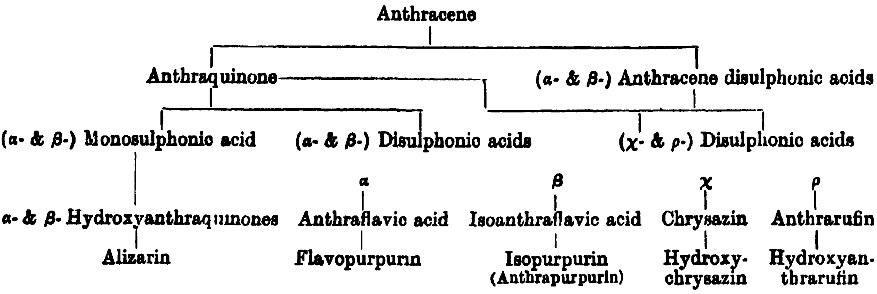
The free acids obtained by decomposing the salts by an acid are both readily soluble in alcohol and water, but insoluble in ether and benzene; the α-acid crystallises in small yellow crystals, the β-acid in beautiful yellow plates.

The salts of the α-acid are sparingly soluble in water and crystallise with difficulty; those of the β-acid are readily soluble and crystallise with the greatest ease.

The sodium salt of the α-acid crystallises with $7H_2O$, that of the β-acid with $4H_2O$.

Literature.—Schultz (Chemie des Steinkohlentheers, 709, 712); Perkin (Chem. Soc. Trans. 1870, 133); Graebe and Liebermann (Annalen, 160, 134); Crossley (J. Amer. Chem. Soc. 1915, 37, 2178).

The relation of the various colouring matters of this group to anthracene, anthraquinone, and its sulphonic acids is easily understood from the following table (Schultz):—



Anthracene
Anthraquinone
(α- & β-) Anthracene disulphonic acids
(α- & β-) Monosulphonic acid
(α- & β-) Disulphonic acids
(χ- & ρ-) Disulphonic acids
α
β
χ
ρ
α- & β- Hydroxyanthraquinones
Anthraflavic acid
Isoanthraflavic acid
Chrysazin
Anthrarufin
Alizarin
Flavopurpurin
Isopurpurin (Anthrapurpurin)
Hydroxychrysazin
Hydroxyanthrarufin

The behaviour of the anthraquinone disulphonic acids on fusion with potash is exactly similar to that of the monosulphonic acid. Just as this acid on fusion with potash is first converted into monohydroxyanthraquinone and then by oxidation into dihydroxyanthraquinone (alizarin), so the anthraquinone disulphonic acids in the first place yield the corresponding dihydroxyanthraquinones, which then by the further action of the potash are converted into trihydroxyanthraquinones.

The sulphonic acids of anthraquinone are important intermediates apart from their conversion into the various hydroxy derivatives. The sulphonic group may be displaced by amino, alkylamino-, and arylamino- groups, usually by treatment with ammonia or an amine at a high temperature and occasionally in the presence of a copper compound, sodium carbonate, or an oxidising agent. Moreover, the chloro- derivatives of anthraquinone are most conveniently prepared by the action of sodium chlorate on a solution of an anthraquinone sulphonic acid in dilute hydrochloric acid at

90°-100°. For example, 1 : 5-dichloroanthraquinone used for the manufacture of Indanthrene Violet R.N. is obtained in this way from anthraquinone-1 : 5-disulphonic acid (D. R. P. 205195).

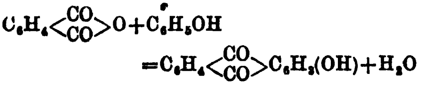
Hydroxyanthraquinones.

I. Monohydroxyanthraquinones

$$C_6H_4{<}\begin{matrix}CO\\CO\end{matrix}{>}C_6H_3OH$$

1- Hydroxyanthraquinone. Erythroxyanthraquinone.

This substance is formed together with 2-hydroxyanthraquinone by strongly heating a mixture of phenol and phthalic anhydride with sulphuric acid



$$C_6H_4{<}\begin{matrix}CO\\CO\end{matrix}{>}O+C_6H_5OH$$
$$=C_6H_4{<}\begin{matrix}CO\\CO\end{matrix}{>}C_6H_3(OH)+H_2O$$

Also by heating 1-bromanthraquinone with potash to 160° or by acting on 1-amidoanthraquinone with nitrous acid in concentrated sulphuric acid solution.

The most satisfactory method of preparation consists in heating anthraquinone-1-sulphonic acid with water and an oxide, or hydroxide of an alkaline earth metal under pressure.

1-Hydroxyanthraquinone crystallises from alcohol in orange-red needles which melt at 190°. When fused with potash it gives alizarin. The substance does not dye mordanted fabrics.

1-Acetoxyanthraquinone, prepared by boiling erythroxyanthraquinone with acetic anhydride and sodium acetate, crystallises in yellow needles from alcohol and melts at 176°-179°.

1-Methoxyanthraquinone is obtained by the action of boiling methyl alcoholic potash on 1-nitroanthraquinone.

This is the simplest example of a very general reaction in the anthraquinone series. The substance is yellow, microcrystalline, and melts at 140°-145°.

Literature.—Baeyer and Caro (Ber. 7, 969); Pechmann (Ber. 12, 2128); Römer (Ber. 15, 1793), Liebermann and Hagen (Ber. 15, 1804); Hoechste Farbwerke (D. R. P. 97688).

2- Hydroxyanthraquinone.

This substance is obtained synthetically (together with erythroxyanthraquinone) by heating a mixture of phenol, phthalic anhydride, and sulphuric acid. The mixed hydroxyanthraquinones can be separated by means of baryta water, since the barium salt of 1- hydroxyanthraquinone is insoluble, whilst the 2- hydroxy compound is easily soluble. It crystallises from alcohol in yellow plates which melt at 323° and readily sublimes at a higher temperature.

It can be obtained in various ways from anthraquinone or its derivatives.

An easy preparation consists in melting anthraquinone sulphonic acid or 2- bromanthraquinone with potash.

The action of ammonium persulphate on a solution of anthraquinone in concentrated sulphuric acid containing sulphur trioxide leads to the production of 2-hydroxyanthraquinone, alizarin, and purpurin.

Alizarin is reduced to 2-hydroxyanthraquinone by the action of alkaline stannous chloride; or alizarin amide, obtained by the action of ammonia on alizarin, yields this substance when treated with ethyl nitrite.

A very curious reaction of this hydroxyanthraquinone, and one which involves migration of an oxygen atom, is its conversion to quinizarin by treatment with nitrous acid in sulphuric acid solution and in the presence of boric acid.

Literature.—Graebe and Liebermann (Annalen, 160, 141); Baeyer and Caro (Ber. 7, 969); Liebermann and Fisher (Ber. 8, 975); Liebermann (Annalen, 183, 208); Wacker (J. Pr. Chem. [2] 54, 89); Bayer & Co. (D. R. P. 86830).

Dihydroxyanthraquinones.

Alizarin

1 : 2-dihydroxyanthraquinone

$$C_6H_4{<}\begin{matrix}CO\\CO\end{matrix}{>}C_6H_2(OH)_2.$$

Alizarin occurs in madder as the glucoside ruberythric acid, and also in Chay root (*Oldenlandia umbellata*) and some species of rhubarb.

It is obtained from its glucoside by the action of dilute acids or of ferments.

$$\underset{\text{Ruberythric acid.}}{C_{26}H_{28}O_{14}} + 2H_2O = \underset{\text{Alizarin.}}{C_{14}H_8O_4} + \underset{\text{Glucose.}}{2C_6H_{12}O_6.}$$

It may be prepared artificially by many methods.

Thus alizarin is produced by fusing dichloranthraquinone, dibromanthraquinone, anthraquinone, mono- or di-sulphonic acids with potash. Rufigallic acid yields alizarin when reduced with sodium amalgam.

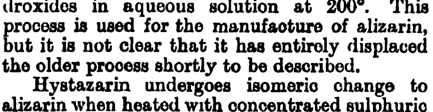
On the other hand, anthraquinone may be directly oxidised to alizarin by the action of ammonium persulphate in concentrated sulphuric acid solution.

Good yields of alizarin are said to be obtained by heating anthraquinone with sodium chlorate and a mixture of sodium and potassium hydroxides in aqueous solution at 200°. This process is used for the manufacture of alizarin, but it is not clear that it has entirely displaced the older process shortly to be described.

Hystazarin undergoes isomeric change to alizarin when heated with concentrated sulphuric acid to 200° for two and a half hours.

Alizarin may be synthesised by processes not involving the intermediate formation of anthraquinone.

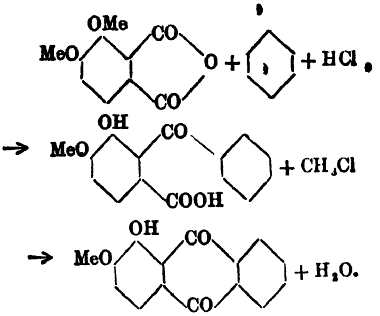
Together with hystazarin it is produced when a mixture of catechol and phthalic anhydride is heated with sulphuric acid at 200°.



$$\underset{\text{Phthalic anhydride.}}{C_6H_4{<}\begin{matrix}CO\\CO\end{matrix}{>}O} + \underset{\text{Catechol.}}{C_6H_4(OH)_2}$$
$$=\underset{\text{Alizarin.}}{C_6H_4{<}\begin{matrix}CO\\CO\end{matrix}{>}C_6H_2(OH)_2 1:2} + H_2O.$$

A method somewhat similar in principle is the following :—

Hemipinic anhydride condenses with benzene in the presence of aluminium chloride, yielding the methyl ether of dihydroxybenzoylbenzoic acid. This latter substance, on treatment with hot sulphuric acid, is converted into alizarin methyl ether, which is hydrolysed by aluminium chloride to alizarin. The following formulæ represent this series of reactions :—



Alizarin methyl ether.

Lagodzinski has converted 1 : 2-anthraquinone into alizarin by reducing this *o*-quinone to 1 : 2-dihydroxyanthracene, the diacetyl derivative of which yields diacetylalizarin on oxidation with chromic acid in acetic acid solution. The diacetate is then hydrolysed.

Finally, alizarin is frequently formed in relatively small proportion in the reduction of 1-nitroanthraquinone, for example, by means of sodium sulphide.

MANUFACTURE OF ALIZARIN.

1. *Anthraquinone process.*—Anthracene, the basis of alizarin, is obtained entirely from the coal-tar oils boiling above 300°, the so-called 'last runnings' of the tar distiller. These heavy oils are redistilled and the anthracene oils collected as soon as the distillate on cooling commences to solidify. In this way a semi-solid greenish-looking mass is obtained, which, after roughly freeing from excess of oil by treatment in hydraulic presses, is the starting-point in the alizarin factory. This crude product contains only about 30–40 p.c. anthracene, the remainder consisting of phenanthrene, naphthalene, carbazol, and small quantities of other hydrocarbons.

The first operation necessary in the manufacture of alizarin is that of purifying the crude anthracene obtained from the tar distillers, in order to obtain a product fit for the subsequent oxidation to anthraquinone.

This process of purification varies considerably in different countries, but the following method may be given as having been used with much success.

The crude anthracene is first ground between edge-runners, and then thoroughly agitated with boiling petroleum spirit in large iron vessels fitted with stirrers and heated with steam.

About 1500 to 1800 lbs. of crude anthracene and 300 gallons of petroleum spirit are used in one operation, the amount of the latter varying slightly according to the quality of the anthracene employed. After boiling for an hour or two, the product is allowed to cool, filtered through coarse canvas, and the anthracene on the filter washed with a little clean petroleum spirit. The pasty mass thus obtained is next treated with steam to remove the excess of petroleum spirit, and then sublimed. The sublimation process is best carried out by melting the anthracene in an iron pot, called the 'subliming pot,' and then blowing in superheated steam. This carries the anthracene vapour forward through a long pipe, where it meets a spray of water, which serves to condense both it and the steam. The anthracene is thus obtained in an extremely finely divided state, much more suitable for oxidation than when simply ground under edge-runners as it used to be. Another process of purification of anthracene consists in washing in a neutral solvent, such as coal tar naphtha, with concentrated sulphuric acid. This treatment removes the basic impurities, and the anthracene is further purified by sublimation. The next step consists in converting the anthracene into anthraquinone by oxidation with bichromate of potash (or soda) and sulphuric acid—an operation which is usually done in the following way:—The anthracene is placed in lead-lined tanks with about twice its weight of the bichromate (dissolved in water), the requisite amount of dilute sulphuric acid is slowly added, and the mass kept well boiled and agitated by a steam jet connected with a Körting's injector.

The whole is then transferred to settling tanks, the crude yellowish-brown anthraquinone well washed by decantation until free from green chrome liquors, well drained, and freed from water as completely as possible by placing it in canvas bags and exposing it to great pressure in a hydraulic press. The amount of oxidiser required to convert the crude anthracene into anthraquinone is of course regulated by the purity of the sample employed, pure anthracene requiring about 1·66 times its weight of potassium bichromate to convert it into anthraquinone.

Instead of potassium bichromate, the sodium salt is now very often used on account of its cheapness.

The anthraquinone thus obtained is still very impure, and must be carefully purified before it can be converted into sulphonic acid. In purifying anthraquinone two methods may be employed:

(1) The anthraquinone is sublimed, and then, if necessary, recrystallised from high boiling coal-tar naphtha.

(2) The anthraquinone is treated with concentrated sulphuric acid.

When the first process is employed, the anthraquinone is melted in iron pots and subjected to the action of super-heated steam. The steam carries the vapour of the anthraquinone with it, and on condensation a fine, almost impalpable powder is obtained, which, when dried and recrystallised from high-boiling coal-tar naphtha, consists of nearly pure anthraquinone.

In this country this process has now been almost abandoned; method (2) having entirely taken its place.

The working of this method is based on the fact that crude anthraquinone when treated with sulphuric acid at 100° dissolves, but is not acted on. The impurities, however, become converted into sulphonic acids, which, being easily soluble, can be removed by treating the product with water, when nearly pure anthraquinone is left behind.

In carrying out this operation a mixture of 1 part of crude anthraquinone and 3 parts of sulphuric acid is placed in large circular lead-lined iron pots, and heated by steam for twenty-four hours, the whole being continuously agitated by a stirrer.

The blackish-looking product is then run into shallow tanks, and exposed to the action of damp air, or a gentle current of steam, until the acid has become diluted. In a short time anthraquinone separates out as a light-brown crystalline powder, which, after washing by dilute soda and by decantation, pressing, and thoroughly drying, is found to contain about 95 p.c. of pure substance.

According to recent patents anthraquinone is best purified by crystallisation from liquid sulphur dioxide or from aniline.

The following account of the manufacture of anthraquinone is given by Cain (Manufacture of Intermediate Products for Dyes, p. 235) as an abstract of a communication by Grandmougin (Rev. prod. chim. 1917, 20, 20):—'The oxidation is effected in lead-lined tubs of about 10–12 cubic metres' capacity (about 2500 gallons), fitted with lead-covered agitators and direct steam pipes, also of lead. 150 kilos of sublimed anthracene are mixed with 3000–4000 litres of water, and the mixture is heated at 75°; 2000 litres of a solution containing 300 kilos of sodium dichromate and 600 kilos of sulphuric acid (66° Be.) are now run in slowly, the temperature being gradually raised to about 95°. The oxidation requires twelve to sixteen hours, and it is important not to add the chromic acid solution too quickly or to work in a too concentrated solution, otherwise much frothing occurs.

'Tests are made by filtering a sample, washing, and subliming it over a naked flame. With a little practice it is easy to distinguish the fine needles of anthraquinone from the silvery leaflets of anthracene. The absorption of the chromic acid can also be ascertained by titration with ferrous sulphate. When the operation is finished, the contents of the tub are run into an egg and blown through a filter press, where the anthraquinone is thoroughly washed, the filtrate being collected in order to recover the chromium. The yield from an anthracene of good quality is about 110 parts of anthraquinone from 100 parts of anthracene. The anthraquinone so obtained is purified by sublimation with super-heated steam; the pan is heated by super-heated water and the sublimed anthraquinone condensed by means of a water jet.'

Other processes for the oxidation of anthracene have been suggested but have not yet displaced the chromic acid method. A brief summary of these methods may be appended:—

(1) Oxidation of anthracene by oxides of nitrogen and air or oxygen alone or in the presence of various catalysts or substances capable of absorbing the oxides of nitrogen. Occasionally the anthracene is mixed with neutral substances, such as powdered glass or pumice. In one process anthracene is added to a solution of nitrogen peroxide in nitrobenzene and the temperature gradually raised to 100°. Anthraquinone is formed, and the nitric oxide is recovered and converted into peroxide for use in a further operation.

(2) Oxidation of anthracene by nitric acid. This is usually carried out in nitrobenzene solution and sometimes in the presence of mercuric nitrate.

(3) Oxidation of anthracene by means of sodium nitrate in the presence of magnesium chloride between 125° and 145°.

(4) Oxidation of anthracene by oxygen in the presence of aqueous ammonia and copper oxide at 170°. Nickel, cobalt, iron, and lead compounds may be used as catalysts instead of copper oxide.

(5) Electrolytic oxidation of anthracene may be carried out in a chromic acid bath or in 20 p.c. sulphuric acid solution in the presence of cerium sulphate.

(6) Oxidation of anthracene by means of ozonised air. In this case the hydrocarbon is dissolved in sulphuric acid.

(7) Oxidation of anthracene by means of a chlorate in aqueous solution in presence of an iron salt.

The following patents deal with the oxidation of anthracene: Eng. Pats. 5539, 1892; 17635, 1901; 759, 1882; 19178, 1902; 8431, 1887; 16312, 1909; 11472, 1910; 12055, 1914; 5514, 1915. Fr. Pats. 220621, 149017, 328069, 416735, 472216. U.S. Pats. 729502, 757136, 1083051, 1103383, 1119546. Ger. Pats. 68474, 137495, 21681, 109012, 152063, 215335, 207170, 234289, 254710, 256623, 268049; Anm. H 61262, 292681.

The next stage in the manufacture of alizarin is the conversion of anthraquinone into its sulphonic acid.

This operation, which consists in heating anthraquinone with fuming sulphuric acid, is conducted in large iron pots capable of holding from 30 to 40 gallons. The amount of fuming sulphuric acid employed depends on the nature of the sulphonic acid required. In preparing the monosulphonic acid, 1 part of fuming acid (contained 40–50 p.c. SO_3) and 1 to 1¼ parts of anthraquinone are used.

The mixture is gradually heated by means of an oil-bath to 170°, or even to 190°, and kept at this temperature for eight or ten hours, the stirrer being kept constantly in motion.

The product, which contains, besides anthraquinonemonosulphonic acid, a little disulphonic acid, and some unacted-on anthraquinone, is diluted with water, passed through a filter-press to remove the anthraquinone, and neutralised with caustic soda.

In a short time the whole becomes quite thick owing to the separation of the sparingly soluble soda salt of anthraquinonemonosulphonic acid, the easily soluble salts of the disulphonic acids remaining in solution.

The crystalline salt is collected in filter-presses, washed with a little very dilute sulphuric acid, and thus obtained practically pure in beautiful, brilliant, pearly scales.

In preparing the disulphonic acids of anthraquinone, the operation is similar to the above, the only difference being that more fuming sulphuric acid is used and the sulphonation conducted at a much higher temperature (about 260°).

The next operation consists in the conversion of the product just described, and called 'soda salt,' into colouring matter, a change which is accomplished by heating it strongly with caustic soda and a little potassium chlorate.

If the potassium chlorate is not added, a considerable loss is incurred owing to the reducing action of a large quantity of nascent hydrogen, always formed during the fusion, which converts the soda salt partially into anthraquinone and hydroanthraquinone. The fusion is conducted in large wrought-iron cylinders fitted with stirrers and heated with hot air. The usual charge is 700 lbs. caustic soda (70 p.c.) dissolved in water, 1300 lbs. of a concentrated solution of 'soda salt,' and 13 to 15 p.c. of potassium chlorate, the amount of this latter substance varying slightly with the nature of the salt used, the monosulphonic salt requiring more chlorate than the disulphonic salt.

The temperature is maintained at about 180° for at least twenty-four hours and often much longer, the progress of the decomposition being controlled from time to time by extracting small quantities of the melt and examining them in the laboratory.

The product thus obtained is an intense purple fluid, becoming thick on cooling and containing the colouring matter as sodium salt besides sodium sulphite and an excess of caustic soda.

To separate the colour the melt is run into large wooden tanks, diluted with water, and boiled with dilute sulphuric acid.

This causes the solution to become orange in colour owing to the precipitation of artificial alizarin.

After being allowed to settle, the supernatant liquor is run off, the alizarin forced into filter-presses and carefully washed until free from acid and saline matter. The colouring matter is then made up to a definite strength (10 p.c. or 20 p.c. paste as required) by transferring it to large wooden tubs fitted with powerful stirrers, and thoroughly mixing it with water.

Pure alizarin thus prepared produces a blue shade of Turkey-red, and anthrapurpurin (produced by fusing sodium anthraquinonedisulphonate with caustic soda) a red shade, so that by varying the amounts of these two constituents any intermediate shade required by the market can be obtained.

The foregoing may be now supplemented by a description of the manufacture of alizarin which is given by Ullmann. The sulphonation of anthraquinone is carried out in acid-resisting cast-iron vessels heated by super-heated steam. The pots have a diameter of 1165 mm., and height of 1235 mm., and are surmounted by covers which are fitted with a manhole, stirrer, pipe for introducing pressure, plunging tube for thermometer, and a contrivance for the automatic registration of temperature. 300 kilos of sublimed anthraquinone and 200 kilos of recovered quinone (the portion of the substance which is recovered from the sulphonations) are mixed with 400 kilos of oleum (20 p.c. SO_3) and 200 kilos oleum (60 p.c. SO_3), and the mixture heated at 145° during eight hours. This procedure may be modified by introducing half the amount of acid and heating four hours, after which the remainder is introduced during three hours more, and in one or two portions. Before the reaction mass cools it is forced into a lead-lined vat containing 1·5–2 cbm. water with continuous stirring. Further dilution to 5 cbm. is then made, and the mixture heated by the introduction of steam. Between 80 and 120 kilos of anthraquinone remain unattacked and are recovered by filtration through a press. The filtrate is mixed with 85 kilos caustic soda an amount which still leaves the liquor strongly acid, being only about three-eighths of that theoretically required for neutralisation. The difficultly soluble 'silver salt' separates, and is collected in a press. The filtrate is submitted to vacuum evaporation to 22°–23° Bé. (measured while hot), and underneath the evaporator there is a vat provided with stirring apparatus, and into which the liquor is allowed to run for crystallisation. The process is facilitated by providing the vat with a double jacket for cooling. The 'silver salt' is collected in a filter press and washed with brine, in which it is sparingly soluble. The yield of dry salt amounts altogether to 450–500 kilos. It requires no further purification for the preparation of alizarin of bluish shade. The mother-liquor from the monosulphonate is neutralised with lime, and the gypsum separated, after which the calcium salts are converted into sodium salts by means of sodium carbonate and the solution again filtered from chalk. Evaporation yields the 2 : 6- isomeride, and finally the 2 : 7-, but it is perhaps more usual to blow the concentrated mixture directly into the alkali fusion apparatus. The fusion of silver salt with alkali is carried out in a series of horizontally placed cylinders provided with stirring gear and heated by means of super-heated steam. They have to be capable of resisting a pressure of 12 atmospheres. The capacity is about 3550 litres, and they are about 2000 mm. long and have an inside diameter of 1400 mm. The following example of a fusion may be regarded as typical; 1687 cbm. of caustic soda solution (45° Bé.) containing 1030 kilos NaOH, together with 125 kilos saltpetre, are introduced into the pot and heated to about 125°, after which 625 kilos of moist silver salt (66·4 p.c.), corresponding to 415 kilos of the dry substance, are gradually added. The temperature is then raised to 180°, and the pressure reaches 4–4·5 atmospheres. After 36–48 hours the process is usually complete. This is confirmed by testing a sample by boiling with milk of lime, filtering from the sparingly soluble calcium alizarate and acidifying the filtrate, when an incomplete operation is indicated by the separation of golden flakes of oxyanthraquinone. The melt is diluted down to 6° Bé. in large lead-lined tanks, and acidified at 60° with sulphuric acid. For alizarin of especially blue shade the diluted alkali fusion melt is treated in boiling solution with milk of lime until a drop of the liquid placed on filter-paper gives a clear red rim. The calcium salt is then separated and decomposed with hydrochloric acid. The precipitated alizarin is collected in filter presses and washed until the filtrate is free from acid. The press-cakes are analysed for content of anhydrous ash-free alizarin, and on the basis of the analysis a 20 p.c. paste is made in a special mixer made of pitch pine. The paste has a thin appearance, but if it should be desired thicker it suffices to add 0·5–1 p.c. of salt. The thickening of the paste which follows is a most singular phenomenon, and resembles in appearance the salting out of a dye although, of course, the suspended solid is not increased in amount. For some Eastern markets a still thicker paste is prepared by the addition of glycerin, dextrin, molasses, or starch. Alizarin in lumps of such a character that paste may be prepared from them as desired is made by mixing 20 p.c. paste with starch, and then filtering off and very carefully and gradually drying the mixture. As much water as possible is removed by pressure, and the remainder in a vacuum at a temperature not exceeding 60°. During the whole process of alizarin manufacture it is most important that the water used should be soft and as free as possible from iron. Iron in the water will absolutely ruin the value of a batch of alizarin from the point of view of purity of shade. If through some defect in the apparatus a batch should become contaminated it is useless to attempt to purify the dye by solution in alkali, and reprecipitation with acid in view of the circumstance that the objectionable iron derivatives (*cf.* the alizarinferrates below) are reprecipitated along with the colouring matter. The best treatment is with hot dilute hydrochloric acid and just sufficient potassium chlorate to produce a clear yellow colour.

2. *Dichloranthracene process.*—In manufacturing alizarin by this process, which appears to have been abandoned in favour of that already described, it is necessary, in the first place, to purify the anthracene used much more thoroughly than is the case in the anthraquinone process.

For this purpose the anthracene, after washing with petroleum spirit as described in the last process, is submitted to distillation with potash. This removes the carbazol and the phenolic substances present in the crude anthracene, and as, besides this, a considerable quantity of the other impurities are charred during the distillation, the anthracene resulting, although still very impure, is found to be greatly improved in quality.

In carrying out this operation 100 parts of washed anthracene, 30 parts of potash, and 6 parts of powdered lime are thoroughly ground together under edge-runners, the mixture introduced into iron retorts and distilled. The distillate, which consists of pale-yellow cakes containing about 50 p.c. of pure anthracene, is now sufficiently pure for conversion into dichloranthracene.

In chlorinating anthracene, leaden chambers are used, technically known as 'chlorine ovens.' These are 10 ft. long, 4 ft. 6 in. wide, and 1 ft. 6 in. deep, and are used in pairs, connected at one end in order that any chlorine escaping from the first oven may come in contact with a fresh amount of anthracene and thus prevent loss.

400 lbs. of anthracene are put into each oven, and subjected to the action of a rapid current of chlorine for about five or six hours.

The anthracene first fuses and gets dark in colour, hydrochloric acid being evolved in abundance; but after a time this fluid product begins to deposit crystals and soon becomes a semi-solid mass. In order to purify this crude product, it is first freed from hydrochloric acid by washing with dilute caustic soda, and then pressed between linen cloths in a hydraulic press, by which means a considerable quantity of a thick dark oily product, technically known as 'chlorine oils,' is got rid of.

The yellow cakes of dichloranthracene thus obtained are still not pure enough for use; they must next be soaked in coal-tar naphtha for some time and pressed, this operation being repeated until a product is obtained which contains 84 p.c. of pure substance.

The next process consists in converting the dichloranthracene into the sulpho- acids of anthraquinone by treating it with ordinary concentrated sulphuric acid. This decomposition is accomplished in iron pots capable of holding about 30 gallons and fitted with iron covers in which there is an opening for the escape of the acid vapours formed during the reaction.

These pots are charged with 350 lbs. of concentrated sulphuric acid and heated to 140°–160° by means of an ordinary fire, the dichloranthracene (70 lbs.) being shovelled in in small quantities at a time. After all the dichloranthracene has been added and the frothing due to the evolution of the hydrochloric and sulphurous acids produced during the decomposition has subsided, the temperature is gradually raised to 260° and then maintained at this point until a sample taken out on a glass rod and diluted with water forms a nearly clear solution devoid of fluorescence.

The product contains now the mono- and disulphonic acids of anthraquinone, the latter of which greatly predominates.

These crude sulphonic acids are next diluted with water in a large wooden tank and boiled with slaked lime until neutralised. The neutral product is then forced into filter presses to separate the calcium sulphate, the clear filtrate mixed with the washing of the calcium sulphate, evaporated until it contains about 15 p.c. of lime salts, and then treated with sufficient sodium carbonate to precipitate all the lime as carbonate.

The solution of the sodium salts of the sulphonic acids is siphoned from the precipitated calcium carbonate, concentrated until it contains 30 p.c. of soda salts, and then converted into colouring matter by fusion with caustic soda, as described in the last process.

3. *Direct conversion of anthraquinone into alizarin.*—In the preparation of anthraquinone-β-sulphonic acid it is very difficult to avoid the production of some disulphonic acid, and even if the alizarin is purified as described below, the shades obtained on mordanted fabrics are not quite identical with those given by the chemically pure dyestuff. The Badische Anilin und Soda Fabrik claim (D. R. P. 116526) that a remarkably pure alizarin dyeing bluish shades of alizarin red on the usual alumina mordant may be prepared from anthraquinone under the following conditions:—Anthraquinone (100 parts) is heated with a solution of sodium or potassium hydroxide (300 parts) and sodium chlorate (20–30 parts) in water (100 parts) at 200° in an open vessel or autoclave until the oxidising agent is expended. The product is dissolved in water and air blown in order to oxidise anthranols, and the alizarin is then precipitated by the addition of milk of lime. The precipitated salt is decomposed by hydrochloric acid, and the alizarin is separated from accompanying anthraquinone by solution in dilute aqueous sodium hydroxide and acidification of the filtered solution. Other processes have been suggested in which anthraquinone is heated with sodium or potassium hydroxides in the presence of sodium sulphite, with or without an oxidising agent such as sodium chlorate.

Purification of artificial alizarin. Commercial alizarin contains as impurities hydroxyanthraquinone, anthrapurpurin, flavopurpurin, and small quantities of other colouring matters.

In order to separate the alizarin from these, the crude commercial product is dissolved in dilute caustic soda, and the solution treated with carbonic acid until two-thirds of the colouring matter has been precipitated as acid sodium salt. The precipitate is collected, washed with water, decomposed with hydrochloric acid, the crude alizarin thus obtained dissolved in caustic soda, and the treatment with carbonic acid repeated twice more.

The purified product is then boiled with baryta water to remove hydroxyanthraquinone and anthraflavic acid (which dissolve), the barium salt of alizarin is collected, washed, decomposed by hydrochloric acid, and the alizarin either sublimed or recrystallised from alcohol.

Another method of separation is based on the temperatures at which the various constituents of the mixture sublime. Alizarin itself sublimes at 110°, flavopurpurin and anthrapurpurin at 160° and 170° respectively.

Alizarin crystallises from alcohol in red needles or prisms, which melt at 282°. With care alizarin can be sublimed in magnificent deep-red prisms, which, if the operation be performed on a large scale, may be obtained over an inch in length.

It dissolves in alkalis with a purple colour, and is completely precipitated from this solution by the addition of lime or baryta in the form of a blue precipitate of the calcium or barium salt. Heated with acetic anhydride to 160° alizarin forms a diacetyl compound $C_{14}H_6O_2(C_2H_3O)_2O_2$, which crystallises from alcohol in long yellow needles, melting at 160°. When treated with nitrous acid, alizarin yields anthraquinone. Nitric acid acts violently on alizarin with evolution of red vapours and formation of phthalic and oxalic acids. Distillation with zinc reduces alizarin to anthracene.

Alizarin is converted into purpurin by means of sulphuric acid at 225°. In Knecht and Hibbert's titanous chloride reduction method for the estimation of reducible substances it is found that one molecule of alizarin requires for reduction four atoms of hydrogen. On the other hand, Alizarin Orange (see below) is reduced to aminoalizarin under similar conditions.

When fused with alkaline hydroxides at a fairly high temperature, protocatechuic acid and benzoic acid are formed.

Salts of alizarin. *Calcium alizarate*

$$CaC_{14}H_6O_4,H_2O$$

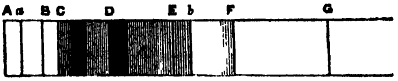
is precipitated by adding calcium chloride to an ammoniacal solution of alizarin as a purple mass. *Barium alizarate* $BaC_{14}H_6O_4,H_2O$ is prepared, like the calcium salt, by mixing an alkaline solution of alizarin with barium chloride. It is deep-violet when moist, almost black when dry, and very sparingly soluble in water. *Aluminium alizarate* $(C_{14}H_6O_4)_3Al_2O_6$(?) is obtained by precipitating an alkaline solution of alizarin with alum or aluminium hydroxide. It is a very fine red or rose-red precipitate. *Lead alizarate* $C_{14}H_6O_4Pb$ is obtained by mixing an alcoholic solution of alizarin with an alcoholic solution of sugar of lead.

Potassium hydrogen alizarate forms a compound with alizarin, brown-red crystals

$$C_{14}H_7O_4K ; C_{14}H_8O_4,$$

and a similar *tri*potassium *di*alizarate has been described. These substances are analogous to the quadroxalates.

Alizarin can readily be detected by means of the spectroscope, as it gives in alkaline solution two sharp absorption bands, one at D and one near G, as will readily be seen from the accompanying figure, which shows the absorption



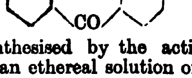
spectrum of a solution of alizarin in alcoholic potash.

Alizarin ferric acid $Fe(C_{14}H_6O_4)_3H_3$ yields well-crystallised sodium, ammonium, and potassium salts. The latter crystallises with $8H_2O$, and is obtained by the addition of alcoholic potassium hydroxide to a mixture of alcoholic solutions of alizarin and ferric acetate.

Literature.—Anderson (J. 1847–48, 749); Stenhouse (J. 1864, 543); Rochleder (Ber. 3, 295); Perkin (Chem. Soc. Trans. 23, 141); Graebe and Liebermann (Annalen Suppl. 7, 300; Ber. 3, 359); Baeyer and Caro (Ber. 7, 972); Liebermann (Annalen, 183, 206); Liebermann and Dehnst (Ber. 12, 1293); Schunck (Annalen, 66, 187); Wolff and Strecker (Annalen, 75, 8); Lagodzinski (Ber. 28, 1428); Widman (Ber. 9, 856); Liebermann and Hohenemser (Ber. 35, 1779); D. Chem. 1906, 19, 669; Ber. 41, 361); Tyrer (Trans. 97, 1778); Hildebrand, Ellefson, and Beebe (J. Amer. Chem. Soc. 1917, 39, 2301).

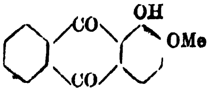
Other derivatives of alizarin. When treated with the ordinary re-agents, such as bromine, nitric acid, &c., alizarin forms a variety of valuable substitution products, some of which are used to a considerable extent as dyeing agents. The most important of these are the following:—

Alizarin α-methyl ether



may be synthesised by the action of diazomethane on an ethereal solution of monoacetylalizarin. Owing to the fact that monacetylalizarin is really a mixture of the two possible isomerides, the process results in a mixture of the two isomeric methyl ethers. Addition of alcoholic potassium hydroxide to the mixture precipitates the β-ether as potassium salt, the α-methyl ether remaining in the solution. The substance crystallises from aqueous methyl alcohol in slender orange-yellow needles melting at 178°–179°, and identical with a constituent of chay root (*q.v.*) (Oesch and Perkin, Proc. Chem. Soc. 1914, 30). The methoxy groups in aromatic compounds (except the nitrophenol ethers) are almost always resistant to alkaline hydrolysis, but this substance may be hydrolysed to alizarin by the prolonged action of boiling aqueous baryta. Acetylalizarin *a*-methyl ether occurs in yellow needles, melting at 212°.

Alizarin-β-methyl ether



The synthesis of this substance from hemipinic acid has already been described.

It can also be produced by treating the monopotassium salt of alizarin with methyl iodide or methyl sulphate.

The substance crystallises from alcohol, and has the melting-point 224°–226°.

The dimethyl ether is not obtained by acting on the potassium salt of the monomethyl ether with methyl iodide.

The substance can, however, be obtained by reducing alizarin to desoxyalizarin and methylating the latter by means of methyl sulphate and sodium hydroxide in the usual manner. On oxidation of the resulting product with sodium chromate and acetic acid alizarin dimethyl ether is obtained in golden yellow needles. It is identical with a product obtained from 2-hydroxyanthraquinone by successive methylation, nitration, and treatment with methyl alcoholic sodium methoxide.

Oesch and Perkin (*l.c.*) have also obtained the substance by the methylation of alizarin *a*-methyl ether with methyl sulphate and potassium hydroxide.

Alizarin diethyl ether

$$C_6H_4{<}\begin{matrix}CO\\CO\end{matrix}{>}C_6H_2{<}\begin{matrix}OEt\ (1)\\OEt\ (2)\end{matrix}$$

can be prepared by heating alizarin with potash and potassium ethyl sulphate at 160° (Habermann, Monatsh. 5, 228).

Monobromalizarin

$$C_6H_4{<}\begin{matrix}CO\\CO\end{matrix}{>}C_6HBr{<}\begin{matrix}OH\ (1)\\OH\ (2)\end{matrix}$$

This derivative can be prepared by heating alizarin with bromine and carbon disulphide to 180°–190° for four or five hours.

It is better prepared, however, by sulphonating alizarin with fuming sulphuric acid, and subsequently treating the solution with bromine.

It crystallises from glacial acetic acid in orange-coloured needles, which, when heated, first melt to an orange-coloured liquid and then sublime in orange-red needles.

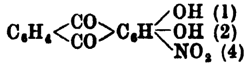
As a dyeing agent, monobromalizarin retains all the properties of combining with mordants possessed by alizarin, and the colours produced appear to be equally fast. The shade of colour produced is, however, not the same, the reds being less purple, and the purples less blue than those produced by alizarin.

Literature.—Perkin (Chem. Soc. Trans. 27, 401).

3 - Bromo - 1 : 2 - dihydroxyanthraquinone (D. R. PP. 77179, 78643) is obtained by the action of bromine on a solution of alizarin-3-sulphonic acid at 95°. It may or may not be identical with the above-described bromoalizarin. It forms brown-red needles, melting at 260°–261°, and yields a pale yellow diacetyl derivative, melting at 204°–205°. The solution of the substance in dilute sodium hydroxide is blue-violet.

3-Chloro-1 : 2-dihydroxyanthraquinone is similarly prepared and melts at 270°–271°. On benzoylation in pyridine solution a *dibenzoyl derivative*, melting at 184°, is obtained. On oxidation by means of sulphuric acid it yields 3-*chloro*-1 : 2 : 4-*trihydroxyanthraquinone* (chloropurpurin), melting at 242°–244°, and on nitration in acetic acid solution 3-*chloro*-4-*nitro*-1 : 2-*dihydroxyanthraquinone* is the product. The latter occurs in orange-yellow needles, which decompose at above 220°. The nitroxyl may be displaced by anilino on heating the substance with aniline, and the product crystallises in nearly black needles or plates melting at 223°-224° (Heller and Skraup, Ber. 46, 2703).

a-Nitroalizarin, Alizarin brown,



$$C_6H_4{<}\begin{matrix}CO\\CO\end{matrix}{>}C_6H{<}\begin{matrix}OH\ (1)\\OH\ (2)\\NO_2\ (4)\end{matrix}$$

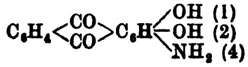
This substance is obtained by treating diacetyl or dibenzoyl alizarin with nitric acid.

It is manufactured by dissolving alizarin in fuming sulphuric acid and after cooling to −5° to −10°, treating with the calculated quantity of nitric acid dissolved in sulphuric acid.

a-Nitroalizarin crystallises from alcohol or glacial acetic acid in golden-yellow needles, melting at 194°–196°. It dissolves in caustic alkali with a blue-violet colour, but if only a minute quantity of alkali is employed the solution is of a fine crimson colour. The alkaline solution gives two absorption bands similar to alizarin. Nitroalizarin is easily reduced in alkaline solution with sodium amalgam or ammonium sulphide and amidoalizarin is the product.

On warming with sulphuric acid 1 : 2 : 3 : 4-tetrahydroxyanthraquinone is produced.

a-Aminoalizarin. Alizarin garnet, Alizarin cardinal



$$C_6H_4{<}\begin{matrix}CO\\CO\end{matrix}{>}C_6H{<}\begin{matrix}OH\ (1)\\OH\ (2)\\NH_2\ (4)\end{matrix}$$

This valuable dye-stuff is obtained by the reduction of *a*-nitroalizarin. It crystallises from alcohol in small needles of a nearly black colour, but possessing a slight greenish metallic reflection.

Its alcoholic solution gives two absorption bands; the first is a little beyond D and the second near C. There is also a faint line close to F.

An excess of acetic anhydride at the boiling-point converts *a*-aminoalizarin into a *diacetyl derivative*, which crystallises in red-brown leaflets melting at 245°, whilst it appears that the moderated action of the reagent produces an isomeric diacetate crystallising in lustrous yellow needles. The *monobenzoyl derivative* is obtained by heating a suspension of the substance in nitrobenzene with benzoyl chloride. It occurs in brown needles, melting at 310°. Further action of benzoyl chloride produces the *dibenzoyl derivative*—light brown needles, melting at 255°. *a*-Aminoalizarin yields a sulphonic acid on treatment with fuming acid, and this may be changed into purpurin sulphonic acid by the action of nitrous acid. The diazonium derivatives obtained from α-aminoalizarin are relatively stable, and on strongly heating purpurin is obtained as a sublimate. Alizarin-α-diazochloride does not couple with known intermediates with formation of azo- compounds.

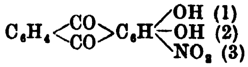
Dyeing Properties of α-Nitro- and α-Aminoalizarin. These colouring matters possess the power of dyeing ordinary madder mordants. α-Nitroalizarin gives with alumina mordants very clear orange-red colours, not unlike some of the colours produced with aurin, and with iron mordants reddish-purple colours. Aminoalizarin gives with alumina mordants purple colours, and with iron a bluish or steel-like colour.

It is used for wool-dyeing and calico-printing.

Alizarin Maroon is a mixture of aminoalizarins and purpurins obtained by the reduction of the product of nitration of commercial alizarin in sulphuric acid solution. On alumina mordants it produces a garnet red, maroon on chrome.

Literature.—Perkin (Chem. Soc. Trans. 30, 578); Brasch (Ber. 24, 1610); Schunck and Römer (Ber. 12, 587); D. R. PP. 66811, 74431, 74598; Schultz and Erber (J. pr. Chem. 74, 275).

β-Nitroalizarin, Alizarin Orange



$$\mathrm{C_6H_4}<\begin{matrix}\mathrm{CO}\\ \mathrm{CO}\end{matrix}>\mathrm{C_6H}<\begin{matrix}\mathrm{OH}\ (1)\\ \mathrm{OH}\ (2)\\ \mathrm{NO_2}\ (3)\end{matrix}$$

β-Nitroalizarin is prepared by the action of nitric acid on alizarin and also by boiling dinitro-2-hydroxyanthraquinone with caustic soda of 20 p.c.

It is manufactured in large quantities by the action of nitric acid on alizarin dissolved in sulphuric acid containing boric acid. The influence of the boric acid on the position attacked by the nitric acid is probably due to the formation of a boric ester of alizarin.

The crude β-nitroalizarin is purified by crystallisation from glacial acetic acid.

β-Nitroalizarin crystallises in orange-yellow needles which melt with decomposition at 244°. When carefully heated it sublimes, with a good deal of decomposition, in yellow needles. Dissolved in alkalis it forms a purple solution; the *sodium* salt is insoluble in an excess of caustic soda. The *calcium* salt is an insoluble violet-red precipitate, which is not decomposed by carbonic acid (distinction from alizarin). Treated with glycerol and sulphuric acid, β-nitroalizarin is converted into alizarin blue.

The diacetate of β-nitroalizarin crystallises in yellow needles melting at 218°.

β-Nitroalizarin is prepared on the large scale, and comes into the market under the name of 'Alizarin orange.' In dyeing it is applied to the various fibres in the same way as alizarin; but although it yields fast colours, it has as yet found only comparatively limited employment. Applied to wool, it gives the following shades:—

With an aluminium mordant it yields a very good orange; with stannous chloride mordant, a reddish or yellowish orange, according to the amount of mordant used; with copper sulphate mordant, a good reddish-brown is obtained; with ferrous sulphate, a purplish-brown; and with bichromate of potash, a dull brownish-red. The dye may also be applied to unmordanted wool in a bath containing acetic or oxalic acids.

Literature.—Rosenstiehl (Bull. Soc. chim. 26, 63); Schunck and Römer (Ber. 12, 584); Simon (Ber. 15, 692); Bayer & Co. D. R. P. 74562; Barnes (J. Soc. Dyers & Col. 15, [1] 11).

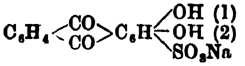
β-Aminoalizarin is changed by benzoyl chloride into a *dibenzoyl derivative*, yellow needles melting at 252°, and this may be hydrolysed by sulphuric acid to a *monobenzoate* melting at 275°. In contradistinction from the corresponding α-derivative, alizarin-β-diazochloride couples with R-salt in alkaline solution, but the product has feeble tinctorial power.

Alizarin Imide. This derivative of alizarin is obtained by heating the substance with ammonia under pressure (Bayer), and also by reducing freshly precipitated alizarin in ammoniacal suspension with zinc dust followed by air oxidation of the resulting solution. According to Prud'homme, alizarin and other hydroxyanthraquinones may be converted into condensation products with ammonia by heating in glycerol with ammonium carbonate. Scholl and Partheg prepare the substance by heating alizarin with aqueous ammonia at 140°. It may be crystallised from pyridine and decomposes with evolution of ammonia at 250°. It is regarded as 1-*hydroxy*-2-*aminoanthraquinone imide*.

Literature.—Prud'homme (Bull. Soc. chim. [iii.] 35, 71; *ibid.* 666); Scholl and Partheg (Ber. 39, 1201).

Leucoalizarin, 1 : 2-Dihydroxyanthranol. This substance is easily prepared by warming alizarin with a dilute alkaline solution of sodium hydrosulphite. It crystallises from acetic acid in brown leaflets melting at 150°, and is easily reoxidised into alizarin (Grandmougin, Rev. Gen. Nat. Col. 21, 44).

Alizarin Red S, Alizarin Powder W (By.), **Alizarin Red WS** (M. L. B.)



$$\mathrm{C_6H_4}<\begin{matrix}\mathrm{CO}\\ \mathrm{CO}\end{matrix}>\mathrm{C_6H}<\begin{matrix}\mathrm{OH}\ (1)\\ \mathrm{OH}\ (2)\\ \mathrm{SO_3Na}\end{matrix}$$

This dyestuff is the sodium salt of the monosulphonic acid of alizarin. It is easily prepared by the action of concentrated sulphuric acid on alizarin.

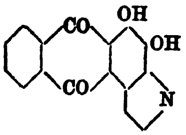
It yields brilliant scarlet red shades with an aluminium mordant, bordeaux red with chromium.

Like many alizarin derivatives, this substance is an indicator. It is more sensitive than methyl orange, the colour change occurring between $\mathrm{P\overset{+}{H}}=3{\cdot}7$ (yellow) and $\mathrm{P\overset{+}{H}}=4{\cdot}2$ (pink).

Literature.—Graebe and Liebermann (Annalen, 160, 144); Walpole (J. Soc. Chem. Ind. 1915, 153).

1 : 2-Dihydroxyanthraquinone-3 : 5-disulphonic acid is obtained, together with quinizarin-α-sulphonic acid, when anthraquinone-1-sulphonic acid or its potassium salt is heated with fuming sulphuric acid (40 p.c. SO_3) and boric acid at 130°–135°. The alizarin derivative is separated by taking advantage of its more sparing solubility. On heating with 70 p.c. sulphuric acid the disulphonic acid is changed into an isomeride of Alizarin Red S, namely 1 : 2-dihydroxyanthraquinone-5-sulphonic acid.

Alizarin Blue,



This important colouring matter, discovered by Prud'homme, is obtained by treating β-nitroalizarin with glycerol and sulphuric acid or by treating β-amino alizarin with glycerol, nitrobenzene, and sulphuric acid. Its chemical constitution was first demonstrated by Graebe, who showed that this substance was related to alizarin in precisely the same way as quinoline is to benzene, *i.e.* that alizarin blue is a quinoline of alizarin.

Preparation.—1 part of β-nitroalizarin, 5 parts sulphuric acid, and 1½ glycerol (of sp.gr. 1·262) are mixed and gently heated.

At 107° the reaction commences and soon becomes very violent, the temperature rising to 200°. After the frothing has subsided, the mass is poured into water, the product well boiled, filtered, and the residue extracted three or four times with very dilute sulphuric acid. The combined extracts on cooling deposit the crude alizarin blue sulphate in brown crystals. These are collected, washed with water till neutral, mixed with water, and borax added until the solution becomes brownish-violet. The precipitate thus formed is filtered off, washed with water, and decomposed with a dilute acid, the crude alizarin blue thus obtained being purified by recrystallisation from benzene or glacial acetic acid.

A more recent method of preparation, also due to Prud'homme, consists in heating formyl-β-aminoalizarin with glycerol and sulphuric acid at 100°.

Alizarin blue crystallises from benzene in brownish-violet needles which melt at 270°, and at a higher temperature give off orange-red vapours which condense in the form of blue needles.

It is insoluble in water, sparingly soluble in alcohol and ether, more readily soluble in hot benzene. It dissolves in ammonia, potash, or soda, forming blue solutions which become green when mixed with an excess of alkali.

Alizarin blue combines with both bases and acids.

The barium salt $BaC_{17}H_7NO_4BaO+\frac{1}{2}H_2O$ is a greenish-blue precipitate. The following salts of alizarin blue with acids have been prepared:—

$C_{17}H_9NO_4,HCl$ is a red crystalline precipitate formed by passing dry hydrochloric acid gas through a solution of alizarin blue in boiling benzene. When treated with water it is completely decomposed into its constituents. The sulphate crystallises in red needles. The acetate $C_{17}H_9NO_4.C_2H_4O_2$ crystallises in blue plates.

Alizarin blue also combines with picric acid forming a compound $C_{17}H_9NO_4{\cdot}C_6H_2(NO_2)_3O$, which crystallises from benzene in long orange-red prisms melting at 245°. This compound is completely decomposed by water. One of the most important compounds of alizarin blue is the sodium bisulphite compound

$$C_{17}H_9NO_4{\cdot}2NaHSO_3$$

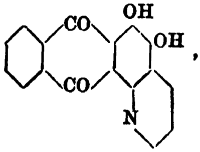
This product is manufactured on a large scale and sold under the name of 'Alizarin Blue S.' It dissolves readily in water, with a brownish-red colour. Alizarin blue is met with in commerce in two forms, viz. as a paste containing about 10 p.c. of dry substance, and as a powder. The former is nearly insoluble in water, while the latter, which is the bisulphite compound (described above), dissolves readily. This soluble kind is now almost entirely used in dyeing. In dyeing cotton with alizarin blue a chromium mordant is used, but in the case of wool, bichromate of potash gives the best results.

Alizarin blue with an alumina or iron mordant is also used for dyeing silk.

Alizarin blue is used largely as a substitute for indigo in calico-printing works. It is one of the most stable colouring matters, and is even said to be faster than indigo itself.

Literature.—Prud'homme (Bull. Soc. chim. 28, 62); Graebe (Annalen, 201, 333); Auerbach (Chem. Soc. Trans. 35, 800); Prud'homme and Rabaut (Bull. Soc. Ind. Mulhouse, 1893, 223).

Alizarin Green S (M)



, $NaHSO_3$.

This dyestuff is prepared from α-aminoalizarin by treatment with glycerol, nitrobenzene, and sulphuric acid, and it may also be produced from formyl-α-aminoalizarin by the action of glycerol and sulphuric acid at 100°. Its production and properties resemble those of alizarin blue. It is employed in printing, and is used with a nickel magnesia mordant.

Purpuroxanthin. 1 : 3-Dihydroxyanthraquinone

$$C_6H_4{<}^{CO}_{CO}{>}C_6H_2{<}^{OH\ (1)}_{OH\ (3)}$$

Purpuroxanthin exists in small quantities in madder. It can be prepared by heating purpurin $C_{14}H_5(OH)_3O_2$ with iodide of phosphorus and water, or more readily by boiling purpurin with caustic soda and chloride of tin.

Preparation. — Purpurin is dissolved in a boiling solution of caustic soda (10 p.c.), and chloride of tin added until the solution loses its deep-red tint and becomes of a yellow colour. Hydrochloric acid is then added, the precipitate washed with strong hydrochloric acid, dissolved in baryta water, reprecipitated with hydrochloric acid and crystallised from alcohol.

Purpurin is also readily reduced by means of an alkaline solution of sodium hydrosulphite.

Purpuroxanthin crystallises in reddish-yellow needles which melt at 262°–263°. It dissolves in alkalis with a reddish colour. If the solution in caustic potash be boiled in the air, it absorbs oxygen, the purpuroxanthin being reconverted into purpurin.

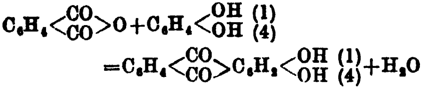
It is not a mordant dyestuff.

Literature.—Schützenberger and Schiffert (Bull. Soc. chim. 4, 12); Liebermann (Annalen, 183, 213); Schunck and Römer (Ber. 10, 172).

Quinizarin. 1 : 4-Dihydroxyanthraquinone

$$C_6H_4<\begin{matrix}CO\\CO\end{matrix}>C_6H_2<\begin{matrix}OH\ (1)\\OH\ (4)\end{matrix},$$

is obtained by heating a mixture of quinol or *p*-chlorphenol and phthalic anhydride with sulphuric acid.



$$C_6H_4<\begin{matrix}CO\\CO\end{matrix}>O+C_6H_4<\begin{matrix}OH\ (1)\\OH\ (4)\end{matrix}$$
$$=C_6H_4<\begin{matrix}CO\\CO\end{matrix}>C_6H_2<\begin{matrix}OH\ (1)\\OH\ (4)\end{matrix}+H_2O$$

Together with alizarin and purpurin, it is obtained by the action of ammonium persulphate on anthraquinone in sulphuric acid solution; also on heating anthraquinone in sulphuric acid, containing boric acid, with nitrous fumes.

Preparation.—Equal parts of *p*-chlorphenol and phthalic anhydride are heated to 200°–210° for some hours, with ten times as much sulphuric acid as chlorphenol used. The product is poured into two or three times its volume of water, and after standing for twenty-four hours, the precipitate is filtered off, washed and pressed.

The crude product is then boiled with water to free it from phthalic acid, dissolved in caustic soda, precipitated with hydrochloric acid and recrystallised from alcohol. In order to remove a small quantity of purpurin, which is nearly always present, the crude quinizarin is then washed with cold dilute caustic soda as long as the solution is coloured red, and the residue recrystallised from toluene.

Quinizarin is also obtained by heating either the 1- or the 2-hydroxyanthraquinones with nitrites and boric acid in sulphuric acid solution at 180°–200°. The formation of quinizarin from 2-hydroxyanthraquinone is certainly remarkable, but the expected product, namely purpurin, is formed in traces only. A process of theoretical interest is that of Dienel (Ber. 1906, 39, 926), who converts α-anthrol by means of a hot aqueous alcoholic solution of sodium nitrite and zinc chloride into two isomeric nitroso-derivatives which may be reduced to amino compounds and oxidised to 1 : 2- and 1 : 4-anthraquinones respectively. The latter crystallises from alcohol in long yellow needles which melt at 206° (*cf.*, however, Haslinger, Ber. 39, 3537, who gives 190°) and by successive reduction, acetylation, oxidation, and hydrolysis may be changed to quinizarin.

Quinizarin crystallises from alcohol in red needles which melt at 192°–193°, and sublime at a high temperature with partial decomposition. It dissolves readily in benzene. The solutions in ether and sulphuric acid are characterised by a beautiful greenish-yellow fluorescence. Quinizarin dissolves in baryta, forming a blue solution from which it is reprecipitated on passing carbonic acid (distinction from alizarin).

The tinctorial effects produced by quinizarin on fabrics mordanted with iron, chromium, or aluminium are about one-tenth of those produced by an equal amount of alizarin.

When fused with potash it is converted into hydroxychrysazin $C_{14}H_8O_5$. Quinizarin forms a diacetate which melts at 200°.

Literature.—Baeyer and Caro (Ber. 8, 152); Schunck and Römer (Ber. 10, 554); Bayer & Co. D. R. P. 81245 (*see* also above).

Leucoquinizarin is obtained by the reduction of quinizarin with sodium hydrosulphite and sodium hydroxide. It is a yellow crystalline substance melting at 135°, and is of importance since it condenses with aromatic amines more readily than quinizarin itself, and is thus employed in the manufacture of some of the important acid dyes of this group.

2-Nitroquinizarin is the product obtained by the nitration of quinizarin in acetic acid or nitrobenzene solution. It forms brick-red crystals which dissolve in sulphuric acid to a cerise solution and dyes wool brown on an alumina mordant, violet-brown on chromed wool.

Quinizarin sulphonic acid is obtained by the action of sodium sulphite on a hot aqueous suspension of quinizarin, preferably in the presence of an oxidising agent such as pyrolusite.

Fuming sulphuric acid (70–80 p.c. SO_3) in large excess converts quinizarin at 20°–40° into 1 : 2 : 5 : 8-tetrahydroxyanthraquinone (Schmidt Bull. Soc. chim. 1914, (15) 12, 1).

The hydrogen atoms in quinizarin are not readily displaced by halogens, but, on the other hand, an additive product, a *hexabromide* is formed at 0°. At 40° the product is *bromoquinizarin dibromide*, and even at temperatures between 100° and 230° only a *dibromoderivative* is produced.

Dichloroquinizarines. 3 : 6-, 3 : 4-, and 4 : 5-Dichlorophthalic anhydrides react with quinol in presence of boric acid to produce dichlorodihydroxybenzoyl benzoic acids which are changed by sulphuric acid into corresponding dichloroquinizarines.

5 : 8-**Dichloroquinizarin** crystallises in brown-red needles melting at 266°, and forms an *acetyl derivative* melting at 170°. When its potassium salt is heated with potassium phenoxide during eight hours at 180° it is changed to 8-*chloro-5-phenoxyquinizarin*, light red needles melting at 243°. The phenoxy derivative is transformed by *p*-toluidine at 150° in presence of potassium and copper acetates into 8-*p-toluidino-5-phenoxyquinizarin* (m.p. 278°). 5 : 8-Dichloroquinizarin reacts similarly with aniline forming 5 : 8-*dianilinoquinizarin* melting at 245°.

5 : 6-**Dichloroquinizarin** melts at 208°, and its *acetyl derivative* at 140°.

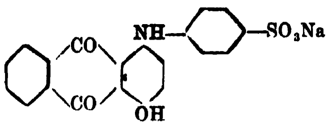
6 : 7-**Dichloroquinizarin** melts at 288° and forms an *acetate* melting at 125°.

Literature.—M. Frey (Ber. 45, 1358).

Acid dyes derived from quinizarin or its derivatives. Quite a considerable sub-group of anthracene dyes have been obtained by acting on quinizarin or its derivatives with amines usually in presence of boric acid. One or two of the hydroxyls of quinizarin may be replaced by arylamino groups, or if desired, one of the groups introduced may be amino or alkylamino. The products are sulphonated and are then acid wool dyes. The firm of Cassella occasionally condense leucoquinizarin with ready formed toluidine sulphonic acid in presence of boric acid. Friedländer and Schick (Zeitsch. Farben u. Textil Chemie, 1902, 2, 429; 1903, 3, 218) have shown that the reaction leading to the formation of these dyes is reversible in the case of the condensation with leucoquinizarin, and have applied this observation in order to hydrolyse some dyes found in commerce and so prove their nature. They find that acid dyes of this series which contain a sulphonated anilino- or toluidino- group will usually yield leucoquinizarin or similar substance, together with an aniline or toluidine sulphonic acid by boiling with stannous chloride in aqueous alcoholic hydrochloric acid solution.

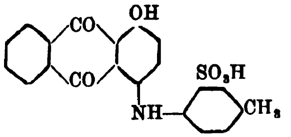
Alizarin Emeraldol G, Alizarin Uranole R, Alizarin Geranol B, Alizarin Heliotrope R, BB, and Alizarin Marine Blue RG, W, are examples of acid dyes of similar type to those described, but of undisclosed constitution.

Quinizarin Blue



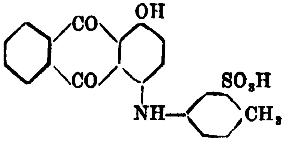
This dyestuff is prepared by heating quinizarin and aniline in molecular proportions and sulphonating the product. From an acid bath it dyes wool a red shade of blue, and gives a greenish-blue with chromed wool.

Alizarin Irisol D (R) (Bayer, D. R. PP 86150 and 91149).



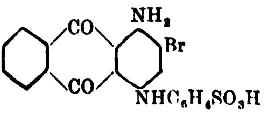
Quinizarin or leucoquinizarin is condensed with *p*-toluidine and the product sulphonated. The substance is isomeric with Alizarin Cyanol Violet (*q.v.*).

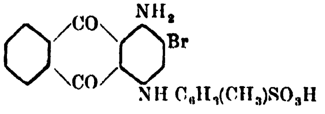
Alizarin Cyanol Violet R (Cassella, D. R. PP. 172464 and 181879).



Leucoquinizarin is condensed with 4-aminotoluene-2-sulphonic acid and the product oxidised.

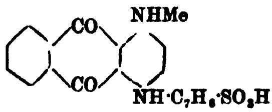
Alizarin Pure Blue and **Alizarin Blue GG** have the respective formulæ :—





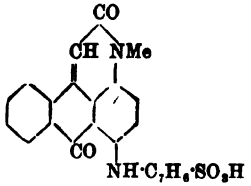
Alizarin Cyanol B (Cassella, D. R. PP. 183395, 114262, 119362). The mixture of 1 : 5- and 1 : 8-anthraquinone disulphonic acids is changed by ammonia and sodium chlorate at 170° to corresponding diamino anthraquinones amd aminoanthraquinonesulphonic acids. The latter are brominated to mixed dibromo-derivatives, and these are condensed with aniline and sulphonated.

Alizarin Astrol



dyes wool greenish-blue from an acid bath.

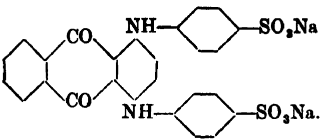
Alizarin Rubinol G, 3G, GW (Bayer, D. R. P. 201904)



is obtained by the sulphonation of *p*-toluidino-N-methylanthrapyridone. It dyes wool in red shades from an acid-bath.

Quinizarin Green.

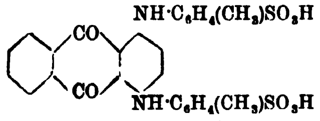
Quinizarin is treated with an excess of aniline and the product sulphonated. The dyestuff is the sodium salt of the sulphonic acid, and has the constitution



The green shades produced on wool from an acid-bath are fast to light and milling.

Anthraquinone Green is the corresponding monosulphonic acid.

Alizarin Cyanine Green E, G Extra, K (Bayer)



This dye is obtained by sulphonating the product of the complete tolylation of quinizarin. It dyes wool from an acid bath a very vivid green. This dye has now displaced for most purposes the Alizarin Viridine which is similarly prepared from Alizarin Bordeaux. An isomeride with very similar properties is *Alizarin Brilliant Green G, SE* (*Cassella*), and the difference in constitution is the same as that between Alizarin Irisol and Alizarin Cyanol Violet. The dye now in question is obtained by carrying to the second stage the condensation between leucoquinizarin and 4-aminotoluene-2-sulphonic acid.

Hystazarin. 2 : 3-Dihydroxyanthraquinone,

$$C_6H_4\begin{matrix}<CO>\\<CO>\end{matrix}C_6H_2\begin{matrix}<OH\ (2)\\<OH.\ (3)\end{matrix}$$

This substance is formed, together with alizarin, when a mixture of pyrocatechol and phthalic anhydride is treated with sulphuric acid—5 grams of pyrocatechol, 6·8 grams phthalic anhydride and 75 grams sulphuric acid are heated for 4½ to 5 hours to 340–150° on a sand-bath.

The resulting product, while still warm, is poured into ¾ litre of water, heated to boiling, and filtered hot.

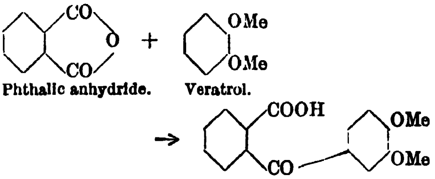
The dark-green precipitate thus obtained is well washed with hot water, dissolved in dilute potash, and the dark-blue solution precipitated by dilute sulphuric acid. The precipitate is washed with water, dried on a porous plate, and treated with boiling alcohol in an extraction apparatus, by which means a considerable portion is dissolved.

The dark-red solution on evaporation yields an orange-red mass, which consists of alizarin and hystazarin. These two substances are readily separated by treatment with boiling benzene, which dissolves the alizarin and leaves the hystazarin; the latter may then be further purified by recrystallisation from acetone.

Yield 1½ p.c. alizarin and 12 p.c. hystazarin of pyrocatechol used.

The following conditions for the preparation have also been published: 30 grams pyrocatechol are heated with 42 grams phthalic anhydride and 300 grams sulphuric acid at 180°–200° for half an hour. Yield of hystazarin was 6 grams, and of alizarin 1 gram.

Hystazarin may be synthesised by the following series of reactions:—Phthalic anhydride condenses with veratrol in carbon disulphide solution under the influence of aluminium chloride.



Phthalic anhydride.

Veratrol.

3 : 4 : dimethoxybenzoylbenzoic acid.

The 3 : 4-dimethoxybenzoylbenzoic acid thus produced yields 2 : 3 : dimethoxyanthraquinone on heating with concentrated sulphuric acid. This is hystazarindimethyl ether and yields hystazarin on demethylation.

Hystazarin crystallises from acetone in orange-yellow needles, which do not melt at 260°.

It is almost insoluble in benzene, difficultly soluble in xylene, soluble in hot alcohol, ether, glacial acetic acid, and acetone.

It dissolves in alkalis with a blue (cornflower) colour, in ammonia with a violet colour, and in concentrated sulphuric acid with a blood-red colour. The barium salt is a blue precipitate, the calcium salt a violet precipitate; both are insoluble in water.

Hystazarin possesses only very feeble tinctorial properties. The faint red colour produced with an aluminium mordant differs in shade from the alizarin red. The solution of hystazarin in dilute sodium hydrate absorbs the yellowish red and violet rays of the spectrum. A very dilute solution shows two lines in the yellow, $\lambda=619{\cdot}8$, $\lambda_1=587{\cdot}4$. Distilled over zinc-dust, hystazarin yields relatively large quantities of anthracene.

Hystazarin is changed by sulphuric acid at 200° slowly into alizarin. It is probable that the reaction is one of hydrolysis into phthalic acid and catechol and subsequent condensation in the ortho- position to the hydroxyl group.

Literature. — Liebermann and Schoeller (Ber. 21, 2501–2508); Lagodzinski and Lorétan (Ber. 28, 118); Liebermann and Hohenemser (Ber. 35, 1778); Schrubsdorf (Ber. 36, 2936).

Diacetyl hystazarin $C_{14}H_6O_2(OC_2H_3O)_2$ crystallises from acetic acid in needles, which melt at 205°–207°.

2 : 3-*di*-**Hydroxyanthranol** is obtained by the reduction of hystazarin with zinc dust and ammonia. It occurs in yellow-brown needles melting at 282°, and forms a *triacetyl derivative* melting at 163°.

1-Nitrohystazarin is obtained when hystazarin is nitrated in sulphuric acid solution by means of a molecular proportion of nitric acid. Further nitration leads to 1 : 4-*dinitrohystazarin*, and both these derivatives have only a slight tinctorial power on mordants.

1 : 4-Dibromohystazarin is obtained by brominating the substance at 150° in a sealed tube. It melts at 127°–129° and dissolves in alkaline solutions with a violet colour.

Anthraflavic acid. 2 : 6-Dihydroxyanthraquinone

$$(6)\ HO{\cdot}C_6H_3{<}\begin{matrix}CO\\CO\end{matrix}{>}C_6H_3{\cdot}OH.\ (2)$$

Anthraflavic acid is prepared by fusing α-anthraquinone disulphonic acid with potash, and is therefore nearly always present in artificial alizarin. Synthetically it has been obtained by heating *m*-hydroxybenzoic acid with sulphuric acid to 190°.

$$2OH{\cdot}C_6H_4{\cdot}COOH = OH{\cdot}C_6H_3{<}\begin{matrix}CO\\CO\end{matrix}{>}C_6H_3{\cdot}OH : H_2O.$$

This mode of formation proves that this substance contains the two hydroxyl groups in different benzene rings.

Anthraflavic acid crystallises from alcohol in yellow needles which melt above 330°. The pure substance when carefully heated sublimes partially in yellow needles, leaving a considerable quantity of a carbonaceous residue. Anthraflavic acid does not dye mordanted cloth. It dissolves in alkalis forming a yellowish-red solution, and in sulphuric acid forming a green solution, the absorption spectrum of which shows a broad band between the blue and the green. Anthraflavic acid forms a number of salts, of which the sodium salt is the most characteristic. This salt is sparingly soluble in water, and is remarkable for the ease with which it crystallises; this distinguishes it from *iso*anthraflavic acid, and gives a ready means of separating these two substances. When treated with acetic anhydride, anthraflavic acid forms a diacetate melting at 228°–229°.

Literature.—Perkin (Chem. Soc. Trans. 1871, 24, 1109; 26, 19); Schunck and Römer (Ber. 9, 379; 11, 970); Liebermann (Ber. 5, 968); Rosenstiehl (Bull. Soc. chim. 29, 401–434); Barth and Senhofer (Ber. 170, 100).

Tetranitroanthraflavic acid consists of yellow needles exploding without fusion at 307°. It is obtained by the action of nitric acid on anthraflavic acid. By the employment of the calculated amount of nitric acid it is possible to obtain a *dinitro derivative* which dyes wool from an acid-bath.

Literature.—Schradinger (Ber. 8, 1487).

*Iso***Anthraflavic acid.** 2 : 7-Dihydroxyanthraquinone

$$\text{(7) } HO\cdot C_6H_3{<}\substack{CO\\ CO}{>}C_6H_3\cdot OH \text{ (2)}$$

is formed when β-anthraquinone disulphonic acid is fused with potash, and is therefore always contained in crude alizarin. In preparing it, crude alizarin is dissolved in dilute caustic soda, the solution precipitated with hydrochloric acid, and the precipitate dissolved in cold baryta water and filtered. (In this way *iso*anthraflavic acid, which forms a soluble baryta compound, is easily separated from alizarin, anthrapurpurin, and anthraflavic acid, which yield insoluble barium compounds.) The filtrate is treated with hydrochloric acid, and the precipitate recrystallised from alcohol. *Iso*anthraflavic acid crystallises in long yellow needles, containing 1 mol. H_2O, which can be driven off at 150°. It melts above 330° and sublimes at a high temperature in lustrous yellow needles. It dissolves easily in alkalis forming a deep-red solution, but it does not dye mordanted cloth. Fused with potash *iso*anthraflavic acid yields anthrapurpurin.

The diacetate of *iso*anthraflavic acid melts at 195°.

Literature.—Schunck and Römer (Ber. 9 379).

Anthrarufin. 1 : 5-Dihydroxyanthraquinone

$$\text{(5) } HO\cdot C_6H_3{<}\substack{CO\\ CO}{>}C_6H_3\cdot OH. \text{ (1)}$$

Anthrarufin is formed together with anthraflavic acid and metabenzdioxyanthraquinone by heating *m*-oxybenzoic acid with sulphuric acid.

(2) $OH\cdot C_6H_4\cdot COOH$

$$=OH\cdot C_6H_3{<}\substack{CO\\ CO}{>}C_6H_3\cdot OH + 2H_2O.$$

It may also be obtained by fusing *o*-anthraquinone disulphonic acid with potash.

Another process depends on the fact that it is the chief product when anthraquinone is oxidised with sulphur trioxide under the following conditions :—Anthraquinone (50 parts) is heated with fuming sulphuric acid (1000 parts containing 80 p.c. SO_3) and boric acid (20 parts) for 36 hours at 100° under pressure.

Anthrarufin is manufactured, mainly as an intermediate for alizarin saphirol, by heating anthraquinone-1 : 5-disulphonic acid with milk of lime under pressure.

Anthrarufin crystallises in yellow needles which melt at 280° and sublime easily at a higher temperature (distinction from anthraflavic acid). It dissolves with difficulty in ammonia and soda, but more readily in potash.

Anthrarufin dissolves in sulphuric acid, forming a deep-red solution, the colour of which is so intense that it is still easily apparent in solutions containing only 1 part in 10,000,000.

Anthrarufin forms a diacetate which melts at 244°-245°.

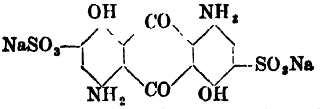
Anthrarufin dimethyl ether is obtained on boiling 1 : 5 : dinitroanthraquinone with methyl alcoholic caustic soda. The substance forms deep-red needles of m.p. 230°.

Literature.—Schunck and Römer (Ber. 11, 1175) ; Liebermann and Dehnst (Ber. 12, 1289) ; Bayer and Co. D. R. P. 101220 ; Pleus (Ber. 35, 2923).

Anthrarufin monoethyl ether occurs in yellow needles melting at 164° and yielding an *acetyl derivative* melting at 173°.

Anthrarufin diethyl ether forms long silky needles melting at 178°.

Alizarin Saphirol B. *Alizarin Delphinol.*



is an important blue acid wool-dye derived from anthrarufin by successive sulphonation, nitration, and reduction. This dyestuff excels in respect to its fastness to light.

It may also be obtained by the reduction of 1 : 5-dinitroanthraquinone in alkaline solution followed by acidification and sulphonation. The first product is a dihydroxylaminoanthraquinone, and this rearranges into an amino-compound by the action of the acid. Dinitroanthrarufin may also form the source of this or a very similar dyestuff into which it is converted by the action of sulphites. *Alizarin Saphirol SE* is the monosulphonic acid. There are also dyestuffs of this type which contain a bromine atom in the anthraquinone nucleus.

Alizarin Celestol is obtained by the action of formaldehyde on Alizarin Saphirol.

1 : 6-**Dihydroxyanthraquinone**

$$\text{(6) } HOC_6H_3{<}\substack{CO\\ CO}{>}C_6H_3OH \text{ (1)}$$

This was the last of the dihydroxyanthraquinones to be obtained, it having been prepared by Frobenius and Hepp in 1907 (Ber. 40, 1048). 1-Nitroanthraquinone-6-sulphonic acid was converted by sodium methoxide into 1-methoxyanthraquinone-6-sulphonic acid, and the latter hydrolysed to a hydroxyanthraquinone sulphonic acid by heating with sulphuric acid. The sodium salt was then prepared and heated with milk of lime at 195° under pressure. The substance crystallises in orange-yellow needles melting at 271°-272°, and dissolving in ammonia or potassium hydroxide to a yellow solution. Oxidation by heating under pressure with a solution of sodium hydroxide and sodium nitrate results in the production of flavopurpurin.

Metabenzdioxyanthraquinone. 1 : 7-Dihydroxyanthraquinone

$$\text{(7) } HO—C_6H_3{<}\substack{CO\\ CO}{>}C_6H_3—OH \text{ (1)}$$

Literature.—Schunck and Römer (Ber. 11, 1176) ; Liebermann and Dehnst (Ber. 12, 1289).

Metabenzdihydroxyanthraquinone $C_{14}H_8O_4$ is formed together with anthraflavic acid and anthrarufin by heating *m*-hydroxybenzoic acid with sulphuric acid (*v. supra*). It is separated from these by treatment with benzene and subsequent recrystallisation from dilute alcohol. Metabenzdihydroxyanthraquinone forms yellowish needles which melt at 291°-293°, and sublime at a higher temperature almost without decomposition. It dissolves in alkalis with a dark-yellow colour, and in concentrated sulphuric acid, forming a brownish-yellow solution, which shows no absorption bands.

The diacetate of metabenzdihydroxyanthraquinone melts at 199°.

Literature.—Schunck and Römer (Ber. 10, 1225); Rosenstiehl (Ber. 9, 946).

Chrysazin. 1 : 8-Dihydroxyanthraquinone is formed by fusing χ-anthraquinonedisulphonic acid with potash, or by treating hydrochrysamid $C_{14}H_2(NH_2)_4(OH)_2O_2$ with nitrous acid and alcohol. (N.B.—Hydrochrysamid is obtained by the reduction of chrysammic acid $C_{14}H_4(NO_2)_4O_4$, which is the product of the action of nitric acid on aloes.)

It is manufactured by heating anthraquinone-1 : 8-disulphonic acid with milk of lime under pressure with or without the addition of calcium chloride.

Chrysazin forms reddish-brown needles, which melt at 191°. It dissolves in alkalis and sulphuric acid, with a red colour. Its diacetate melts at 227°–232°.

Crude dinitroanthraquinone contains a compound which is converted into chrysazin dimethyl ether on treatment with methyl alcoholic potash.

Literature.—Liebermann (Annalen, 183, 184).

Derivatives of Chrysazin.

Monopotassium salt. Chrysazin is dissolved in a little hot dilute potassium hydroxide solution. The salt separates in orange-red needles which contain water of crystallisation, and on heating at 100° becomes anhydrous, the colour changing to violet.

Chrysanthranol, 1 : 8 - Dihydroxyanthranol. This substance, which possesses therapeutic value similar to that which characterises chrysarobin, may be obtained by the reduction of chrysazin with hydriodic acid and phosphorus. It melts at 177°, and forms a triacetyl derivative melting at 210°.

4 : 5-Dichlorochrysazin is obtained by passing chlorine into a suspension of chrysazin in sulphuric acid of such a concentration that the b.p. is 120°.

Chrysazinamide, 1-Amino-8-hydroxyanthraquinone is obtained by saturating a chrysazin paste with ammonia at 0° and heating in a sealed tube.

Chrysazin-disulphonic acid is obtained by sulphonation of chrysazin with oleum (20 p.c. SO_3). It is isolated as a potassium salt, and on fusion with alkali yields a dihydroxychrysazin melting at 292° (acetyl derivative, m.p. 233°–240°) and isomeric, but not identical with a tetrahydroxyanthraquinone obtained by fusing chrysazin with potassium hydroxide in a vacuum. The latter substance occurs in dark red needles melting at 217°, and forming a tetracetyl derivative melting at 195°.

Dinitrochrysazin (probably 4 : 5-dinitro-1 : 8-dihydroxyanthraquinone). Chrysazin dimethyl ether (obtained from 1 : 8-dinitroanthraquinone by the action of sodium methoxide) is nitrated by means of a mixture of nitric and sulphuric acids. The resulting *dinitrochrysazin dimethyl ether* crystallises from chlorobenzene in green needles melting at 232°–233°. It may be hydrolysed by hot 10 p.c. sulphuric acid, and the dinitrochrysazin separates from chlorobenzene in orange-yellow crystals melting at 232°–234°. Chrysazin is coming more and more into use as an intermediate for the preparation of dyestuffs, and, for example, the processes which are used to convert anthrarufin into Alizarin Saphirol may also be applied to chrysazin, and the product is a valuable wool dye. For this reason it is not the invariable practice to separate anthraquinone-1 : 5- and 1 : 8-disulphonic acids, but instead the mixture may be converted into a mixture of anthrarufin and chrysazin, and by successive sulphonation, nitration, and reduction, either with stannous chloride or with sodium sulphide, a useful dye of Alizarin Saphirol type obtained.

There is further a general similarity between quinizarin, anthrarufin, and chrysazin as regards the production of acid dyes by condensation with aromatic amines followed by sulphonation. Thus condensation of anthrarufin and *p*-toluidine followed by sulphonation of the product leads to the dyestuff *Anthraquinone Violet*, and similar products may be prepared from chrysazin. Chrysazin is not a mordant dyestuff, but dinitro, dihydroxylamino, and diaminochrysazins can be applied to mordanted fabrics. The dinitro compound dyes chromed wool blue.

Literature.—Schrubsdorff (Ber. 36, 2936); Wobling (Ber. 36, 2941); Nölting (Chem. Zeit. 1910, 977; J. Soc. Chem. Ind. 1898, 372; 1900, 342; 1906, 314).

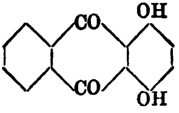
Dihydroxyanthraquinone (?), described as isochrysazin, has been obtained by Lifschütz (Ber. 17, 897) by treating dinitroanthraquinone with concentrated sulphuric acid.

It crystallises from alcohol and ether in deep-red needles, which melt at 175°–180°. It dissolves in alkalis and in ammonia with a reddish-violet colour, and in sulphuric acid with a reddish yellow colour. When heated it sublimes readily, and at a comparatively low temperature, in orange-red plates or needles. It does not dye mordanted cloth.

The *diacetyl compound* melts at 160°–165°.

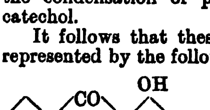
In view of the fact that dinitroanthraquinone is a mixture of the 1 : 5- and 1 : 8-isomerides, it appears very probable that this supposed dihydroxyanthraquinone is a mixture.

Constitution of the dihydroxyanthraquinones. The synthesis of quinizarin from phthalic anhydride and quinol establishes its constitution as 1 : 4-dihydroxyanthraquinone

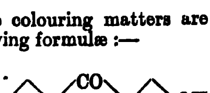


Further alizarin and hystazarin are produced by the condensation of phthalic anhydride with catechol.

It follows that these colouring matters are represented by the following formulæ :—



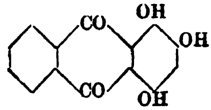
I.



II.

The synthesis of alizarin from hemipinic acid is conclusive evidence that the formula I. represents alizarin, and consequently II. is the structure of hystazarin.

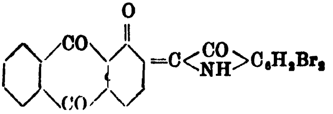
Again, purpurin is produced by the oxidation of both alizarin and quinizarin, and must therefore be 1 : 2 : 4-trihydroxyanthraquinone



On reduction it yields neither alizarin nor quinizarin, but purpuroxanthin, which is obviously 2 : 4-dihydroxyanthraquinone (the same position as 1 : 3).

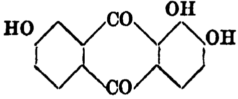
Similar arguments can be developed with respect to the remaining isomerides of alizarin.

Alizarin Indigo G (Bayer, D. R. P. 237199)



This is a vat dye obtained by the condensation of dibromoisatin chloride with α-anthrol. The solution in sodium hydrosulphite is yellow-brown, and cotton is dyed in pure greenish-blue shades of excellent fastness.

III. **Trihydroxyanthraquinones: Anthrapurpurin, *Iso*purpurin, Hydroxy*iso*anthraflavic acid.** 1 : 2 : 7-Trihydroxyanthraquinone



This important colouring matter is contained in crude artificial alizarin. It is formed by fusing β-anthraquinonedisulphonic acid, *iso*anthraflavic acid, metabenzdihydroxyanthraquinone, or α-dibromanthraquinone with potash.

The preparation of this substance is a somewhat tedious process, dependent on the fact that anthrapurpurin differs from alizarin in the behaviour of its alumina lake. The former, on treatment with an alkaline carbonate, is dissolved, whilst the alizarin lake remains unattacked. The solution containing the anthrapurpurin is filtered from the alizarin lake, heated to boiling, and acidified with hydrochloric acid. The anthrapurpurin thus obtained is purified by conversion into its difficultly soluble sodium compound, and from this, by precipitation with barium chloride, the barium salt is obtained, which is decomposed with hydrochloric acid. The precipitate is collected on a filter, well washed with water and recrystallised from glacial acetic acid.

As already mentioned above, the manufacture of alizarin always implies the production of a certain amount of the anthraquinone 2 : 6- and 2 : 7-disulphonic acids, and the methods by which these substances are isolated have been discussed. On fusion with alkali it is possible to obtain from these sulphonic acids either the corresponding dihydroxyanthraquinones or, on the other hand, to imitate the alizarin fusion and to introduce a further hydroxyl group. In this way anthrapurpurin and flavopurpurin are produced on a commercial scale. The temperature of the fusion must be considerably higher than that which suffices for the conversion of 'silver salt' into alizarin. The conversion of anthraflavic acid and isoanthraflavic acid into corresponding trihydroxyanthraquinones occurs with very different rapidity, the former substance (which yields anthrapurpurin) reacting sluggishly. Wedekind and Co. (D. R. P. 194945) fuse 100 parts of anthraflavic acid with 50 parts of saltpetre and 1500 volume parts of caustic lye (b.p. 185°) at 215°–225°. Bayer (D. R. PP. 205097 and 223103) employ only a 20 p.c. caustic soda solution and a temperature of 180°–200°. If, however, in fusing the disulphonic acids with alkali the temperature necessary is quickly reached, it is probable the reaction first leads to alizarin sulphonic acids, which are subsequently changed to anthrapurpurin and flavopurpurin. The following example of the proportions used in the fusion may be given :—

Two cbm. of the disulphonic acids liquor (obtained as already described) containing solid in suspension and with a dry content amounting to 27·65 p.c., equivalent to 553 kg. of the sodium salts, is mixed with 180 kg. saltpetre and 1012 litres of soda lye of 45° Bé. (containing 618 kg. NaOH). This mixture is heated nearly to boiling, and three drums of solid caustic soda then added (795 kg.). This procedure ensures the rapid heating of the mixture which is so necessary to obtain good results. The reaction is carried out in apparatus similar to that used for the preparation of alizarin, and the operation of fusion occupies 48 hours. The product is worked up much in the same way as alizarin, and is brought into commerce in the form of a paste. The impurity present in these trihydroxyanthraquinones is usually anthraflavic acid, and this may be separated by taking advantage of the insolubility of the sodium salt of anthraflavic acid in sodium hydroxide solution of 10°–12° Bé In order to separate the anthraflavic acid it is accordingly merely necessary to dilute to this concentration and filter off the sodium anthraflavate.

Anthrapurpurin crystallises in orange-coloured needles, which melt above 330°, and, when carefully heated, sublime in long red needles. It dissolves in alkalis with a violet colour ; the solution shows the same absorption spectrum as alizarin

With acetic anhydride anthrapurpurin forms a triacetate $C_{14}H_5(C_2H_3O)_3O_5$, which crystallises in yellow needles, melting at 220°.

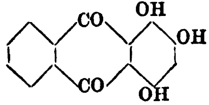
By careful hydrolysis the triacetyl derivative may be converted to a diacetyl derivative, a micro-crystalline pale yellow powder which melts at 175°–178°, and is also obtained by the moderated acetylation of anthrapurpurin. This substance possesses therapeutic value. When heated with ammonia, anthrapurpurin is converted into anthrapurpurinamide

$$C_{14}H_5(NH_2)(OH)_2O_2$$

Anthrapurpurin has the same affinity for mordants as alizarin ; the colours it produces are also analogous to some extent, as it produces reds with alumina, purples and blacks with iron mordants. There is, however, a considerable difference in the shade of colour produced, the reds being much purer and less blue than those of alizarin, whilst the purples are bluer and the blacks more intense. When used in Turkey-red dyeing it produces very brilliant colours of a scarlet shade, which are of remarkable permanence.

Literature.—Perkin (Chem. Soc. Trans. 25, 659; 26, 425; 29, 851); Caro (Ber. 9, 682); Schunck and Römer (Ber. 9, 679; 10, 972, 1823; 13, 42); Rosenstiehl (Bull. Soc. chim. 29, 405); Auerbach (J. 1874, 488); Ullmann (Enzyk, der Tech. Chem. under Alizarin).

Purpurin 1 : 2 : 4-Trihydroxyanthraquinone



Purpurin occurs along with alizarin in madder, probably as a glucoside. In order to separate it from alizarin, the mixture of the two substances is repeatedly recrystallised from a hot solution of alum, in which purpurin is more soluble than alizarin, or the mixture is dissolved in caustic soda and the solution saturated with carbonic acid. This precipitates the alizarin, but not the purpurin.

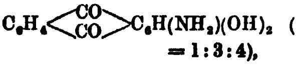
Purpurin is obtained when alizarin or quinizarin (1 pt.) is heated with pyrolusite (1 pt.) and concentrated sulphuric acid (8–10 pts.) at 160°. The oxidation of alizarin to purpurin is also effected by the action of ammonium persulphate in sulphuric acid containing sulphuric anhydride. α-Aminoalizarin is changed to purpurin by the action of nitrous acid in sulphuric acid solution, or by the action of sulphuric acid alone at 150°. Alizarin yields purpurin by the action of sulphuric acid at 225°. Alizarin sulphonic acid is oxidised by heating with sulphuric acid and a nitrate to purpurin sulphonic acid, and the latter yields purpurin on heating under pressure with dilute mineral acids. Anthraquinone-1-sulphonic acid if heated with oleum containing a high percentage of SO_3 is changed to a sulphuric ether which is hydrolysed by heating with sulphuric acid, and the product is purpurin-1-sulphonic acid. This dyes alum mordanted wool in red shades, and may be converted into purpurin.

Purpurin crystallises from dilute alcohol in long orange-coloured needles, which contain 1 mol. H_2O. The pure substance begins to sublime at 150°, and melts at 253°. It is slightly soluble in water, forming a deep yellow solution; in alkalis it dissolves with a purple-red colour; in alkaline carbonates with a red colour. The solution in alkalis shows two marked absorption bands in the green. Purpurin also dissolves readily in ether, carbon disulphide, benzene, and acetic acid; these solutions give two absorption bands, one at F and the other near E; the solution in sulphuric acid shows another line in the yellow. When boiled with acetic anhydride it yields a triacetate,

$$C_{14}H_5(C_2H_3O)_3O_5,$$

which crystallises in yellow needles, melting at 192°–193°.

Aqueous ammonia at 150° converts purpurin into purpurinamide



$$C_6H_4{<}\begin{matrix}CO\\CO\end{matrix}{>}C_6H(NH_2)(OH)_2 \quad (OH:OH:NH_2 = 1:3:4),$$

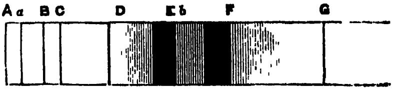
which, when boiled with ethyl nitrite, yields purpuroxanthin,

$$C_6H_4{<}\begin{matrix}CO\\CO\end{matrix}{>}C_6H_2{<}\begin{matrix}OH\ (1)\\OH.\ (3)\end{matrix}$$

Purpuroxanthin is also the product when purpurin is reduced with either alkaline stannous chloride or sodium amalgam. If, however, zinc-dust be employed as the reducing agent in weakly alkaline, neutral, or acid solution, then the leuco- compound of quinizarin is obtained. Purpurin is converted into 2-anilino-1 : 4-dihydroxyanthraquinone when heated with a mixture of aniline and aniline hydrochloride. A certain amount of dianilino-hydroxyanthraquinone is produced at the same time.

Purpurin dyes fabrics much in the same way as alizarin and anthrapurpurin, there being, however, a difference in the shades. The reds produced by purpurin are much yellower, and the browns (with chrome mordant) much more intense than are produced either by alizarin or anthrapurpurin.

The following figure shows the absorption spectrum of a solution of purpurin in aluminium sulphate :—

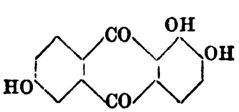


Alizarin Blue Black B, 3B, G (Bayer), is obtained by the condensation of purpurin with aniline followed by sulphonation of the product. The dye is applied on a chromium mordant.

Purpurin-3 : 8-disulphonic acid is obtained by heating the potassium salt of anthraquinone-1 : 5-disulphonic acid with boric acid and 40 p.c. oleum under 6–7 atmos. pressure. The purpurin disulphonic acid so produced forms a potassium salt which crystallises from dilute hydrochloric acid in yellow red leaflets which have a bronze lustre. Heated at 180° with 70 p.c. sulphuric acid the disulphonic acid is changed to *purpurin*-8-*sulphonic acid*, and in the presence of a mercury salt into purpurin itself (Bayer, D. R. P. 172688). The action of alkali sulphites on purpurin leads to the production of *purpurin*-3-*sulphonic acid*, which may readily be reconverted into purpurin.

3-Chloropurpurin is formed along with *dichloropurpuroxanthin* by the action of sulphuryl chloride on a sulphuric acid solution of 2 : 4-dihydroxybenzoylbenzoic acid in the presence of boric acid. It crystallises in deep red needles melting at 270°–273° (Mettler, Ber. 45, 800).

Flavopurpurin. 1 2 : 6-Trihydroxyanthraquinone

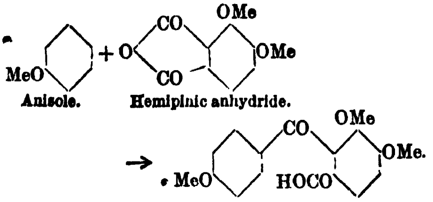


Flavopurpurin occurs in commercial artificial alizarin, but is with difficulty isolated from this product, owing to the fact that its chemical properties agree so closely with those of anthrapurpurin, which is also nearly always present in artificial alizarin, that it can only with difficulty be separated from this substance.

It is prepared by fusing β-anthraquinonedisulphonic acid or anthraflavic acid with potash or soda with or without the addition of a nitrate or chlorate. The details of the technical preparation have been discussed above under *Anthrapurpurin.*

It may be synthesised by the following series of reactions :—

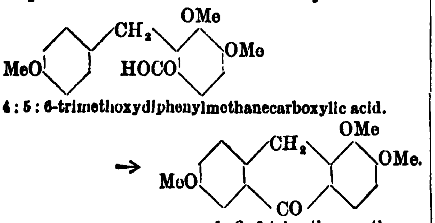
Hemipinic anhydride condenses with anisole in the presence of anhydrous aluminium trichloride, yielding the trimethyl ether of 4 : 5 : 6-trihydroxybenzoyl benzoic acid.



Anisole. Hemipinic anhydride.

Trimethoxybenzoylbenzoic acid.

This benzophenone derivative is reduced by zinc-dust and concentrated hydrochloric acid, and the product is 4 : 5 : 6-trimethoxydiphenylmethanecarboxylic acid, which is changed by sulphuric acid to 1 : 2 : 6-trimethoxyanthrone.



4 : 5 : 6-trimethoxydiphenylmethanecarboxylic acid.

1 : 2 : 6-trimethoxyanthrone.

1 : 2 : 6-trimethoxyanthrone crystallises from benzene in small needles melting at 170°. It is oxidised by chromic acid in glacial acetic acid solution to the trimethyl ether of flavopurpurin, which consists of yellow needles, crystallises from acetic acid, and melts at 225°. The trimethyl ether is hydrolysed to flavopurpurin by the action of aluminium chloride at 210°.

Flavopurpurin crystallises from alcohol in anhydrous yellow needles, sparingly soluble in water, but readily soluble in cold alcohol. Its melting-point lies above 330°.

It dissolves in caustic alkalis with a purple colour; the solution shows two absorption bands, one in the blue and the other near the red, but a little further removed than the alizarin band.

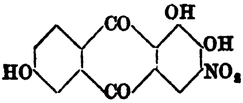
Flavopurpurin dyes mordanted fabrics similarly to alizarin, there being, however, a slight difference in the shades produced. The red shade is somewhat duller and yellower; the brown shade is also yellower. Flavopurpurin dyes wool mordanted with tin crystals and cream of tartar a bright yellowish orange.

When heated with acetic anhydride, flavopurpurin yields a triacetate $C_{14}H_5(C_2H_3O)_3O_5$, which crystallises from alcohol in golden-yellow plates melting at 238°.

Direct methylation converts flavopurpurin into a dimethyl ether, but, as in the case of alizarin, a trimethyl ether is obtained by oxidation of the product of methylation of deoxyflavopurpurin (Graebe, Ber. 38, 152).

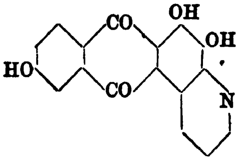
Alizarin Red 3 W. S. is the sodium salt of the monosulphonic acid of flavopurpurin.

Alizarin Orange G. Nitroflavopurpurin.



is similarly constituted to β-nitroalizarine. It is obtained by the nitration of flavopurpurin with ordinary nitric acid. Fast orange shades can be produced by applying this compound with an aluminium mordant.

On treatment with glycerol and sulphuric acid a trihydroxyanthraquinone quinoline of the constitution

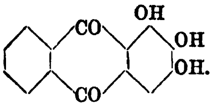


is produced, the bisulphite compound of which is the dyestuff **Alizarin Black P.**

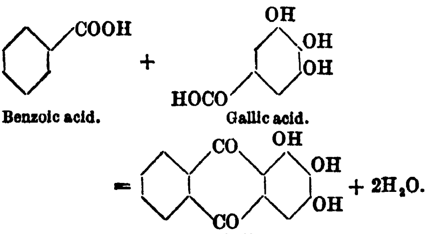
It is used for producing a fast violet grey to black in cotton-printing.

Literature.—Caro (Ber. 9, 682); Schunck and Römer (Ber. 9. 679; 10, 1823; 13, 42): Bistrzycki and Yssel de Schepper (Ber. 31, 2798).

Anthragallol. 1 : 2 : 3-Trihydroxyanthraquinone.



Anthragallol does not itself occur in nature, but its three isomeric dimethyl ethers have been found in Chay root (*Oldenlandia umbellata*). Anthragallol is formed when a mixture of gallic acid (1 pt.), benzoic acid (2 pts.), and sulphuric acid (20 pts.) are heated to 125° for eight hours.



Benzoic acid. Gallic acid.

Anthragallol.

The product is poured into water, well washed, and recrystallised from alcohol.

It is also obtained from 1 : 3-dinitro-2-hydroxyanthraquinone (the nitration product of 2-hydroxyanthraquinone) by reduction in strongly alkaline solution. Or 1 : 3-diamino-2-hydroxyanthraquinone may be converted to anthragallol by heating with hydrochloric acid under pressure.

Anthragallol crystallises in yellow needles which, when heated to 290°, sublime without melting. It is sparingly soluble in water, chloroform, or carbon disulphide; readily soluble in alcohol, ether, or glacial acetic acid.

It dissolves in alkalis forming a green solution.

Its triacetate $C_{14}H_5(C_2H_3O)_3O_5$ melts at 171°-173°.

With an excess of ammonia anthragallol reacts, forming anthragallolamide, 1-amido-2 : 3-dihydroxyanthraquinone.

Literature.—Seuberlich (Ber. 10, 39).

By the action of dimethyl sulphate in boiling nitrobenzene and in presence of anhydrous sodium carbonate anthragallol yields the *dimethyl ether* which occurs in orange needles melting at 159°-160°, and forms an *acetyl derivative* melting at 167°. Concentrated sulphuric acid hydrolyses this substance at 100° and forms a monomethyl ether melting at 233° (acetyl derivative, m.p. 184°), whilst the action of a great excess of methyl sulphate and sodium carbonate at 180° converts either the monomethyl ether or the dimethyl ether into anthragallol trimethyl ether, which is lemon-yellow and melts at 168° (Böck, Monatsh. 23, (9) 1008).

Hydroxyanthrarufin, 1 : 2 : 5-Trihydroxyanthraquinone. This substance is readily obtained by heating anthrarufin with a mixture of sodium and potassium hydroxides at 180°-185° in the presence of water and sodium nitrate. It is also produced when alizarin is dissolved in 70 p.c. oleum to which boric acid has been added, and the mixture agitated at 30°-35° until a pure violet solution has been obtained. The sulphuric ester so produced is then hydrolysed in the usual manner. The two methods combined determine the constitution of this trihydroxyanthraquinone which crystallises from acetic acid in red needles melting at 273°-274°, and forms a triacetate melting at 227°. Hydroxyanthrarufin is a valuable mordant dyestuff.

Literature.—Liebermann and Boeck (Ber. 11, 1716); Liebermann and Dehnst (Ber. 12, 1289); M. L. B. (D. R. PP. 195028 and 196980); By (D. R. P. 156960); Ziegler (J. pr. Chem. 86, 297).

Hydroxychrysazin, 1 : 2 : 8-trihydroxyanthraquinone. Chrysazin is converted into this substance by fusion with aqueous sodium and potassium hydroxides in presence of sodium nitrate at 180°. It crystallises in orange needles melting at 230°, and forms a triacetyl derivative melting at 219°. The *dimethyl ether* forms light yellow needles melting at 157°.

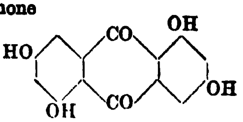
1 : 4 : 8-Trihydroxyanthraquinone. Oxidation of chrysazin by means of 80 p.c. oleum and boric acid at 25°-35° yields the sulphuric ester of this isomeride, and on heating with ordinary sulphuric acid the substance is obtained. It separates from pyridine in brown-red needles with green metallic reflex and dissolves in aqueous sodium hydroxide, and also in sulphuric acid to a violet solution (By, D. R. P. 161026). This compound is also obtained by the reduction of Alizarin Bordeaux.

1 : 3 : 8-Trihydroxyanthraquinone. The trihydroxyanthraquinone obtained from rhein through its amide and dihydroxyaminoanthraquinone (Oesterle, Arch. Pharm. 1912, 250, 301) is not identical with hydroxychrysazin, and since rhein must be either chrysazin-2- or 3-carboxylic acid, this fact favours the latter theory. 1 : 3 : 8-Trihydroxyanthraquinone melts at 277°-278°, and yields a triacetyl derivative melting at 197°-198°.

1 : 4 : 6-Trihydroxyanthraquinone is the chief product when 4-aminophthalic anhydride is heated with quinol and concentrated sulphuric acid at 170°-190°.

IV. Tetrahydroxyanthraquinones.

Anthrachrysone 1 : 3 : 5 : 7-Tetrahydroxyanthraquinone

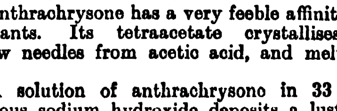


The preparation of this body is effected by heating 3 : 5-dihydroxybenzoic acid with 10 parts of sulphuric acid for 3 to 5 hours.

The substance consists of silky yellow needles when crystallised from alcohol, or it can be sublimed with partial decomposition in leaflets. It does not melt at 360°.

Anthrachrysone has a very feeble affinity for mordants. Its tetraacetate crystallises in yellow needles from acetic acid, and melts at 253°.

A solution of anthrachrysone in 33 p.c. aqueous sodium hydroxide deposits a lustrous vivid red sodium salt which is converted into a crystalline ammonium salt by ammonium chloride. A crystalline potassium salt is also known, and when this is heated with methyl sulphate at 180°-190° it is converted into anthrachrysone dimethyl ether which crystallises from nitrobenzene in golden brown columns and forms a sodium salt crystallising in orange-red needles. The diacetyl derivative melts at 256°. The methylation also results in the production of a small proportion of anthrachrysone tetramethyl ether which crystallises in golden-yellow prisms melting at 294° (Fischer and Ziegler, J. pr. Chem. 1912, ii. 86, 297). Anthrachrysone condenses with secondary bases, such as diethylamine, and formaldehyde, with the production of tetraalkyldiaminodimethylanthrachrysones. The compound



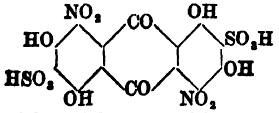
is obtained from diethylamine (M. L. B., D. R. P. 188189).

Literature.—Hohenemer (Ber. 35, 2305); Barth Senhofer (Annalen, 164, 109); Noah (Ber. 19, 755).

1 : 3 : 5 : 7-Tetrahydroxyanthraquinone-2 : 6-disulphonic acid is obtained by heating anthrachrysone with an excess of fuming sulphuric acid (D. R. P. 70803). It forms a characteristic *sodium salt* which crystallises in glistening coppery platelets. By the action of chlorine it is converted into a *dichloro- derivative*, whilst, on the other hand, sodium hypochlorite converts the sodium salt into *dichloroanthrachrysone* by elimination of the sulphonic groups. *Dibromoanthrachrysone* is obtained by bromination of anthrachrysone in acetic acid solution. It melts at above 290°, and occurs in orange-red needles. The action of bromine on a solution of the disulphonic acid in dilute acetic acid is to produce *tetrabromoanthrachrysone*, dark-red needles melting above 300°.

Various dyestuffs are derived from anthrachrysone.

Dinitroanthrachrysonedisulphonic acid



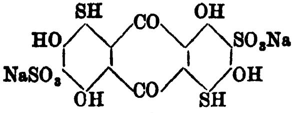
is prepared by sulphonation, followed by nitration of anthrachrysone.

It is a fast brown wool dye.

On reduction it yields diaminoanthrachrysonedisulphonic acid, which dyes wool violet from an acid-bath, or blue on a chromium mordant.

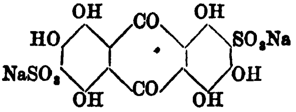
If, however, the reduction is carried out in alkaline solution with sodium sulphide, then the dyestuff **Acid Alizarin Green B and G** results.

The constitution of this product is



It dyes chromed wool a fast, pure green.

Acid Alizarin Blue BB and GR



is obtained by boiling diaminoanthrachrysone disulphonic acid with alkali. A red shade is produced on wool from an acid-bath, which on chroming develops a beautiful blue, exceedingly fast to light milling, acids or alkalis.

8-Nitro-4-anilino-1 : 3 : 5 : 7-tetrahydroxyanthraquinone-2 : 6-disulphonic acid is obtained in the form of its trisodium salt (dark bluish-violet crystals with coppery lustre) by heating a solution of 4 : 8-dinitro-1 : 3 : 5 : 7-tetrahydroxyanthraquinone-2 : 6-disulphonic acid in aqueous sodium carbonate with aniline. A similar replacement of the nitroxyl by anilino occurs with the unsulphonated dinitro- compound (Heller and Skraup, Ber. 46, 2703; D. R. P. 71964).

Rufiopin, 1 : 2 : 5 : 6-Tetrahydroxyanthraquinone.

This tetrahydroxyanthraquinone is obtained by heating opianic or hemipinic acids with sulphuric acid at 180°.

Also by fusing the disulphonic acid of anthrarufin with potash.

It forms a reddish-yellow crust from ether, and can be sublimed in orange needles.

It gives a violet-red solution in dilute alkalis or in sulphuric acid. A curious property of rufiopin is its stability towards fusion with potash.

The substance is of no value as a dyestuff, since it gives only dull-brown shades with mordants.

Literature.—Liebermann and Chojnacki (Annalen, 162, 323); D. R. P. 103988.

α- and β-Hydroxyanthragallols.

A mixture of these substances is produced when equimolecular proportions of gallic and *m*-hydroxybenzoic acids are heated at 150°, with 10 parts of sulphuric acid for twenty hours.

The product is poured into water and the dried precipitate extracted with alcohol. This extract is evaporated and the residue treated with hot benzene. The α- compound passes into solution, whilst the β- remains undissolved.

α-Hydroxyanthragallol crystallises from alcohol in golden yellow micro- needles. It forms a green solution in alkalis, whilst that in sulphuric acid is violet, and shows two absorption bands between F and D. With mordants it behaves similarly to rufigallic acid.

Its tetraacetyl derivative melts at 207°–209°.

β-Hydroxyanthragallol crystallises from alcohol and occurs in red needles. Its brown-red solution in sulphuric acid shows two absorption bands between E and H.

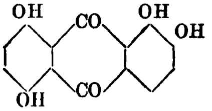
The tetra-acetate crystallises from glacial acetic acid in lemon-yellow tables of m.p. 189°.

Literature.—Noah (Annalen, 241, 270).

1 : 2 : 3 : 4-Tetrahydroxyanthraquinone is obtained by heating anthragallol with sulphuric acid in the presence of boric acid at 200°–240°. It consists of green needles soluble in both alkalis and sulphuric acid with red colour. The tetraacetyl derivative melts at 205°.

Literature.—Bayer and Co. D. R. P. 86968.

Alizarin bordeaux (Quinalizarin). 1 : 2 : 5 : 8-Tetrahydroxyanthraquinone



Alizarin bordeaux is by far the most important of the tetrahydroxyanthraquinones.

It has been obtained by the hydrolysis of its dimethyl ether (*see* below) with a solution of hydrochloric acid in acetic acid at 200°.

It is prepared by heating alizarin (1 pt.) with sulphuric acid (10 pts. containing 80 p.c. SO_3) for four days at 25°–50°. This yields the sulphuric acid ester of alizarin bordeaux, to obtain which the reaction product is rendered alkaline and then boiled with an excess of hydrochloric acid.

It is found that the oxidation of alizarin occurs more readily in presence of boric acid.

Alizarin bordeaux can be obtained in deep red needles with green metallic reflection.

On an aluminium mordant it produces bordeaux shades; violet blue on chromium.

The tetraacetate crystallises from chloroform-alcohol in micro- needles of m.p. 201°.

Dimethyl ether.

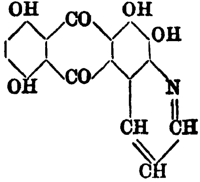
This substance is synthesised by heating hemipinic acid and quinol with sulphuric acid to 130°.

The brown-red micro leaflets obtained by crystallisation from benzene melt at 225°–230°.

Literature.—Schmidt (J. pr. Chem. [2] 43, 239); Liebermann and Wense (Annalen, 240, 299).

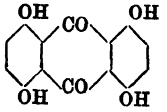
Alizarin Green S (B).

Alizarin blue can be oxidised by means of sulphur trioxide, and the product on treatment with sulphuric acid gives a dihydroxyalizarin blue of the probable constitution



Alizarin Green S (B) is the bisulphite compound of this tetrahydroxyanthraquinone quinoline. It dyes very fast bluish-greens on chromed wool.

1 : 4 : 5 : 8-Tetrahydroxyanthraquinone



This substance has been obtained by the action of sulphuric acid on *pp*-dinitroanthrarufin (By, D. R. PP. 125579, 162033), but the following method establishes the constitution of the substance :—

5 : 8-Dichloroquinizarin is heated for 20 hours at 250° with milk of lime and copper. The product is acidified with hydrochloric acid, and the substance may then be collected and crystallised from a mixture of benzene and ligroin. The brown needles melt at 246°, and dissolve in alkaline solutions with a cornflower-blue colouration. The sulphuric acid solution exhibits two bands in the red and yellow respectively.

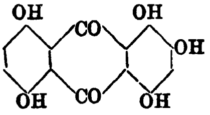
It is interesting that this tetrahydroxyanthraquinone has powerful mordant dyestuff properties (Frey, Ber. 45, 1361).

The tetraacetyl derivative forms light yellow needles melting at 250° with decomposition, and the difficultly soluble blue potassium salt is converted by methyl sulphate at 180° into a tetramethyl ether, which crystallises in lustrous orange leaflets and melts at 317° (Fischer and Zeigler, J. pr. Chem. 1912, ii. 86, 297).

Dihydroxychrysazins. Two isomeric tetrahydroxyanthraquinones have been obtained from chrysazin. The first (Schrubsdorff, Ber. 35, 2936) by fusion of chrysazin with potassium hydroxide. This isomeride sublimes *in vacuo*, forms dark-red needles melting at 217°, and intensely colours ordinary mordants. Its acetate melts at 195°. The second compound (Wobling, Ber. 36, 2941) is obtained by fusing chrysazin disulphonic acid with alkali. This melts at 292°, and also colours mordants. Its tetraacetyl derivative melts at 233°.

V. Pentahydroxyanthraquinones.

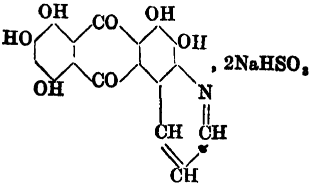
Alizarin cyanine R. 1 : 2 4 : 5 : 8-Pentahydroxyanthraquinone



This valuable substance is obtained by the oxidation of alizarin bordeaux with pyrolusite in sulphuric acid solution. The sulphonic acid ether so produced is hydrolysed by boiling with dilute acid. This oxidation is entirely analogous to that by which purpurin is produced from alizarin. The substance crystallises in bronze-coloured leaflets from nitrobenzene. The blue solution in concentrated sulphuric acid exhibits red fluorescence.

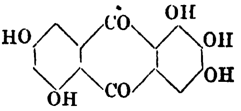
Alizarin cyanine R. yields a handsome blue chromium lake.

Alizarin Indigo Blue S.



is the bisulphite compound of the pentahydroxyanthraquinone quinoline, obtained by the further oxidation of alizarin Green S (B) with concentrated sulphuric acid at 200°. It yields fast indigo-blue shades on crome mordanted wool.

Dihydroxyanthragallol. 1 : 2 : 3 : 5 : 7-Pentahydroxyanthraquinone



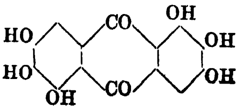
Equimolecular amounts of gallic acid and 3 : 5-dihydroxybenzoic acid are heated to 160° for ten minutes with ten times their weight of sulphuric acid. The product contains dihydroxyanthragallol, rufigallic acid, and anthrachrysone. In order to separate them, advantage is taken of the fact that only dihydroxyanthragallol pentaacetate is soluble in alcohol. The acetate so obtained is hydrolysed with cold sulphuric acid.

Dihydroxyanthragallol crystallises from alcohol in small red needles, which do not melt at 360°. The substance is similar in tinctorial properties to rufigallic acid.

The pentaacetate melts at 229°.

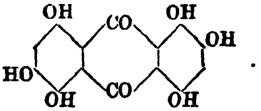
Literature.—Noah (Annalen, 241, 275).

VI. Hexahydroxyanthraquinones. Rufigallol. Rufigallic acid, 1 : 2 : 3 : 5 : 6 : 7-Hexahydroxyanthraquinone



Rufigallic acid is produced when gallic acid is heated with concentrated sulphuric acid at 140°. It may be sublimed in yellow needles. A violet solution is obtained with alkalis, red with sulphuric acid. Baryta produces a blue insoluble precipitate. Alizarin is obtained by the reduction of rufigallic acid with sodium amalgam. The substance is a good example of a polygenetic dyestuff, and yields with aluminium, iron, and chromium mordants, red, violet, and brown respectively. The colours are, however, not pure in tone.

Anthracene Blue. 1 : 2 : 4 : 5 : 6 : 8-hexahydroxyanthraquinone



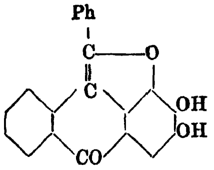
Anthracene blue is an important dyestuff, and can be obtained from erythroxyanthraquinone, anthrarufin, or anthrachrysone, by the oxidising action of sulphur trioxide in sulphuric acid in the presence of boric acid.

It is best prepared by the action of 40 p.c. oleum with or without the addition of sulphur on 1 : 5-dinitroanthraquinone, and treatment of the product with ordinary sulphuric acid.

The solution in concentrated sulphuric acid is violet-blue and shows a brown fluorescence. The aluminium lake is violet and the chromium lake blue.

Its disulphonic acid is Acid alizarin blue B B, mentioned above, and prepared from anthrachrysone.

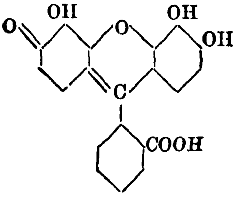
Benzoin Yellow



is prepared by the condensation of benzoïn with gallic acid under the influence of sulphuric acid.

It dyes wool on a chromium mordant a fast yellow (except to light).

Galleïn $C_{20}H_{12}O_7$



Galleïn is formed by heating pyrogallol with phthalic anhydride.

Preparation.—A mixture of 1 part of phthalic anhydride and 2 parts of pyrogallol are heated to 190°–200°, the product dissolved in alcohol, and the colouring matter precipitated by the addition of water. The crude galleïn thus obtained is dissolved in alcohol, reprecipitated with water, and, after repeating this operation a few times, converted into the acetate by heating with acetic anhydride. This is recrystallised several times, and decomposed with potash.

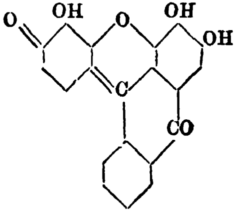
Galleïn crystallises from alcohol in small greenish crystals. It is insoluble in chloroform and benzene, sparingly soluble in water and ether, readily soluble in alcohol, forming a dark-red solution. It dissolves in cold concentrated sulphuric acid without change; on warming the solution cœruleïn is formed.

Galleïn dissolves in small quantities of potash or soda with a red colour; excess of alkali produces a blue solution. Heated to 150° with acetic anhydride galleïn yields a tetracetate of hydrogalleïn.

Galleïn (often called anthracene violet) is sold in the form of a reddish-brown powder, or a 10 p.c. paste; not very soluble in cold water, but readily so in hot. With all the usual alizarin mordants galleïn produces purple colours, which are fast to light and soap; those obtained by the use of chromium and iron are bluish, those with tin reddish, those with aluminium intermediate in tone.

Literature.—Baeyer (Ber. 4, 457 and 663); Buchka (Annalen, 209, 261); Orndorff and Brewer (Amer. Chem. J. 1901, 97).

Cœrulein $C_{20}H_{10}O_6$



Cœrulein is prepared by heating 1 part of gallein and 20 parts of sulphuric acid to 200°, and precipitating the colouring matter by adding a large quantity of water. It is thus obtained as a bluish-black mass, which, when rubbed, acquires a metallic appearance. It is almost insoluble in water, ether, and alcohol, more readily soluble in acetic acid.

It dissolves in alkalis with a green colour, in acids with an olive-brown colour. With bisulphite of soda cœruleïn forms an easily soluble compound. With acetic anhydride it forms a triacetate. Cœrulein (anthracene green) is sold in two forms, either as a bluish-black paste containing 10–20 p.c. cœrulein, or as a black powder.

The former is insoluble in water, the latter, known as cœruleïn S, is soluble in water, and is indeed a bisulphite compound of cœruleïn.

Cœruleïn is mostly employed in calico-printing for producing very fast olive-green shades. Whatever the mordant used, only different shades of olive-green are produced.

Literature.—Baeyer (Ber. 4, 556, 663); Orndorff and Brewer (Amer. Chem. J. 1901, 97).

F. H. G., W. H. P. and R. R.

ALIZARIN (Natural) *v.* CHAY ROOT and MADDER.

ALIZARIN AND METHYL ETHER *v.* CHAY ROOT.

ALIZARIN BLACK, -BLUE, -BORDEAUX, BROWN, -CARDINAL, -CYANINE, -GARNET, GREENS, -MAROON, -ORANGE, -REDS, -SAPHIROL *v.* ALIZARIN AND ALLIED COLOURING MATTERS.

ALIZARIN YELLOW *v.* AZO- COLOURING MATTERS; KETONES.

ALKALI ALBUMIN *v.* PROTEINS.

ALKALI BLUE. *Nicholson's blue. Sodium triphenyl-rosaniline sulphonate* (*v.* TRIPHENYL METHANE COLOURING MATTERS).

ALKALI BROWNS, -YELLOW *v.* AZO- COLOURING MATTERS.

ALKALIMETRY *v.* ACIDIMETRY.

ALKALI WASTE *v.* *Soda manufacture,* art. SODIUM.

ALKALOIDS. The alkaloids are nitrogenous basic carbon compounds occurring mostly in plants, but a few animals, *e.g.* the salamander, contain bases similar in every respect to the typical vegetable alkaloids. The exact demarcation of the group is difficult; generally the alkaloids may be said to contain heterocyclic nitrogen, to be soluble in solvents immiscible with water and to have a complicated molecular structure. These characters are, as a rule, not possessed by the simpler amines and betaines derived from the amino- acids of proteins, nor by choline and other bases of general biological importance, which, in contradistinction to the typical alkaloids, are not limited to one, or a few, species of plants or animals. For a full account of these amines, betaines, choline, &c., *v.* Barger, The Simpler Natural Bases, Longmans, 1914. A list of books dealing with alkaloids is given at the end of this article.

The discovery of the first alkaloid is due to the German pharmacist Sertürner, who, in 1805, isolated from opium a substance 'morphium,' which he described more fully in 1817 as a basic, salt-forming substance having the principal physiological action of the drug. The discovery of morphine was quickly followed by that of other alkaloids, made chiefly by Pelletier and Caventou. The first volatile alkaloid, coniïne, was isolated in 1827 by Giesecke, and nicotine in 1828 by Posselt and Riemann.

Distribution and mode of formation. No alkaloids have been obtained from algæ and mosses, hardly any from fungi, a few only from vascular cryptogams and gymnosperms, more from monocotyledons, but the vast majority from dicotyledons. Certain large orders, *e.g.* *Compositæ Gramineæ,* are very poor in alkaloids, others such as the *Ranunculaceæ, Solanaceæ, Papaveraceæ* are typically rich. Generally an alkaloid is limited to a single genus or order; berberine, however, occurs in several orders. The total alkaloids of a plant usually consist of a mixture of several bases often closely related, which may be present in very different amounts.

The older view that alkaloids are plastic materials capable of further utilisation by plants has been disproved by Clautriau (Ann. Soc. belge de Microsc. 1894, 18; Ann. Soc. roy. Sci. méd. nat. Bruxelles, 1900, 9), who concludes that they are waste products, only of use as a means of defence on account of their poisonous properties. The amount of alkaloid is generally greatest in the mature plant and in the periphery (bark) or in hibernating parts (root); it varies greatly in different organs. Weight for weight young shoots and leaves may contain more than older ones. For methods of microscopical localisation, *see* Errera, Maistriau, and Clautriau (Ann. Soc. belge de microsc. 1888, 12; Clautriau, *ibid.* 1894, 18).

The mode of origin of alkaloids in plants is not understood and has given rise to much speculation (Czapek, Biochemie der Pflanzen, 1905, ii. 267; Windaus and Knoop, Beitr. chem. Physiol. Path. 1905, 6, 392; Pictet, Arch. Sci. phys. nat. 1905, 243, 329; 1906, 244, 389; Tunmann, Arch. Pharm. 1910, 248, 644; Winterstein und Trier, Die Alkaloide, 1910, 263).; The most fruitful contribution is probably that of Robinson (Trans. Chem. Soc. 1917, 111, 876), who utilises only reactions which can be carried out in the laboratory at the ordinary temperature and shows how several of the principal alkaloids might be built up from ammonia, formaldehyde, ornithine, lysine, and degradation products of carbohydrates, such as citric and acetonedicarboxylic acids. These substances are imagined to undergo aldol and similar condensations, and it is interesting to note that Robinson has actually synthesised tropinone in aqueous solution at room temperature from succindialdehyde, methylamine, and calcium acetonedicarboxylate.

The alkaloids may be classified chemically according to the heterocyclic rings in which nitrogen occurs, as derivatives of pyrrolidine (*e.g.* hygrine), of pyridine (*e.g.* arecoline), of piperidine (*e.g.* piperine), of glyoxaline (*e.g.* pilocarpine), of indole (*e.g.* physostigmine), of quinoline (*e.g.* quinine), and of *iso*quinoline (*e.g.* papaverine); another group contains alkaloids without heterocyclic ring, derivatives of aliphatic amines (*e.g.* narceine). Some alkaloids may be classified under two of the above or under additional groups; thus atropine and cocaine contain both a pyrrolidine and a piperidine ring, caffeine contains a pyrimidine ring in addition to glyoxaline. No chemical classification can be complete, and a large number of alkaloids of insufficiently known constitution have perforce to be arranged according to the plants (or animals) from which they are derived.

Method of extraction and isolation. Generally speaking, alkaloids, whether occurring in the free state or as salts of organic acids, are extracted from the finely powdered material by means of strong spirit. After distilling off the alcohol, the bases are extracted from the residue by dilute acids, liberated by the addition of ammonia or sodium carbonate and extracted by chloroform, ether, or carbon tetrachloride. This gives the total alkaloidal content of the plant, except where a quaternary base is present, when methods similar to those employed for the simpler natural bases, *e.g.* precipitation with mercuric chloride or phosphotungstic acid, are utilised. Certain stable alkaloids may be extracted from a mixture of the finely powdered plant with lime or magnesia by an organic solvent; in other cases (*e.g.* caffeine in tea) extractions with boiling water may be employed.

The 'total alkaloids' of plants obtained by the above methods are mixtures for which no general method of separation can be given. In some cases, caustic soda may be used to separate the phenolic from the non-phenolic bases; in others, fractional extraction of the ether or chloroform solution of the bases with acid brings about a separation; or, again, a fractionation may be effected by regenerating the bases from acid solution by an alkali in the presence of light petroleum or ether, in which only a part of the mixture is soluble. After suitable preliminary treatment on these lines, alkaloids often crystallise as the free base, but if not, it is generally possible to crystallise a salt with a strong or weak acid. A convenient method is to add to the dry ethereal solution of the alkaloid, contained in a tall stoppered cylinder, small amounts of an ethereal or concentrated alcoholic solution of the acid, until no more alkaloidal salt is precipitated, shaking after each addition. If excess of acid is avoided, the flocculent precipitate can be readily washed by decantation and is then crystallised from alcohol, with or without ether. The choice of the proper acid is sometimes of great importance, *e.g.* for physostigmine the salicylate is the best salt, and for ergotoxine the phosphate. Acid oxalates are frequently valuable, whilst aurichlorides are useful for Solanaceous alkaloids and picrates for simple bases, but no general rule can be given. For further information concerning the methods of separating and characterising alkaloids, *see* Allen's Commercial Organic Analysis, vol. vi. 1912, 171–177. and the articles in this dictionary on CINCHONA, IPECACUANHA, and OPIUM ALKALOIDS.

Physical and chemical characters of the alkaloids. Nearly all are solids, and then mostly crystalline; a few (coniine, nicotine) are liquids, and are volatile with steam. In a high vacuum even complex alkaloids may often be sublimed or distilled on a small scale, *e.g.* strychnine. Most alkaloids are optically active; the specific rotation of the free base in a dissociating solvent may differ considerably from that of the ion of a salt in the same solvent, and the two may even have opposite signs (*e.g.* nicotine and its salts) (*cf.* Carr and Reynolds, Chem. Soc. Trans. 1910, 97, 1328).

The majority of the typical alkaloids are insoluble, or very sparingly soluble, in water; their best solvent is alcohol. Usually they are also dissolved by chloroform, less generally by ether, benzene, or amyl alcohol, sometimes by light petroleum. Simple amines, betaines, purine derivatives, and quaternary alkaloids like columbamine, are often more soluble in water than in organic solvents. The aqueous solutions of the alkaloids are often strongly alkaline to litmus, but a few alkaloids which are acid amides (colchicine, caffeine, piperine) are so feebly basic that they may be extracted from acid solution by chloroform, owing to the extensive hydrolysis of their salts. In these cases the salts are mostly not obtainable in a pure crystalline condition. Alkaloidal salts are generally more or less readily soluble in water and in alcohol, but as a rule not in chloroform or ether. Salts of the more complex alkaloids may be very little soluble in excess of the acid, if the latter is highly dissociated (mineral acids or even oxalic acid).

The vast majority of alkaloids are tertiary bases. A few (carpaine, cytisine, ephedrine) are secondary bases; the betaines, berberine, columbamine, &c., are quaternary. Primary bases are only found among amines derived from the amino- acids of protein and not among true alkaloids; they seem to be formed only by bacteria and fungi.

Most of the alkaloids are monacid bases even when they contain several atoms of nitrogen in the molecule. Thus, pilocarpine with two, physostigmine with three, and ergotoxine with five nitrogen atoms are monacid bases. Quinine is the best known example of a *di*-acid alkaloid.

Certain alkaloids or their salts can be hydrogenated in aqueous solution or suspension by means of molecular hydrogen in presence of nickel suboxide, or a colloidal metal of the platinum group, at the normal temperature and pressure or at increased pressures. Thus quinine hydrochloride yields hydroquinine, morphine yields dihydromorphine, and codeine yields dihydrocodeine, whilst cinnamylcocaine gives hydrocinnamylcocaine, an oily liquid decomposed by heat. Strychnine and brucine yield the corresponding dihydrides, and colchicine gives the tetrahydro- derivative. The reduction of these alkaloids may also be effected by nascent hydrogen liberated from formic acid by the action of finely divided metals of the platinum group ($HCOOH=H_2+CO_2$). Quinine, morphine, codeine, and other opium alkaloids may be converted into dihydro- derivatives (Eng. Pat. 10204, 1913; 14247, 1913; D. R. PP. 306939; 230724; 260233; U.S. Pat. 989604; Eng. Pat. 3948, 1912).

General alkaloidal precipitants. *Auric chloride* $AuCl_3$ combines with alkaloidal hydrochlorides to form well-defined aurichlorides of the composition $B,HAuCl_4$, generally sparingly soluble in water, and obtained as pale-yellow precipitates on mixing the gold and alkaloidal chlorides in aqueous solution. The aurichlorides may be recrystallised from alcohol or water acidulated with hydrochloric acid, and are most useful for characterising Solanaceous alkaloids. Occasionally gold chloride is reduced to metallic gold with formation of a red gold sol. The aurichlorides may be analysed by simple ignition, or by combustion, or by decomposition with hydrogen sulphide; in the last case the alkaloid is recovered unchanged by making the filtrate from the gold sulphide alkaline and extracting with chloroform. In a few cases, when alcoholic solutions of gold chloride and of the alkaloid are mixed, stable crystalline salts (auric chloride compounds) of the composition $B,AuCl_3$ are obtained (Dunstan and Ince, Chem. Soc. Trans. 1891, 59, 271). For other aurichloride compounds of abnormal composition, *see* Dunstan and collaborators (Chem. Soc. Trans. 1893, 63, 201, 445; 1900, 77, 57).

Platinic chloride in aqueous solution may precipitate platinichlorides of the composition B_2,H_2PtCl_6, which are generally more soluble than the aurichlorides and are analysed in the same way. In both cases the estimation of the chlorine may be useful.

Picric acid precipitates the solutions of most alkaloidal salts, and the resulting picrates may often be crystallised (from water or alcohol). The alkaloid may be recovered by extracting it from alkaline solution by chloroform, or the picric acid may be removed from acid solution by shaking with ether or benzene. The picric acid is conveniently estimated without the loss of the alkaloid, by nitron (Busch, Ber. 1905, 38, 861).

Picrolonic acid (4-nitro-1-*p*-nitrophenyl-3-methyl-5-pyrazolone) in alcoholic solution behaves similarly (*e.g.* Warren and Weiss, J. Biol. Chem. 1907, 3, 327). The picrolonates are less soluble than the picrates, and are of most use when the base and its picrate are readily soluble in water (histidine, arginine).

The above four precipitants may be used for obtaining crystalline salts for analysis and characterisation. *Mercuric chloride* is occasionally used for the same purpose, but more frequently only for preparative purposes (*see* quaternary bases, above). The following reagents are more sensitive, but generally give only amorphous precipitates, unsuitable for analysis.

Bismuth potassium iodide (Dragendorff's or

Kraut's reagent) has been used for isolating simple water soluble bases, which are recovered by grinding up the brick-red precipitate with freshly prepared lead hydroxide. After filtration the last traces of lead are removed by hydrogen sulphide. Cadmium potassium iodide is also employed as a general alkaloidal precipitant.

Iodine dissolved in aqueous potassium iodide (Wagner's or Bouchardat's reagent) is one of the most general. In dilute solutions a reddish-brown precipitate is formed, which in strong solution aggregates at once to a greenish-black mass, and consists of periodides of variable composition. Many periodides crystallise from alcohol, the crystals being green by reflected, and red by transmitted light (*cf.* herapathite, under QUININE). The recovery of the alkaloid from a periodide may be effected by decolourising with sodium thiosulphate or sulphur dioxide, and shaking out from alkaline solution, or, if this is impossible, grinding up the periodide with 'molecular' copper, when only the iodide of the base remains in aqueous solution.

Potassium mercuric iodide (Mayer's or Tanret's reagent) prepared by adding potassium iodide to mercuric chloride until the mercuric iodide at first precipitated, is re-dissolved, is the best general reagent for detecting alkaloids, and may afford an extremely delicate test. Some alkaloids are most completely precipitated in neutral, others in faintly acid, a few in more strongly acid solution. In very dilute solution only an opalescence is produced, in more concentrated solution a yellowish-white flocculent precipitate occurs, from which the alkaloid may be recovered by suspension in water and passing hydrogen sulphide. In spite of its variable composition, the precipitate may be used to some extent for quantitative purposes (*see* next section).

Tannic acid is merely a colloidal precipitant for complex substances, and precipitates alkaloids, along with some glucosides, peptones, &c.

For a full discussion of the above and other alkaloidal reagents, *see* Allen's Commercial Organic Analysis, 1912, vol. vi. 185–197.

Quantitative estimation of alkaloids. As a rule only the 'total alkaloid' can be determined, although in a few cases of technical importance (*e.g.* cinchona and strychnos alkaloids, *q.v.*) individual alkaloids may be estimated in a mixture. The estimation of the total alkaloid is based on the same principles as the isolation. Keller (Schweiz, Wochenschr. f. Chem. u. Pharm. 1894, 32, 44) mixed the finely powdered drug with magnesium oxide, or moistened it with ammonia, and extracted it with ether, or a mixture of ether and chloroform. An aliquot portion of the extract is shaken with dilute acid, the aqueous solution is rendered alkaline and again shaken several times with ether or chloroform. The alkaloid left on evaporation of the solvent may be weighed, but in most cases it is more satisfactory to titrate it in aqueous or dilute alcoholic solution. Of the various indicators suggested methyl orange and methyl red are theoretically and practically the best in most cases; the latter indicator is said to be quite satisfactory for all the official alkaloids. In special cases haematoxylin is used, and sometimes iodeosin (*see* Allen's Commercial Organic Analysis, vol. vi. 178–183; and von Korczynski, Die Methoden der exakten quantitativen Bestimmungen der Alkaloide, Berlin, 1913). The last-named compilation gives, *i.a.*, all the methods of the German Pharmacopoeia; the U. S. P. may also be consulted. A different principle is involved in the use of Mayer's reagent, which, as a rule, gives much less accurate results. As a titration method this is probably best employed in the form given it by Heikel (Chem. Zeit. 1908, 32, 1149, 1162, 1186, 1212). Potassium mercuric iodide is chiefly useful for quantities too small to be titrated with acid, and should then be used in a nephelometric comparison with alkaloidal solutions of known strength (*cf.* Ramsden and Lipkin, Ann. trop. Med. Parasitol. 1918, 11, 443, who thus estimate quinine in blood and urine with considerable accuracy; minute quantities of other alkaloids can doubtless be estimated in the same way).

Toxicological detection of alkaloids. The principles are similar to those involved in extracting alkaloids from plants, but owing to the minuteness of quantities present and the possible presence of putrefactive and other bases, great care is required. For details of the methods of Stas-Otto, Dragendorff, &c., *see* Wynter Blyth, Poisons, their Effects and Detection, 1909; Kippenberger, Zeit. anal. Chem. 1895, 34, 294; Schmidt, Pharmazeutische Chemie, ii. 1911, 1550–58. Colour reactions are of little use for identifying an unknown alkaloid, especially if impure (*v.* Allen's Commercial Organic Analysis, 1912, vol. vi. 197–201). Pharmacological tests are much more useful.

Bibliography of alkaloids (arranged chronologically).

I. Guareschi. Einführung in das Studium der Alkaloide, transl. from the Italian by H. Kunz-Krause. Berlin, 1896. (Includes many bases, natural and synthetic, not generally regarded as alkaloids.)

J. W. Brühl. Roscoe-Schorlemmer's Lehrbuch der Chemie, vol. viii. 1901. (A complete account, especially theoretical, with full literature references; unfortunately now somewhat out of date.)

A. Pictet. The Vegetable Alkaloids, transl. by H. C. Biddle. New York, 1904. (Deals with questions of constitution and synthesis.)

E. Winterstein und G. Trier. Die Alkaloide, 1910. (Less detailed than the above or following; speculations on the mode of formation of alkaloids in plants; physiological action; includes the simpler amines, betaines, &c.)

J. Schmidt, in Abderhalden's Biochemisches Handlexicon, vol. v. pp. 1–452. Berlin, 1911. (Chiefly for literature references.)

E. Schmidt, Pharmazeutische Chemie, 1911, vol. ii. pp. 1541–1855. (Very complete; mentions many little-known alkaloids; unfortunately no literature references; deals most fully with official alkaloids.)

Allen's Commercial Organic Analysis, 1912, vol. vi. pp. 167–726, and 1913, vol. vii. pp. 1–94. (Full analytical and technical accounts of the better-known alkaloids.)

T. A. Henry. The Plant Alkaloids. London, 1913, pp. vi.–466. (The most complete general account in English.)

For questions of constitution and synthesis, the following monographs are useful:—

J. Schmidt. Ueber die Erforschung der Konstitution und die Versuche zur Synthese wichtiger Pflanzenalkaloide. Stuttgart, 1900; and the triennial supplements, Die Alkaloidchemie in den Jahren, 1900–1904, 1904–1907, 1907–1911. G. B. and F. L. P.

ALKANET. The Arabic name *Al-henne*, modified to *alkanna* or *al-kenna*, was originally applied to the lythraceous shrub *Lawsonia alba* (Lam.), the root of which was described as *Radix Alkannæ vera*, in contradistinction to the root of our alkanna, which is *Anchusa tinctoria* (Lam.), and which became known as *Radix Alkannæ spuria tinctoria*. The latter, or *False alkanet*, is also known as *Orcanette*, Fr.; *Orkanet*, Ger.; Languedoc bugloss or dyers' bugloss, *Radix Alkannæ spuria*. A rough plant with downy spear-shaped leaves, and clusters of purplish or reddish flowers; belongs to the *Boraginaceæ*. Found in Asia Minor, Greece, Hungary, &c. The roots, which have an astringent taste, occur in commerce, varying from the thickness of a quill to that of a finger.

Alkanet is one of the more ancient dyestuffs, having been employed by the Romans, but, on the other hand, it does not appear at any time to have attained such importance as madder, indigo, or even turmeric. The colouring matter of alkanet, known as *anchusin* or *alkannin*, has been examined by several chemists, but it is doubtful whether this compound has as yet been obtained in a chemically pure condition. Its composition is variously given as $C_{17}H_{10}O_4$ (Pelletier, Annalen, 6, 27), $C_{35}H_{20}O_8$ (Bolley and Wydlers, Annalen, 62, 41), $C_{15}H_{14}O_4$ (Carnelutti and Nasini, Ber. 13, 1514), and $C_{15}H_{14}O_4$ or $C_{15}H_{12}O_4$ (Liebermann and Römer, Ber. 20, 2428).

Alkannin forms a dark-red amorphous powder possessing a beetle-green iridescence, is readily soluble in most of the usual solvents, and its alkaline solution is deep-blue coloured. On distillation with zinc-dust it gives, according to Liebermann and Römer, both methylanthracene and anthracene.

Diacetylalkannin $C_{15}H_{12}O_4(C_2H_3O)_2$ forms a dull yellow micro-crystalline powder (C. and N.).

According to Eriksson (Ber. Deut. pharm. Ges. 1910, 20, 202), alkannin consists of two red pigments, the one being coloured green and the other blue by the action of alkalis. Red crystals have been observed by Tschirch in spaces in the cortex of old specimens of alkanet root. As alkannin is insoluble in water, in dyeing with alkanet an alcoholic extract is usually employed; and with aluminium and iron mordanted fabrics, violet and grey shades are respectively produced. These colours, however, are not fast to light, and are somewhat readily affected by weak alkalis or acids.

Haussmann of Mulhouse introduced alkanet into calico-printing, and for a short time it appears to have played a quite important part, but it is now little if at all employed in Europe for ordinary dyeing purposes. It is still used for colouring artificial wines, pomades, hair-oils, sweets, &c., and for these purposes it is well adapted on account of its ready solubility and harmless nature.

Böttger (J. pr. Chem. 107, 146) and Eng (Jahres. 70, 935) recommend the use of papers stained by alkanet as indicators in alkalimetry.

According to Jolin (Chem. Schriften über Alkanna, iv. 84), Thomson (Pharm. J. [3] 16, 860), and Eriksson (*l.c.*), alkanet root contains from 5 to 6 p.c. of anchusin. A. G. P.

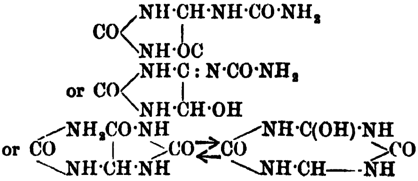
ALKANNA or **AL-KENNA.** The powdered root and leaves of the *Lawsonia alba* (Lam.), used in the East for dyeing the nails, teeth, hair, and garments. Used in Persia mixed with lime for dyeing the tails of horses.

ALKANNIN (ANCHUSIN) *v.* ALKANET.

ALKASAL *v.* SYNTHETIC DRUGS.

ALLANITE (*v.* ORTHITE). This is variously regarded as a synonym or as a variety of orthite. The original allanite was discovered at Kakarsuatsiak in east Greenland by C. L. Giesecke in 1806, described by T. Allen in 1808, and named by T. Thomson in 1810. Similar material has been found at numerous other localities in Greenland (O. B. Böggild, Mineralogia Groenlandica, Kjöbenhavn, 1905). L. J. S.

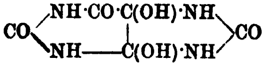
ALLANTOIN. *Glyoxyldiureide* $C_4H_6O_3N_4$



(Titherley, Chem. Soc. Trans. 1913, 103, 1336; Biltz, Ber. 1913, 46, 3410; Mendel and Dakin. Chem. Soc. Trans. 1915, 107, 434) was found originally in the allantoic liquid of cows (Vauquelin and Buniva, Ann. Chim. 23, 269; Lassaigne, Ann. Chim. Phys. [2] 17, 301) and in the urine of newly-born calves (Wöhler, Annalen, 70, 229); it occurs in the blood of the pig and ox (Hunter, J. Biol. Chem. 1917, 28, 369–374); in beetroot (Smokenski, Zeitsch. Ver Dtsch. Zuckerind, 1910, 1251); in root of *phaseolus multiflorus* (Power and Salway, Pharm. J. 1913, [4] 36, 552); in *Anabasis aretioides* and other plants (Stieger, Zeitsch. physiol. Chem. 1913, 86, 269; Johnson, J. Amer. Chem. Soc. 1914, 36, 1, 339); also in the young leaves, buds, and stem of the plane tree (*Platanus orientalis*); sycamore (*Acer pseudoplatanus*); in the bark of the horse-chestnut (*Æsculus hippocastanum*); in comfrey root (Titherley and Coppin, Pharm. J. 1912, 34, 92); and in rice polishings (Funk, J. of Physiol. 45, 75). Under normal conditions of growth 0·25 gram allantoïn may be isolated from 440 grams of fresh young leaves of the plane, but when the branches are cut in bud and the buds allowed to open in water, the amount of allantoïn increases to 0·5 or 1 p.c. of the dried leaves (Schulze and Barbieri, Ber. 1881, 14, 1602; J. pr. Chem. [2] 25, 145; Schulze and Bosshead, Zeitsch. physiol. Chem. 1884, 9, 420). It has been found in the nitrogenous constituents of wheat-germs (Richardson and Crampton, Ber. 1886, 19, 1180); in tobacco seeds (Scurti and Perciabosco, Gazz. chim. ital. 1906, 36, ii. 626); and in crude beet juice (v. Lippman, Ber. 1896, 29, 2652). Allantoïn is a normal constituent of the urine of mammals; the amount varies in different species, being greatest in the dog and least in man (Frerichs, Städeler, J. 1854, 7, 714; Wiechowski, Biochem.

Zeitsch. 1909, 19, 368; Schittenhelm, Zeitsch. physiol. Chem. 1909, 63, 248, 269, 283, 289). The whole quantity of allantoïn excreted by man on a milk and vegetable diet may be derived directly from the food (Ackroyd, Bio-Chem. J. 1911, 5, 400). In the case of the dog the amount of allantoïn in the urine is increased after a diet of animal food (Salkowski, Ber. 1878, 11, 500), of calf's thymus (Cohn. Zeitsch. physiol. Chem. 1898, 25, 507; Mendel, Amer. J. Physiol. 6, xiv.–xv.; M'Lachlan, Proc. Roy. Soc. Edin. 1906, 26, 95; and on increasing the ingestion of water per day from 900 to 3450 c.c. there is an increase of 20 p.c. in output (Fairhall and Hawk, J. Amer. Chem. Soc. 1912, 34, 546). There is about 30 p.c. increase in elimination of allantoïn if adrenaline is introduced (Falta, Zeitsch. exp. Path. Ther. 15, 356). It is also increased after the administration of uric acid (Salkowski, Ber. 1876, 9, 719; Swain, Amer. J. Physiol. 1910, 6, 38; Wiechowski, Beitr. Chem. Physiol. Path. 1908, 11, 109; Biochem. Zeitsch. 1910, 25, 431), or of nucleic acid (Mendel, *l.c.*; Schittenhelm, Zeitsch. physiol. Chem. 1910, 66, 53; Wiechowski, *l.c.*). Allantoïn is therefore to be regarded as an end-product of uric acid metabolism in the case of such animals as dogs and rabbits (Wiechowski, *l.c.*; Schittenhelm, *l.c.*). For the importance of allantoin as end-product in purine metabolism in monkeys, *see* Hunter and Giveus, Pro. Amer. Physiol. Soc. 1910, xv.–xvi.; Amer. J. Physiol. 27, 1910–1911, xv. Allantoïn is of therapeutic value (Funk, J. of Physiol. 45, 489–492), and is used to induce cell proliferation in cases of burns, &c. (Titherley and Coppin, Pharm. J. 1912 [iv.] 34, 92–94). Allantoïn injected increases the blood pressure (Backmann, Zentral. blatt f. Physiol. 26, 166).

The method of preparation of allantoïn by oxidising uric acid with lead peroxide in presence of water is due to Liebig and Wöhler (Annalen, 1838, 26, 245); it has been modified by Mulder (Annalen, 1871, 159, 349), who effects the oxidation in dilute acetic acid solution and in bright daylight; by this method 100 grams of uric acid yield 30–32 grams of allantoïn. A quantitative yield of allantoïn is obtained when uric acid is oxidised by an alkaline solution of potassium permanganate, and the intermediate compound



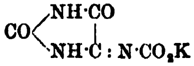
$$\mathrm{CO}\left\langle\begin{array}{l}\mathrm{NH{\cdot}CO{\cdot}C(OH){\cdot}NH}\\ \mathrm{NH{-\!\!-\!\!-}C(OH){\cdot}NH}\end{array}\right\rangle\mathrm{CO}$$

decomposed by acetic acid (Sundvik, Zeitsch. physiol. Chem. 1904, 41, 343; Behrend, Annalen, 1904, 333, 141; and 1915, 410, 340–341). Allantoïn is also obtained by the action of nitrous acid on dialuric acid (Gibbs, Annalen Suppl. 1870, 7, 337). The synthesis of allantoïn has been effected (1) by Grimaux (Compt. rend. 1876, 83, 62) by heating a mixture of glyoxylic acid (1 part) and carbamide (2 parts) at 100° for 8–10 hours; (2) by Michael (Amer. Chem. J. 1883, 5, 198) by heating a mixture of mesoxalic acid and carbamide in equal proportions at 110°; (3) by Simon and Chavanne (Compt. rend. 1906, 143, 51) by the action of ammonia or alkali hydroxides on ethyl allantoate $CH(NH{\cdot}CO{\cdot}NH_2)_2CO_2Et$, obtained by the condensation of ethyl glyoxylate with carbamide; (4) by Behrend and Zieger (Annalen, 1915, 410, 337–373) by condensing uric acid and alloxanic acid in boiling acetic anhydride; (5) by Biltz and Giesler (Ber. 1913, 46, 3424) by the action of potassium cyanate on 5-amino hydantoïn hydrochloride; and (6) by Biltz and Heyn (Annalen, 1916, 413, 39) by the action of barium hydroxide solution on spiro-5,5,-dihydantoin.

Allantoïn is readily soluble in boiling water sparingly so in cold (1 : 131·5 at 21·8°) (Grimaux Ann. Chim. Phys. 1877, [v.] 11, 389); it is optically inactive (Mendel and Dakin, J. Biol. Chem. 1910, 7, 153); crystallises in glassy monoclinic prisms (Dauber, Annalen, 1849, 71, 511; Hunter, Biochem. J. 28, 369); its heat of combustion at constant pressure is +413·8 Cal. (*cf.* Emery, Benedict, Amer. J. Physiol. 28, 1911, 303), and heat of formation +170·4 Cal. (Matignon, Ann. Chim. Phys. 1893, [vi.] 28, 106). It melts at 227° (Titherley and Coppin), 235° with decomposition (Watt, Pharm. J. 1917, 45, 283), 235°–236° (decomp.) (Biltz and Heyn, *ibid.* 40); 232° (Hunter, *l.c.*).

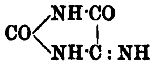
Allantoin forms a silver salt $C_4H_5O_3N_4Ag$ (Liebig and Wöhler, *l.c.*) and a potassium salt $C_4H_5O_3N_4K$ (Mulder, *l.c.*); it also combines with certain metallic oxides to form sparingly soluble compounds; the mercury, copper, zinc, lead, and cadmium derivatives are described by Limpricht (Annalen, 1853, 88, 94). (For the method of estimating allantoïn based on the sparing solubility of the silver and mercury derivatives, *see* Loewi, Zeitsch. anal. Chem. 1900, 39, 266; Poduschka, *ibid.* 267). Allantoïn from even 0·1 p.c. solution can be nearly quantitatively precipitated with mercuric chloride and sodium hydroxide or carbonate (Hunter, J. Biol. Chem. 1916, 28, 270). For titrimetric estimation in urine, *see* Handovsky (Zeitsch. physiol. Chem. 90, 211–220); for estimation in urine and in presence of sugar, Plimmer and Skelton (Biochem. J. 1914, 8, 70–73, and 641–648); Giveus (J. Biol. Chem. 1914, 18, 417–424).

Allantoïn is oxidised by potassium ferricyanide in the presence of potassium hydroxide to potassium allantoxanate



$$\mathrm{CO}\left\langle\begin{array}{l}\mathrm{NH{\cdot}CO}\\ \mathrm{NH{\cdot}C:N{\cdot}CO_2K}\end{array}\right.$$

(van Embden, Annalen, 1873, 167, 39); the free acid does not exist, but breaks down, when liberated from its salts, into carbon dioxide and allantoxaïdin



$$\mathrm{CO}\left\langle\begin{array}{l}\mathrm{NH{\cdot}CO}\\ \mathrm{NH{\cdot}C:NH}\end{array}\right.$$

(Ponomareff, Ber. 1878, 11, 2156). For oxidation of with bromine liquors (*see* Cordier, Monatsh. 33, 759–796). Methylallantoïn and isomerides (Fischer and Ach, Ber. 1899, 32, 2745; Biltz and Heyn, Annalen, 1916, 413, 83–85, and 97); 1-*methylallantoïn* (α-methylallantoïn) obtained from 9-methyl uric acid, has m.p. 250°–252° (decomp.), Fischer and Ach, m.p. 255°–259° (corr.) decomp.; 3-methyl allantoïn (β-*methylallantoïn*) crystallises in prisms with one molecule of water, m.p. 226°–227°, decomp., Fischer and Ach, m.p. 225°–227° (corr.) decomp.; 3, 8-*dimethylallantoïn* is obtained from 3, 7-dimethylspiro-dihydantoïn, m.p. 222°, turns yellow (decomp.); 1, 6-

dimethylallantoïn, obtained from 1, 9-dimethylspirodihydantoin, m.p. 226°–227° (K. Th.) (decomp.). M. A. W.

ALLEMONITE. A native alloy of arsenic and antimony, $SbAs_3$, found at Allemont in the Dauphiné, Przibram in Bohemia; and Andreasberg in the Hartz.

ALLMATEIN. Trade name for a condensation product of hæmatoxylin and formaldehyde.

ALLOSAN. Trade name for santalyl allophanate.

ALLOXAN. Mesoxalylcarbamide

$$CO{<}\genfrac{}{}{0pt}{}{NH\cdot CO}{NH\cdot CO}{>}C(OH)_2,3H_2O$$

found by Liebig (Annalen, 121, 81) and by Lang (Zeitsch. anal. Chem. 6, 294) in certain pathological excrétions, is one of the oxidation products of uric acid, and was first prepared by Brugnatelli (Ann. Chim. Phys. 1817, 8, 201; from Giornale di Fisica, decade seconde i. 117), under the name of *erythric acid*, by oxidising uric acid by means of nitric acid, chlorine or iodine. Liebig and Wohler (Annalen, 1838, 26, 256), who systematically studied the oxidation of uric acid, gave to this product the name of *alloxan*, regarding it as bearing the same relation to *allantoin* and *oxalic acid* that *oxaluric acid* does to *oxalic acid* and *urea*. According to Liebig and Wöhler (*l.c.*) and to Gregory (Mem. Chem. Soc. 1848, iii. 44), alloxan can be obtained most readily and with a yield of 90 p.c. by careful oxidation of uric acid by means of nitric acid, sp.gr. 1·412.

According to Schlieper (Annalen, 1845, 55, 261), the oxidation of uric acid to alloxan is more conveniently effected with hydrochloric acid and potassium chlorate; 4 parts of uric acid are mixed with 8 parts of hydrochloric acid, and 1 part of finely powdered potassium chlorate added in successive small quantities, avoiding the liberation of chlorine; after two or three hours the dissolved alloxan is reduced by means of sulphuretted hydrogen to the sparingly soluble *alloxantin*. This is separated from the sulphur by crystallisation from hot water, and oxidised to alloxan by the action of diluted nitric acid. Biltz (Annalen, 1916, 413, 60) prepares alloxan from uric acid in one operation by oxidation with chlorine.

Alloxan crystallises from warm saturated aqueous solution in large triclinic prisms containing $4H_2O$; on exposure to the air or on heating at 100° it loses $3H_2O$, and the dried compound has the composition expressed by the formula

$$CO{<}\genfrac{}{}{0pt}{}{NH\cdot CO}{NH\cdot CO}{>}C(OH)_2$$

(Lang, Grailich, J. 1858, 308; Hartley, Chem. Soc. Trans. 1905, 87, 1802); it is also obtained in oblique rhombic prisms, belonging to the monoclinic system on evaporating an aqueous solution at 65°–70°. The remaining molecule of water is lost at 150°. By heating under reduced pressure it is possible to dehydrate alloxan and its mono- and dimethyl derivaties, all of which sublime unchanged in vacuum.

Alloxan anhydride $C_4H_2O_4NO_2$, yellow rhombic crystals, has m.p. 256° (decomp.).

They are deposited from alcohols containing a little hydrochloric acid in the form of alcoholates; these when heated eliminate the molecule of alcohol and leave a residue with the melting-point of the anhydride (Biltz, Ber. 1912, 45, 3659–3675).

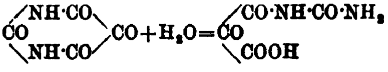
Alloxan anhydride $C_4H_2O_4N_2$, yellow rhombic crystals, has m.p. 256° (decomp.).

When crystals of alloxan are kept for some years in closed vessels they sometimes undergo spontaneous decomposition, forming alloxantin, parabanic acid, and carbon dioxide. According to Gregory (Annalen, 1853, 87, 126), this is due to the presence of traces of nitric acid contained in the water of crystallisation. Similar phenomena were observed by Baumert (Pogg. Ann. 1860, 110, 93), by Heintz (Pogg. Ann. 1860, 111, 436), and by Otto (Annalen Suppl. 1865, 4, 256). Cases of spontaneous explosive decomposition of alloxan are recorded by Wheeler and by Bogert (J. Amer. Chem. Soc. 1910, 32, 809); the products of decomposition being carbon dioxide, carbamide, oxalic acid, and alloxantin (Gortner, J. Amer. Chem. Soc. 1911, 33, 85).

The molecular heat of combustion of alloxan is 276·5 Cal. (Matignon, Ann. Chem. Phys. 1893, [vi.] 28, 300); the dissociation constant is $2{\cdot}32\times10^{-7}$ (Wood, Chem. Soc. Trans. 1906, 89, 1835). The dissociation constant K (in diazoacetic ester solution) $=0{\cdot}03542$, $C_H=0{\cdot}000920$, and the sp. conductivity at 25° (not deducting that of water, $1{\cdot}1\times10^{-5}=1{\cdot}27\times10^{-5}$ (Calcagin, Atti R. Accad. dei Lincei, [5] 25, i. 643–648). In common with the other simple ureides, alloxan shows no absorption bands in its spectrum (Hartley, Chem. Soc. Trans. 1905, 87, 1815).

Alloxan is readily soluble in alcohol or water; the solution is acid to litmus, stains the skin purple, and imparts to it a curious and unpleasant odour. In its physiological action alloxan affects the central nervous system, producing first stimulation, then paralysis. When taken internally it is excreted in the urine as alloxantin and parabanic acid (Lusini, Chem. Zentr. 1895, ii. 311, 727, 838; Koehne, Chem. Zentr. 1894, ii. 296).

Alloxan is readily oxidised by warm dilute nitric acid, forming carbon dioxide and *parabanic acid* (*oxalylcarbamide*) (*q.v.*); is reduced by sulphuretted hydrogen, stannous chloride, zinc, and hydrochloric acid, or by boiling with excess of sulphurous acid to *alloxantin* (*q.v.*); and is readily hydrolysed by alkali carbonates or by the hydroxides or chlorides of the alkaline earths, forming the corresponding salt of *alloxanic acid*. The barium and calcium salts are insoluble.



$$CO{<}\genfrac{}{}{0pt}{}{NH\cdot CO}{NH\cdot CO}{>}CO+H_2O=CO{<}\genfrac{}{}{0pt}{}{CO\cdot NH\cdot CO\cdot NH_2}{COOH}$$

If, however, excess of alkali is employed or the solutions are heated, the hydrolysis is carried to completion with the formation of mesoxalic acid and carbamide (Schlieper, Annalen, 1845, 55, 263; 56, 1; Biltz, Annalen, 1916, 413, 70). Alloxan gives a deep-blue colour with ferrous salts, but no precipitate is formed unless an alkali is present. According to Agrestini (Boll. Chim. Farm. 1902, 41, 5–7; Chem. Zentr. 1902, i. 631), the formation of blue colour is dependent on the presence of a trace of ammonia or caustic alkali, and the same deep-blue colour is also given by *pure* ferric salts under similar conditions. For similarity in the behaviour of triketohydrindene hydrate and alloxan, see Ruhemann (Chem. Soc. Trans. 1911, 99, 793); Traube (Ber. 1911, 44, 3145); Retinger (J. Amer. Chem. Soc. 1917, 39, 1059). Alloxan gives the murexide reaction, and Angrestini (*l.c.*) finds that the ammonia in the reaction can be replaced by certain acid amides, amino acids, or substituted amines; Rosenheim's alloxan test for choline (J. Physiol. 1905, 33, 220), namely, the formation of a deep red-violet colour when a drop of a 1 p.c. solution of choline hydrochloride is evaporated on the water-bath with a few drops of a saturated solution of alloxan, is probably a reaction of the same order.

Other tests for alloxan are (1) the formation of a deep violet-blue colour when a solution of alloxan is boiled for a few minutes with a drop of pyrrole. The colour changes to red on cooling, becoming green and then intensely blue on the addition of alkali. (2) The blue-green solution obtained on mixing concentrated sulphuric acid solutions of alloxan (or alloxantin) and pyrocatechol, the colour changes to an intense green on dilution (Agrestini, *l.c.*). Hartley (Chem. Soc. Trans. 1905, 87, 1816) finds that hydrated alloxan, when powdered along with pure calcite, acquires a yellowish-pink tinge. After half an hour the colour is decided and it is permanent; on adding water a red solution is obtained. When alloxan, dried at 100°, is similarly treated, there is no colour developed until water has been added. Alloxanic acid gives no such colour reaction. Alloxan yields alcoholates, phenolates, and sulphites (Biltz, Ber. 1912, 45, 3667–3670), also a compound with hydrogen peroxide $(C_4H_2O_4N_2)_{10}H_2O_2$ (Stolzenberg, Ber. 1916, 49, 1545).

For other derivatives of alloxan, *see* Behrend and Zieger (Annalen, 1915, 410, 337–373).

Potassium alloxan $C_4H_3O_5N_2K$, pale red needles, decomposes about 235°.

Carbamide alloxanate $C_4H_4O_5N_2,CO(NH_2)_2$, crystallises in four-sided prisms, decomposes 155°–156°.

Urea and alloxan also form a compound $C_5H_6O_6N_4$, decomposes 117° or 133°–134°, is probably a salt-like compound. It gives uric acid and glycol when heated; boiled with acetic anhydride it yields an anhydride $C_5H_6O_5N_4$, microscopic needles, m.p. 185°–186°.

Methyl alloxanate $C_5H_6O_5N_2$, prisms, decomposes 175°–176°.

The following *homologues* of alloxan have been described:—*Methylalloxan*

$$\mathrm{CO}\left<\begin{matrix}\mathrm{NMe\cdot CO}\\ \mathrm{NH\cdot CO}\end{matrix}\right>\mathrm{CO}$$

prepared from methyl uric acid (Hill, Ber. 1876, 9, 1092); from ζ-uric acid (Fischer, Ber. 1899, 32, 2731); from theobromine (Maly, Andreasch, Monatsh. 1882, 3, 108; Fischer and Clemm, Ber. 1897, 30, 3090). It crystallises from water in brilliant colourless prisms, becomes anhydrous at 60° in a vacuum, and decomposes at 156°. *Dimethylalloxan*

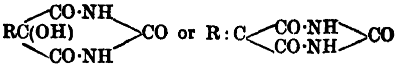
$$\mathrm{CO}\left<\begin{matrix}\mathrm{NMe\cdot CO}\\ \mathrm{NMe\cdot CO}\end{matrix}\right>\mathrm{C(OH)_2,H_2O}$$

prepared by oxidising caffeine (Fischer, Annalen, 1882, 215, 257; Maly, Andreasch, Monatsh. 1882, 3, 96), by boiling dichlorodimethylbarbituric acid with water or silver oxide (Techow, Ber. 1894, 27, 3083), loses $1H_2O$ when dried over sulphuric acid, decomposes at 100°; the anhydrous compound is a pale yellow powder soluble in alcohol and has m.p. 252°–255° (decomp.) (Biltz, Ber. 1912, 45, 3659). *Diethylalloxan* $C_8H_{10}O_4N_2$, prepared by oxidising 1:3-diethylbarbituric acid with nitric acid, containing a little nitrous acid (Sembritzki, Ber. 1897, 30, 1820). *Methylethylalloxan*, from ethyltheobromine by oxidation (Pommerehne, Apoth. Zeit. 1897, 12, 5). Some derivatives of 1:3-diphenylalloxan have been described by Whiteley (Chem. Soc. Trans. 1907, 91, 1344).

Inasmuch as the alloxan molecule contains the mesoxalyl radical

$$\mathrm{(OH)_2C}\left<\begin{matrix}\mathrm{CO\cdot}\\ \mathrm{CO\cdot}\end{matrix}\right. \quad \text{or} \quad \mathrm{OC}\left<\begin{matrix}\mathrm{CO\cdot}\\ \mathrm{CO\cdot}\end{matrix}\right.$$

it forms a wide series of condensation products through the medium of the :C(OH)₂ or :CO group yielding derivatives of the type



$$\mathrm{RC(OH)}\left<\begin{matrix}\mathrm{CO\cdot NH}\\ \mathrm{CO\cdot NH}\end{matrix}\right>\mathrm{CO} \quad \text{or} \quad \mathrm{R:C}\left<\begin{matrix}\mathrm{CO\cdot NH}\\ \mathrm{CO\cdot NH}\end{matrix}\right>\mathrm{CO}$$

respectively. These compounds will be described under the following eight headings.

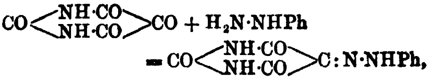
1. Condensation of Alloxan with Bisulphites.—Alloxan forms condensation products of the type $C_4H_2N_2O_4,NaHSO_3,1\frac{1}{2}H_2O$ with alkali bisulphites (Limpricht and Wuth, Annalen, 1858, 108, 41), and with the sulphites of certain organic bases (Pellizzari, Annalen, 1888, 248, 146). *Alloxan ethylamine sulphite* $C_2H_7N\cdot SO_3H_2\cdot C_4H_2N_2O_4,H_2O$; *Alloxan aniline sulphite* $C_6H_7N\cdot SO_3H_2,C_4H_2N_2O_4,2H_2O$; *Alloxan methylaniline sulphite* $C_7H_9N\cdot SO_3H_2,C_4H_2N_2O_4\cdot 2H_2O$; *Alloxan dimethylanilinesulphite* $C_8H_{11}N\cdot SO_3H_2,C_4H_2N_2O_4,4H_2O$, are described and the crystallographic constants are given. The *benzidine* compound contains $1H_2O$; *toluidine, aminobenzoic acid,* and *aspartic acid* yield similar compounds. *Alloxan pyridine sulphite* is triclinic, and anhydrous crystalline derivatives are afforded by *quinoline, picoline, morphine,* and *cinchonine*; the *strychnine* compound has $1H_2O$, and the *brucine* compound $1\frac{1}{2}H_2O$.

2. Condensation of Alloxan with Hydroxylamine.—Alloxan condenses with hydroxylamine hydrochloride (Ceresole, Ber. 1883, 16, 1133) to form the *oxime, violuric acid*

$$\mathrm{CO}\left<\begin{matrix}\mathrm{NH\cdot CO}\\ \mathrm{NH\cdot CO}\end{matrix}\right>\mathrm{C:N\cdot OH}$$

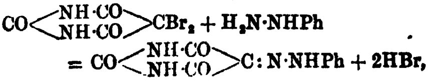
(*q.v.*).

3. Condensation of Alloxan with Hydrazines.—Hydrazones of alloxan and its homologues can be prepared by the condensation of (*a*) the alloxan with the hydrazine



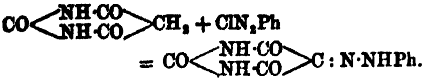
$$\mathrm{CO}\left<\begin{matrix}\mathrm{NH\cdot CO}\\ \mathrm{NH\cdot CO}\end{matrix}\right>\mathrm{CO} + \mathrm{H_2N\cdot NHPh} = \mathrm{CO}\left<\begin{matrix}\mathrm{NH\cdot CO}\\ \mathrm{NH\cdot CO}\end{matrix}\right>\mathrm{C:N\cdot NHPh},$$

(*b*) the dibromo- derivative of the corresponding barbituric acid with the hydrazine



$$\mathrm{CO}\left<\begin{matrix}\mathrm{NH\cdot CO}\\ \mathrm{NH\cdot CO}\end{matrix}\right>\mathrm{CBr_2} + \mathrm{H_2N\cdot NHPh} = \mathrm{CO}\left<\begin{matrix}\mathrm{NH\cdot CO}\\ \mathrm{NH\cdot CO}\end{matrix}\right>\mathrm{C:N\cdot NHPh} + \mathrm{2HBr},$$

(*c*) the corresponding barbituric acid with the diazonium chloride



$$\mathrm{CO{<}\begin{smallmatrix}NH\cdot CO\\ NH\cdot CO\end{smallmatrix}{>}CH_2 + ClN_2Ph = CO{<}\begin{smallmatrix}NH\cdot CO\\ NH\cdot CO\end{smallmatrix}{>}C : N\cdot NHPh.}$$

And the following hydrazones have been prepared by one or more of these methods:—*Alloxanphenylhydrazone*

$$\mathrm{CO{<}\begin{smallmatrix}NH\cdot CO\\ NH\cdot CO\end{smallmatrix}{>}C : N\cdot NHPh}$$

pale-yellow crystals, melts and decomposes at 298°–300°; 1 : 3-*Dimethylalloxanphenylhydrazone*

$$\mathrm{CO{<}\begin{smallmatrix}NMe\cdot CO\\ NMe\cdot CO\end{smallmatrix}{>}C : N\cdot NHPh}$$

slender yellow crystals, m.p. 261° the *o*- and *p*-nitro derivatives are yellow crystalline substances and decompose at 310° and 300° respectively (Kühling, Ber. 1891, 24, 4140; 1898, 31, 1972); *alloxanphenylmethylhydrazone*

$$\mathrm{CO{<}\begin{smallmatrix}NH\cdot CO\\ NH\cdot CO\end{smallmatrix}{>}C : N\cdot NMePh}$$

brick-red hexagonal plates, decomposes at 189°–191° (Whiteley, Chem. Soc. Proc. 1906, 22, 201); *alloxandiphenylhydrazone*

$$\mathrm{CO{<}\begin{smallmatrix}NH\cdot CO\\ NH\cdot CO\end{smallmatrix}{>}C : N\cdot NPh_2,}$$

bright-yellow powder, melts above 270° (Armstrong and Robertson, Chem. Soc. Trans. 1905, 87, 1291); 1 : 3-*diphenylalloxanphenylhydrazone*

$$\mathrm{CO{<}\begin{smallmatrix}NPh\cdot CO\\ NPh\cdot CO\end{smallmatrix}{>}C : N\cdot NHPh}$$

bright-yellow needles that decompose at 265°, the *p-nitro* derivative forms yellow prisms with a purple reflex and melt and decompose at 274°; 1 : 3-*diphenylalloxanphenylmethylhydrazone*

$$\mathrm{CO{<}\begin{smallmatrix}NPh\cdot CO\\ NPh\cdot CO\end{smallmatrix}{>}C : N\cdot NMePh}$$

decomposes at 175° and crystallises in orange red prisms or bright-yellow needles; 1 : 3-*diphenylalloxandiphenylhydrazone*

$$\mathrm{CO{<}\begin{smallmatrix}NPh\cdot CO\\ NPh\cdot CO\end{smallmatrix}{>}C : N\cdot NPh_2}$$

melts and decomposes at 254°–255°, and forms yellow crystals yielding an orange-red powder on trituration; 1 : 3-*diphenylalloxanphenylbenzylhydrazone*

$$\mathrm{CO{<}\begin{smallmatrix}NPh\cdot CO\\ NPh\cdot CO\end{smallmatrix}{>}C : N\cdot NPh\cdot CH_2Ph}$$

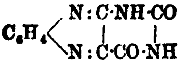
melts and decomposes at 130°, crystallises from benzene in bright-yellow needles, and from methyl alcohol in bright-red prisms; from toluene a mixture of the red prisms and yellow needles is obtained (Whiteley, Chem. Soc. Trans. 1907, 91, 1344); *alloxancyanophenylhydrazone*

$$\mathrm{CO{<}\begin{smallmatrix}NH\cdot CO\\ NH\cdot CO\end{smallmatrix}{>}C : N\cdot NPh\cdot CN}$$

from alloxan and aminophenylcyanamide, straw-yellow compound, m.p. 286° (Rolla, Gazz. chim. ital. 1907, 37, i. 623).

4. Condensation of Alloxan with Semicarbazide.—This reaction has been studied by Bromberg (Ber. 1897, 30, 131). He describes the compounds *alloxansemicarbazide* $C_5H_9O_6N_5$ and *dimethylalloxansemicarbazide* $C_7H_{11}O_5N_5$, but was not successful in determining their constitution.

5. Condensation of Alloxan with Diamines.—In the condensation of alloxan with *o*-diamines the ketonic carbonyl and one of the adjacent carbimido- groups take part, and the product is an *azine*; *alloxazine*

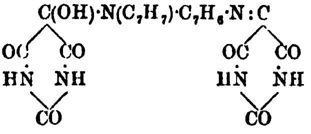


obtained from *o*-phenylenediamine, forms yellow microscopic crystals that decompose above 300°; similar derivatives were obtained from 3 : 4-diaminotoluene and *a*-β-diaminonaphthalene (Kühling, Ber. 1891, 24, 2363); for the effect of oxidising and reducing agents on these compounds, compare Kühling, Ber. 1895, 28, 1968; 1899, 32, 1650).

The condensation of alloxan with monosubstituted *o*-diamines results in the formation of two compounds according as one or more alloxan molecules take part in the reaction. Thus alloxan condenses with *orthaminoditolylamine* at the ordinary temperature to form *alloxanylorthaminoditolylamine*

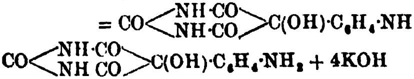
$$\mathrm{C_7H_7\cdot NH\cdot C_7H_6\cdot N : C{<}\begin{smallmatrix}CO\cdot NH\\ CO\cdot NH\end{smallmatrix}{>}CO}$$

glittering yellow prisms, that melt and decompose at 252°, and dissolve in concentrated sulphuric acid with a deep red colour; if, however, the condensation is effected in the presence of fuming hydrochloric acid and the mixture is boiled, *dialloxanylorthaminoditolylamine*



is formed. It is crystalline, and blackens at 300°, dissolves readily in alkali carbonates, and gives a deep-blue solution in concentrated sulphuric acid. Dimethylalloxan gives similar derivatives (Kühling, Ber. 1893, 26, 540), and similar condensation products are obtained from alloxan and phenyl-*o*-phenylenediamine, *o*-aminodi-*p*-tolylamine, and N-methyl-*o*-phenylenediamine (Kühling and Kaselitz, Ber. 1906; 39, 1314); and from tetramethyl-*m*-phenylenediamine (Sachs and Appenzeller, Ber. 1908, 41, 91).

6. Condensation of Alloxan with Aromatic amines.—Alloxan condenses readily with primary aromatic amines (Pellizzari, Gazz. chim. ital. 1895, 17, 419) to form aminoaryl substituted dialuric acids, yielding on hydrolysis with alkali, the corresponding tartronic acid (*q.v.*). Thus aniline and alloxan give *p*-aminophenyldialuric acid, and this on hydrolysis yields *p*-aminophenyltartronic acid



$$\mathrm{CO{<}\begin{smallmatrix}NH\cdot CO\\ NH\cdot CO\end{smallmatrix}{>}C(OH)_2 + C_6H_5\cdot NH_2 = CO{<}\begin{smallmatrix}NH\cdot CO\\ NH\cdot CO\end{smallmatrix}{>}C(OH)\cdot C_6H_4\cdot NH_2.}$$

$$\mathrm{CO{<}\begin{smallmatrix}NH\cdot CO\\ NH\ CO\end{smallmatrix}{>}C(OH)\cdot C_6H_4\cdot NH_2 + 4KOH = NH_2\cdot C_6H_4\cdot C(OH)(CO_2K)_2 + 2NH_3 + K_2CO_3.}$$

In view of the importance of these compounds as sources of tartronic acids, their preparation forms the subject of a patent, D. R. P. 112174 (Frdl. 1900–1902, 158–159), in which the amino-aryl- dialuric and tartronic acids obtained from

the following bases are described: ethylaniline, diethylaniline, benzylaniline, methylbenzylaniline, ethylbenzylaniline, diphenylamine, *p*-toluidine, *o*-ethyltoluidine, *o*-anisidine, methyl-*o*-anisidine, *o*-phenetidine, *m*-chloraniline, *m*-chlordimethylaniline, and *m*-chlordiethylaniline.

By careful oxidation with potassium permanganate of the alkali salts of the tartronic acids, or by oxidising the corresponding dialuric acid with mercuric oxide in presence of potassium hydroxide, the corresponding glyoxylic acid (*q.v.*) can be obtained

$$NH_2{\cdot}C_6H_4{\cdot}C(OH)(CO_2H)_2 + O = NH_2{\cdot}C_6H_4{\cdot}CO{\cdot}CO_2H + CO_2 + H_2O$$

and the preparation by these methods of an important series of glyoxylic acids forms the subject of patents D. R. P. 117021, 26/11, 1900; and 117168, 3/12, 1900.

Alloxan condenses also with pyrazolone bases to form derivatives of dialuric acid (tartronylcarbamide), and these on hydrolysis with cold caustic alkali yield the corresponding substituted tartronimides (Pellizzari, Gazz. chim. ital. 1888, 18, 340). Thus *phenylmethylpyrazolonetartronyl carbamide*

$$\begin{matrix}NPh{\cdot}CO\\ |\\ N=CMe\end{matrix}\!\!>CH{\cdot}C(OH)\!<\!\begin{matrix}CO{\cdot}NH\\ CO{\cdot}NH\end{matrix}\!>CO,3H_2O$$

forms long yellow needles that decompose at 170°–178°, and yield *phenylmethylpyrazolonetartronimide*

$$\begin{matrix}NPh{\cdot}CO\\ |\\ N=CMe\end{matrix}\!\!>CH{\cdot}C(OH)\!<\!\begin{matrix}CO\\ CO\end{matrix}\!>NH$$

on hydrolysis; *phenyldimethylpyrazolonetartronylcarbamide*

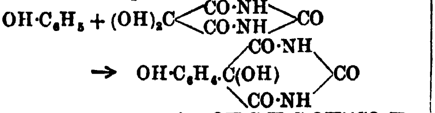
$$\begin{matrix}NPh{\cdot}CO\\ |\\ NMe{\cdot}CMe\end{matrix}\!\!>C{\cdot}C(OH)\!<\!\begin{matrix}CO{\cdot}NH\\ CO{\cdot}NH\end{matrix}\!>CO$$

melts and decomposes at 261°, and yields *phenyldimethylpyrazolonetartronimide*

$$\begin{matrix}NPh{\cdot}CO\\ |\\ NMe{\cdot}CMe\end{matrix}\!\!>C{\cdot}C(OH)\!<\!\begin{matrix}CO\\ CO\end{matrix}\!>NH$$

decomposing at 245°–250°.

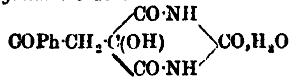
7. **Condensation of Alloxan with Phenols.**—Alloxan condenses in the presence of hydrogen chloride, sulphuric acid, or zinc chloride with mono- or polyhydroxy- phenols to form derivatives of dialuric acid (tartronylcarbamide), that promise to be of value for pharmaceutical purposes, and are readily converted by hydrolysis into the corresponding tartronic acid:



$$OH{\cdot}C_6H_5 + (OH)_2C\!<\!\begin{matrix}CO{\cdot}NH\\ CO{\cdot}NH\end{matrix}\!>CO \rightarrow OH{\cdot}C_6H_4{\cdot}C(OH)\!<\!\begin{matrix}CO{\cdot}NH\\ CO{\cdot}NH\end{matrix}\!>CO \rightarrow OH{\cdot}C_6H_4C(OH)(CO_2H)_2.$$

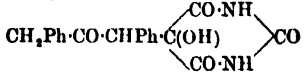
A description of the compounds obtained from alloxan and the phenolic compounds, phenol, *m*-cresol, *p*-cresol, guaiacol, pyrocatechol, resorcinol, hydroquinone, pyrogallol, *a*-naphthol, is given in D. R. P. 107720, 25/8, 1898; 113722, 9/7, 1900; 114904, 17/9, 1900; and the tartronic acids derived from them are described in D. R. P. 115817, 8/10, 1900.

8. **Condensation of Alloxan with Ketones.**—Alloxan condenses with acetophenone and certain of its homologues to form phenacyldialuric acid or its derivatives of which the following are described by Kühling (Ber. 1905, 38, 3003). Kühling and Schneider (Ber. 1909, 42, 1285): *phenacyldialuric acid*



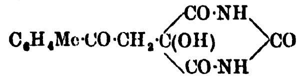
$$COPh{\cdot}CH_2{\cdot}C(OH)\!<\!\begin{matrix}CO{\cdot}NH\\ CO{\cdot}NH\end{matrix}\!>CO,H_2O$$

m.p. 212°, with decomposition; the *bromo-derivative* decomposes at 217°; *p-ethoxyphenacyldialuric acid* $C_{14}H_{14}O_6N_2$, m.p. 214°; the *bromo-* derivative, decomposes at 201°; *aγ-diphenylacetonyldialuric acid*



$$CH_2Ph{\cdot}CO{\cdot}CHPh{\cdot}C(OH)\!<\!\begin{matrix}CO{\cdot}NH\\ CO{\cdot}NH\end{matrix}\!>CO$$

m.p. 233° with decomposition; *p-methylphenacyldialuric acid*



$$C_6H_4Me{\cdot}CO{\cdot}CH_2{\cdot}C(OH)\!<\!\begin{matrix}CO{\cdot}NH\\ CO{\cdot}NH\end{matrix}\!>CO$$

m.p. 241°–242°, with decomposition; the *acetyl* derivative decomposes at 220°, the *benzoyl* at 215°; *p-methoxyphenacyldialuric acid* $C_{13}H_{12}O_6N_2$ decomposes at 227°, and yields an *acetyl* derivative, m.p. 207°.

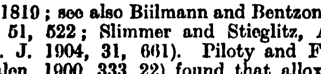
For condensation products of alloxan and substituted rhodamic acids (*see* Butscher, Monatsh. 1911, 32, 9–19), and alloxan with amino-antipyrine (*see* Meyer, Compt. rend. 1911, 152, 1677).

M. A. W.

ALLOXANIC ACID *v.* ALLOXAN; and Biltz, Heyn, Bergius (Annalen, 1916, 413, 368); Behrend and Zieger (Annalen, 1915, 410, 337).

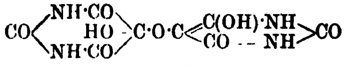
ALLOXANTIN $C_8H_6O_8N_4,2H_2O$ (Ritthausen, Ber. 1896, 29, 892) exists in small quantities in crude beet-juice (Lippmann, Ber. 1896, 29, 2645), and forms 34 to 36 p.c. of the products when *convicin* from sow-beans (*Vicia faba minor*) or from vetches (*Vicia sativa*) is hydrolysed by dilute mineral acids (Ritthausen, *l.c.*; J. pr. Chem. 1899, [ii.] 59, 487). Johnson (J. Amer. Chem. Soc. 1914, 36, 337–343) discusses its origin in plants. Alloxantin was first prepared by Liebig and Wöhler (Annalen, 1838, 26, 262) by oxidising uric acid with dilute nitric acid; or by the direct union of alloxan and dialuric acid, or by reducing a cold aqueous solution of alloxan with sulphuretted hydrogen or stannous chloride. According to Vitali (Chem. Zentr. 1898, i. 665, from Boll. Chim. Farm. 37, 65), the reduction can also be effected by means of hydriodic acid. Alloxantin was synthesised by Grimaux (Compt. rend. 1878, 87, 752) by heating malonic acid, carbamide and phosphoryl chloride at 150°, and passing sulphuretted hydrogen through a nitric acid solution of the crude product; or by passing sulphuretted hydrogen through a hot aqueous solution of dibromobarbituric acid (Compt. rend. 1879, 88, 86). Koech (Annalen, 1901, 315, 246) describes the conversion of *iso*dialuric acid into alloxantin by heating it with guanidine and acetic acid; the change seems to be due to the transformation of the *iso*dialuric acid into dialuric acid by the action of the base, and the subsequent oxidation of the dialuric acid to alloxantin, since, if the reaction is conducted in an atmosphere of carbon dioxide, dialuric acid only is obtained. An aqueous suspension of alloxantin possesses considerable oxygen consuming power (Thunberg, Skand. Arch. Physiol. 1916, 33, 217).

Alloxantin crystallises from aqueous solutions in small sharp rhombic prisms, containing 2 mols. H_2O; it becomes anhydrous after heating for 1-1½ hours at 150°, or for 5 hours at 107°–110°; it decomposes at 170° into hydurilic acid, ammonia, carbon monoxide, carbon dioxide, and oxalic acid; *turns* yellow at 225°, and decomposes at 253°–255° (Biltz, Ber. 1912, 45, 3675). It is decomposed into barbituric acid and parabanic acid when heated with concentrated sulphuric acid at 120°, or into allituric acid $C_6H_6O_4N_4$ when boiled with excess of hydrochloric acid (Schlieper, Annalen, 1845, 56, 20). Alloxantin is sparingly soluble in cold water (0·2885 gram per 100 c.c. at 25°, of which about 22 p.c. is undissociated, Biilman and Bentzon, Ber. 1918, 51, 522), yielding an acid solution that reduces solutions of silver salts, and gives a characteristic violet-blue precipitate with baryta water, changing on warming into the colourless barium alloxanate which undergoes further decomposition into barium mesoxalate and barium carbonate (Liebig and Wöhler, Annalen, 1838, 26, 312). Alloxantin has a molecular heat of combustion = 584·7 Cals. (Matignon, Ann. Chim. Phys. 1893, [6] 28, 323), and a freshly prepared aqueous solution shows a remarkable absorption band in the ultraviolet, which disappears upon keeping the solution, owing to the decomposition of the alloxantin into alloxan and dialuric acid (Hartley, Chem. Soc. Trans. 1905, 87, 1814). For this reason Hartley expresses the constitution of alloxantin by the formula



$$CO\left<\begin{matrix}NH\cdot CO\\ HO-\\ NH\cdot CO\end{matrix}\right>C\cdot O\cdot C\left<\begin{matrix}CO\cdot NH\\ -H\\ CO\cdot NH\end{matrix}\right>CO$$

(*ibid.* 1810; see also Biilmann and Bentzon, Ber. 1918, 51, 522; Slimmer and Stieglitz, Amer. Chem. J. 1904, 31, 661). Piloty and Finckh (Annalen, 1900, 333, 22) found that alloxantin was resolved into alloxan and dimethylamine dialurate, by boiling with dimethylamine acetate, and suggest the constitutional formula



$$CO\left<\begin{matrix}NH\cdot CO\\ HO-\\ NH\cdot CO\end{matrix}\right>C\cdot O\cdot C\left<\begin{matrix}C(OH)\cdot NH\\ CO\ --\ NH\end{matrix}\right>CO$$

in which the relationship between alloxantin and alloxan is the same as that existing between quinhydrone and quinone. In diazo acetic ester the dissociation constant is 0·0000331, concentration of H ions 0·00001644, and sp. conductivity at 25° (not deducting that of water $1,1\times10^{-6}$) $1,13\times10^{-5}$ (Calcagni, Atti. R. Accad. dei Lincei. [5] 25, i. 643; *see* also Richter, Ber. 1911, 44, 2155; Johnson, J. Amer. Chem. Soc. 1914, 36, 337).

Alloxantin is readily converted into murexide (*q.v.*) by the action of ammonia, into alloxan by mild oxidising agents, and into dialuric acid by reducing agents. In its physiological action alloxantin resembles alloxan, but is especially poisonous to cold-blooded animals, the blood showing strong reducing properties; when taken internally it appears in the urine as parabanic acid, and in smaller quantities as dialuric acid, murexide, and alloxantin itself (Kowalewski, Chem. Zentr. 1887, 1296; Susini, Ann. Chim. Farm. 1895, 21, 241; 1896, 22, 341, 385).

Acetylalloxantin $C_{10}H_8O_9N_4,H_2O$, obtained by the interaction of acetyl dialuric acid and alloxan, crystallises in thin leaflets, becomes anhydrous when kept in a vacuum over sulphuric acid, melts and decomposes at 263°–265°, and is slowly hydrolysed by hot water with the formation of alloxantin.

Benzoylalloxantin $C_{15}H_{10}O_9N_4,H_2O$, similarly formed from benzoyl dialuric acid and alloxan, crystallises in colourless six-sided plates, and melts at 253°–255° (Behrend and Friedrich, Annalen, 1906, 344, 1).

Alloxantin is decomposed when boiled in an aqueous solution of the hydrochloride of a primary amine, yielding alloxan, together with the corresponding *dibarbiturylalkylamine*. These are colourless crystalline dibasic acids, hydrolysed by boiling with aqueous alkali hydroxides into dialuric acid and the amine. *Dibarbiturylmethylamine*

$$CO<\begin{matrix}NH\cdot CO\\ NH\cdot CO\end{matrix}>C<\begin{matrix}NMe\\ H\quad H\end{matrix}>C<\begin{matrix}CO\cdot NH\\ CO\cdot NH\end{matrix}>CO$$

decomposes at 280°, *dibarbiturylethylamine* decomposes at 235°, *dibarbiturylphenylamine* becomes blue at 240°, *dibarbituryl-α-naphthylamine* becomes black at 260°, the corresponding β-compound decomposes at 260°, and *dibarbiturylcarbamide* $CO(NH\cdot C_4H_3O_3N_2)_2$ decomposes above 300°.

The following homologues of alloxantin have been prepared: *methylalloxantin* $C_9H_8O_8N_4,3H_2O$ from methylalloxan and dialuric acid (Andreasch, Monatsh. 1882, 3, 431); sym-*dimethylalloxantin* $C_{10}H_{10}O_8N_4,4H_2O$ from methylalloxan (Maly, Andreasch, Monatsh. 1882, 3, 109), unsym-*dimethylalloxantin* $C_{10}H_{10}O_8N_4,H_2O$ from dimethyldialuric acid and alloxan (Andreasch, Monatsh. 1882, 3, 428). *Tetramethylalloxantin* $C_{12}H_{14}O_8N_4$ *amalic* acid (from ἁμαλός = soft, so called on account of its feebly acid reaction), prepared (1) by oxidising caffeine with chlorine or nitric acid (Rochleder, Annalen, 71, 1); (2) by reducing dimethylalloxan with sulphuretted hydrogen (Fischer, Ber. 1881, 14, 1912) or with stannous chloride (Andreasch, Monatsh. 1895, 16, 19); (3) from dimethyldialuric acid and dimethylalloxan (Maly and Andreasch, Monatsh. 1882, 3, 105); (4) by the electrolysis of caffeine in sulphuric acid solution (Pommerehne, Arch. Pharm. 235, 365). *See* Biltz (Ber. 1912, 45, 3673) for the preparation of *dimethyl* and *tetramethylalloxantin* from theobromine and caffeine respectively. *Tetraethylalloxantin* $C_{16}H_{22}O_8N_4$, obtained by reducing diethylalloxan, melts and decomposes at 162° (Sembritzki, Ber. 1897, 30, 1821).

M. A. W.

ALLOXAZINE *v.* ALLOXAN.

ALLOYS *v.* METALLOGRAPHY.

ALLYL. A univalent radicle C_3H_5—, or $CH_2:CH\cdot CH_2$—, isomeric with *propenyl* $CH_3\cdot CH:CH<$.

Allyl acetate $CH_3\cdot CO_2C_3H_5$ boils at 103°–104°/733·9 mm. (Brühl), and has sp.gr. 0·9376 at 0° (Schiff). It is only slightly soluble in water, and has a rather sharp smell. It is prepared by the action of allyl iodide on silver acetate (Zinin, Annalen, 96, 361; Cahours and Hofmann, Annalen, 102, 295; Brühl, Annalen, 200, 179; Schiff, Annalen, 220, 109).

Allyl acetic acid $C_3H_5\cdot CH_2\cdot CO_2H$ boils at

187°–189°, and has sp.gr. 0·98416 at 15° (Perkin). It is slightly soluble in water and its smell resembles that of valerianic acid. It is unaffected by reduction with sodium amalgam, but readily unites with two atoms of bromine. It is prepared by hydrolysing allyl acetoacetic acid ethyl ester with dry sodium ethoxide, or by heating allyl malonic acid (Zeidler, Annalen, 187, 39; Conrad and Bischoff, Annalen, 204, 170; Henry, Chem. Zentr. 1898, ii. 663).

The *chloride* $C_3H_5·CH_2·COCl$ is a thick, pungent-smelling syrup, boiling at 128°/765 mm., and of sp.gr. 1·0739 at 16° (Henry, *l.c.*).

Allylacetone $CH_3·CO·CH_2·C_3H_5$ boils at 128°–130°, and has sp.gr. 0·834 at 27°. It is an unpleasant-smelling liquid. It forms an amorphous compound with sodium bisulphite, and is reduced by sodium amalgam to hexenyl alcohol. It is prepared by hydrolysing allyl acetoacetic acid ethyl ester (70 grams) with crystallized baryta (215 grams) and water (1650 c.c.) (Zeidler, Annalen, 187, 35; Merling, Annalen, 264, 323). Treated with hydroxylamine it yields *allylacetoxime* $CH_3·C(:NOH)·CH_2·C_3H_5$, which is a liquid boiling at 188° (corr.), soluble in alcohol, benzene, ether, acids and alkalis.

Allyl alcohol $C_3H_5·OH$, *i.e.* $CH_2:CH·CH_2·OH$ occurs in raw wood spirit, but only to the extent of about 0·2 p.c. (Aronheim, Ber. 1874, 1381; Grodzki and Kramer, *ibid.* 1492). It is a pungent liquid with a burning taste, and mixes readily with alcohol, water, or ether. It boils at 96·6° (corr.), and has sp.gr. 0·87063 at 0° and 0·8573 at 15°/15° (Thorpe, Chem. Soc. Trans. 1880, 208), D_0 0·86929, and b.p. 96·95° (Wallace and Atkins, Chem. Soc. Trans. 1912, 1183).

It is prepared by slowly distilling glycerol (400 parts) with crystallised oxalic acid (100 parts) and a little ammonium chloride (1 part) to convert any potassium oxalate into chloride. The receiver is changed at 190° and distillation continued up to 260°. It is usually stated that the allyl alcohol is produced by the decomposition of monoformin, but according to Chattaway, the chief source is the normal oxalic ester dioxalin

$$\begin{array}{l} CH_2\text{——}CH·CH_2OH, \\ \,| \qquad\quad\;\; | \\ O·CO·CO·O \end{array}$$

which on heating is resolved into carbon dioxide and allyl alcohol (Chattaway, Chem. Soc. Trans. 1914, 105, 151; *ibid.* 1915, 107, 407). The distillate, containing aqueous allyl alcohol, allyl formate, acrolein, and glycerol, is rectified and dried, first with potassium carbonate, then over solid potash and distilled. When the last traces of water are removed by quicklime it boils at 96·6°. The yield is one-sixth of the weight of oxalic acid taken (Tollens and Henninger, Bull. Soc. chim. [2] 9, 394; Brühl, Annalen, 200, 174; Linnemann, Ber. 1874, 854). Further purification may be effected by prolonged heating with sodium bisulphite and, after removal of the bisulphite, redistilling several times from quicklime (Thorpe).

According to Koehler (Bull. Soc. chim. 1913, [iv.] 13, 1103) the yield of allyl alcohol may be increased from 20 to 32 p.c. by replacing the oxalic acid by formic acid. 100 grams of glycerol are heated with 80 grams of formic acid for an hour on a water-bath and the product fractionally distilled and collected in three fractions: (1) up to 200°; (2) 200°–260°; (3) residue. The saponification index of fraction (2) is determined, and it is then poured on to twice the calculated amount of solid potassium hydroxide. The whole is boiled for an hour, allowed to cool, and the top layer decanted and dried over anhydrous potassium carbonate. The intermediate product is monoformin.

According also to Hoff (K. Danske Videnskab. Selskab. Forhand. 1915, 199) the most satisfactory method of preparing allyl alcohol consists in the direct reduction of glycerol with formic acid. 825 grams of 97 p.c. glycerol and 84·2 grams of 95 p.c. formic acid (mol. props. 5 : 1) are heated together in a retort; the receiver is changed at 200°, and the distillate collected between 200° and 250°. After cooling a further quantity of 165 grams of glycerol and 84·2 grams of formic acid is added, and the distillation carried out as before. This process is repeated ten times. From the distillate between 200° and 250°, which weighs about 1470 grams, allyl alcohol is obtained after treatment with potassium carbonate, the yield being about 54 p.c., calculated either with respect to the glycerol or the formic acid (Chem. Soc. Abstr. 1916, i. 6).

Allyl alcohol is oxidised by chromic acid solution to acrolein and formic acid; and by dilute nitric acid to formic and oxalic acids; whilst potassium permanganate produces acrolein, glycerol, and formic acid. It combines directly with chlorine, bromine, iodine chloride, and cyanogen, producing additive products. It is partially reduced by boiling for some hours with zinc and dilute sulphuric acid to *n*-propyl alcohol. Potassium displaces the hydroxylic hydrogen atom and forms gelatinous potassium allylate.

Denigès (Bull. Soc. chim. 1909, 5, 878) describes the following colour reactions for the detection of allyl alcohol, depending on the formation of (1) glyceraldehyde and (2) dihydroxyacetone and the condensation of these products with various reagents. Bromine water (0·6 c.c. in 100 c.c. water) is added to 0·1 c.c. of allyl alcohol, till a slight permanent colouration is produced, and the liquid is then boiled, cooled, and divided into portions of 0·4 c.c. To each of these 0·1 c.c. of a 5 p.c. solution of codeine, resorcinol, thymol, or β-naphthol is added, followed by 2 c.c. of sulphuric acid (sp.gr. 1·84) and the mixture warmed during 3 or 4 minutes at 100°. Codeine and thymol give reddish-violet colourations, resorcinol wine-red, and β-naphthol yellow with greenish fluorescence. The second series of colour reactions is obtained by adding to the brominated liquid above described 5 c.c. of bromine water (0·6 c.c. in 100 c.c. water), heating during 20 minutes at 100°, then boiling to remove excess of bromine and cooling. This liquid contains dihydroxyacetone, and in the presence of concentrated sulphuric acid gives a deep-blue colour with codeine, orange-red with resorcinol, blood-red with thymol, or green with green fluorescence with β-naphthol (Denigès, Compt. rend. 148, 172, and 282).

Bromine is quantitatively absorbed by allyl alcohol, whether the former is in excess or not, and the reaction is suitable for the exact quantitative estimation of the alcohol, which may be effected either by direct titration with bromine water until a permanent yellow colouration is obtained, or by treating the acidified aqueous solution of the alcohol with an excess of bromide-bromate solution, followed by addition of potassium iodide and titration of the liberated iodine with sodium thiosulphate (Stritar, Monatsh. 1918, 39, 617).

Allylamines.

Monoallylamine $C_3H_5{\cdot}NH_2$ is a liquid boiling at 53·3° and of sp.gr. 0·7799 at 4° and 0·7688 at 15° (Perkin, Chem. Soc. Trans. 1889, 697); b.p. 58° and sp.gr. 0·864 at 15° (Rinne, Annalen, 168, 262); b.p. 56°–56·5°/756·2 mm. (Schiff, Ber. 1886, 565). It is prepared from allyl *iso*cyanate and potash, or from allyl iodide and ammonia, or by reduction of allyl mustard oil with zinc and hydrochloric acid (Oeser, Annalen, 134, 8). It possesses a penetrating smell, which excites tears and produces sneezing. It is miscible with water in all proportions, and is a strong base, forming a crystalline platinichloride $(C_3H_5{\cdot}NH_2)_2PtCl_4$, and sulphate $(C_3H_5{\cdot}NH_2)_2H_2SO_4$. The hydrochloride melts at 105°–110° (Delépine, Bull. Soc. chim. [3] 17, 294) and the picrate at 140°–141° after sintering (Gabriel and Eschenbach, Ber. 1897, 1125).

Diallylamine $(C_3H_5)_2NH$ boils at 111° and is prepared from allylamine and allyl bromide (Ladenburg, Ber. 1881, 1879; Liebermann and Hagen, Ber. 1883, 1641).

Triallylamine $(C_3H_5)_3N$ is a very unpleasant-smelling liquid, boiling at 150°–151° (Pinner, Ber. 1879, 2054); 155°–156°, sp.gr. 0·8094 at 14·3° (Zander, Annalen, 214, 151). It is prepared by distilling tetrallylammonium bromide with large excess of recently fused potash (Grosheintz, Bull. Soc. chim. [2] 31, 391) or from allyl chloride and alcoholic potassium cyanide in the cold (Pinner, *l.c.*); or from allyl chloride and ammonia (Malbot, Bull. Soc. chim. [2] 50, 90). It is displaced from its aqueous solution by potash, and forms a crystalline platinichloride and hydrochloride.

Tetrallylammonium bromide $(C_3H_5)_4NBr$ is a crystalline solid, soluble in alcohol and water, but only slightly so in ether. It is prepared by leading a stream of ammonia into an alcoholic solution of allyl bromide. The product is purified by recrystallisation from alcohol containing a little ether (Grosheintz, Bull. Soc. chim. [2] 31, 390). Treated with moist silver oxide it yields tetrallylammonium hydroxide.

Tetrallylammonium iodide $(C_3H_5)_4NI$ is the main product of the reaction of allyl iodide on ammonia at the ordinary temperature (Cahours and Hofmann, Annalen, 102, 305; Malbot, Ann. Chim. Phys. [6] 13, 488). It is a crystalline solid, insoluble in strong potash solution.

Allylaniline $C_6H_5{\cdot}NHC_3H_5$ is a yellow oil produced by the action of allyl iodide on aniline. It boils at 208°–209° and has sp.gr. 0·982 at 25° (Schiff, Annalen Suppl. 3, 364).

Diallylaniline $C_6H_5{\cdot}N(C_3H_5)_2$ is prepared by adding allyl bromide (1 mol.) to aniline (1 mol.) in a flask fitted with reflux condenser, separating the allyl aniline by the addition of potash, and converting it into diallyl aniline by repeating the process with more allyl bromide (1 mol.). It boils at 243·5°–245°, and has sp.gr. 0·9538 at 19·8° (Zander, Annalen, 214, 149).

Allyl benzene $C_6H_5{\cdot}CH_2{\cdot}CH{:}CH_2$ is obtained zinc-dust to 100° (Chojnacki, J. 1873, 559; Fittig, Annalen, 172, 312). It boils at 155°. The isomeric *propenyl benzene* (and phenyl propylene—$C_6H_5{\cdot}CH:CH{\cdot}CH_3$) is sometimes incorrectly referred to as allyl benzene.

Allyl bromide, *monobrompropylene* $CH_2{:}CH{\cdot}CH_2Br$, boils at 70°–71°, and has sp.gr. 1·4336 at 17° (Zander, Annalen, 214, 144); b.p. 70·5° (corr.) (Thorpe). It is formed by the action of phosphorus tribromide on allyl alcohol, and is prepared by dropping allyl alcohol into a hot solution of potassium bromide in sulphuric acid (1 vol. acid to 1 vol. H_2O) according to Grosheintz (Bull. Soc. chim. [2] 30, 78); or by saturating allyl alcohol with hydrogen bromide at 0° and subsequently heating to boiling for several hours (Jacobi and Merling, Annalen, 278, 11).

Allyl bromide absorbs hydrogen bromide in bright light forming trimethylene bromide; in the dark propylene bromide is also produced (Holleman and Matthes, Proc. K. Akad. Wet. Amster. 1918, 21, 90).

Allyl chloride $CH_2{:}CH{\cdot}CH_2Cl$ boils at 46°, and has sp.gr. 0·9547 at 0° (Tollens, Annalen, 156, 154); 0·9371 at 19·3° (Zander, Annalen, 214, 142); b.p. 45·29° (corr.) (Thorpe). It is prepared by the action of mercuric chloride on allyl iodide, or from allyl oxalate calcium chloride and alcohol at 100° (Oppenheim, Annalen, 140, 205); or, best, by heating allyl alcohol and concentrated hydrochloric acid to 100° for some hours (Eltekow). It combines with hydrogen chloride to form *propylene chloride* $C_3H_6Cl_2$, and with fuming hydrobromic acid yielding 1-chloro-3-bromopropane $CH_2Cl{\cdot}CH_2{\cdot}CH_2Br$

Allyl cyanamide, *sinamine*, $C_3H_5{\cdot}NH{\cdot}CN$, is produced by warming allyl thiocarbamide with lead hydroxide on the water-bath (Will, Annalen, 52, 15). On standing for some months crystals separate from the resulting product. It is prepared by shaking an aqueous solution of allyl thiocarbamide with mercuric oxide until the solution no longer blackens ammoniacal silver nitrate (Andreasch, Monatsh. 2, 780). It is alkaline in reaction, precipitating metallic oxides and replacing ammonia in its salts. The crystals contain $\frac{1}{2}H_2O$ and melt at 100°, giving up their water. It forms a difficultly crystallisable salt with oxalic acid, but not with other acids, and double compounds with mercuric and platinic chlorides.

Allyl cyanide, *crotononitrile*, $C_3H_5{\cdot}CN$, boils at 119° (corr.), and has sp.gr. 0·8491 at 0° and 0·8351 at 15°. It is obtained by the action of allyl iodide on potassium cyanide, and, together with other products, by allowing allyl mustard oil to remain in contact with water for some weeks, and also by the action of acetic anhydride on crotonaldoxime. It has been prepared by Henry (Chem. Zentr. 1898, ii, 662) by the action of phosphorus pentoxide on *a*- or *β*-hydroxy-butyronitrile. It is a liquid with an unpleasant, onion-like smell. On warming to 50°–60° with fuming hydrochloric acid for two hours, chlorobutyric acid is produced. Chromic acid oxidises it to acetic acid, nitric acid to oxalic acid.

Allylenes. Two allylenes are possible and known: symmetrical allylene $CH_2{:}C{:}CH_2$, and unsymmetrical allylene $CH_3{\cdot}C{:}CH$.

Symmetrical allylene, *propadiene*, $CH_2:C:CH_2$, flame. It is prepared by dropping α-bromoallyl bromide (10 grams) into a mixture of 20 grams zinc-dust and 25 grams alcohol (70 p.c.) (Gustavson and Demjanow, J. pr. Chem. [2] 38, 202). It does not precipitate ammoniacal solutions of silver nitrate or cuprous chloride. It is readily absorbed by strong sulphuric acid, and acetone is produced on dilution. When dissolved in absolute ether and heated with sodium to 100°, it changes into the isomeric methyl acetylene It readily forms a tetrabromide $C_3H_4Br_4$ by addition of bromine.

Unsymmetrical allylene, *methyl acetylene* $CH_3C{:}CH$, results from propylene bromide, monobromopropylene, or monochloropropylene by withdrawal of HCl or HBr by means of alcoholic potash, and from symmetrical allylene (*v. supra*). It is an unpleasant-smelling gas, which is liquefied under a pressure of 3–4 atmospheres. It burns with a bright sooty flame. It dissolves readily in ether (30 vols. in 1 of ether at 16°). Potassium permanganate in the cold oxidises it to formic, oxalic, and malonic acids. Explosive compounds are produced by leading it into ammoniacal solutions of silver nitrate or cuprous chloride. Concentrated sulphuric acid readily absorbs it, forming on dilution and distillation acetone mesitylene and allylene sulphonic acid $C_3H_3SO_3H$ (Schrobe, Ber. 1875, 18 and 367). The *barium salt* of the latter is crystalline, easily soluble, and not decomposed on boiling with water. *Cf.* ACETYLENE: homologues of.

Allyl ether $C_3H_5\cdot O\cdot C_3H_5$ boils at 94·3° and has sp.gr. 0·8046 at 18°. It is prepared from allyl iodide and sodium allyl alcoholate, or from allyl iodide and mercuric oxide (Cahours and Hofmann, Annalen, 102, 290; Berthelot and Luca, Ann. Chim. Phys. [3] 48, 291).

Allyl ethyl ether $C_3H_5\cdot O\cdot C_2H_5$ boils at 66°–67°/742·9 mm. (Brühl, Annalen, 200, 178). Prepared from allyl iodide and sodium ethoxide.

Allyl iodide C_3H_5I boils at 102·79° (corr.) (Thorpe and Rodger), and has sp.gr. 1·8696 0°/0°. Berthelot and Luca (Ann. Chim. Phys. [3] 43, 257) obtained it by the action of PI_2 on glycerol. It may be prepared by leaving together for 24 hours red phosphorus (20 grams), allyl alcohol (160 grams), and iodine (254 grams) (Tollens and Henninger, Annalen, 156, 156); or by the following process: 100 grams of iodine and 1500 grams of carefully dehydrated glycerol are brought together in a large vessel, the air displaced by a current of carbon dioxide, and 300 grams of ordinary phosphorus gradually added. The allyl iodide is distilled off in a stream of carbon dioxide, and then contains as impurity some *iso*propyl iodide. According to Rasik Lal Datta (J. Amer. Chem. Soc. 1914, 36, 1005) the use of carbon dioxide is unnecessary. To purify it, it is dissolved in alcohol and shaken with mercury, when the compound HgC_3H_5I is precipitated. This is recrystallised from water and decomposed, regenerating allyl iodide, by distillation with water and the theoretical quantity of iodine (Linnemann, Annalen Suppl. 3, 263). It combines with bromine to form tribromhydrin, and with hydriodic acid to give diiodopropylene. By long heating with about 20 parts of water it is converted into allyl alcohol and hydriodic acid.

Allyl mercaptan C_3H_5SH boils at 90°. With mercuric chloride it yields C_3H_5SHgCl, which crystallises from alcohol in plates (Hofmann and Cahours, Annalen, 102, 292; Gerlich, Annalen, 178, 88).

Allylmethylal *iso***thiocyanate** is the name given to the compound $C_3H_5O\cdot S\cdot CH_2\cdot CN$, prepared by passing a current of formaldehyde gas through glycerol (1 kilo) and allyl *iso*thiocyanate (5 grams) heated to 190° until the weight of the whole is 1400 grams. When cool the product is filtered and the resulting methylal *iso*thiocyanate used as an antiseptic (Piot, Fr. Pat. 330988, 1903).

Allyl mustard oil *v.* MUSTARD OIL and ESSENTIAL OILS.

Allyl nitrite $C_3H_5NO_2$ is obtained by adding glycerol trinitrite to ice-cold allyl alcohol and cautiously distilling off the allyl ester (Bertoni, Gazz. chim. ital. 15, 364). It boils at 43·5°–44·5°, and has sp.gr. 0·9546 at 0°. It is readily decomposed by shaking with water, and yields ethyl nitrite on treatment with ethyl alcohol.

Allyl-phenyl-thiourea $SC\!<\!\begin{smallmatrix}NH\cdot C_3H_5\\ NH\cdot C_6H_5\end{smallmatrix}$ may be prepared from aniline and mustard oil (Zinin, Annalen, 84, 348); or from allylamine and phenyl mustard oil (Weith, Ber. 8, 1529). It forms monoclinic crystals, melting at 98°, and is readily soluble in ether, but not in water.

Allyl pyrrol $C_4H_4NC_3H_5$ is readily obtained by the action of allyl bromide on potassium pyrrol in ether (Ciamician and Dennstedt, Ber. 1882, 2581). It is a light-yellow oil, turning brown on exposure to air. It boils at 105°/48 mm. It is insoluble in water, but dissolves in HCl, producing a red colour.

Allyl sulphate $C_3H_5\cdot HSO_4$ is prepared by adding allyl alcohol (1 vol.) to sulphuric acid diluted with its own volume of water (1 vol.), and leaving at ordinary temperatures for five days. Subsequently the mixture is heated to 70° for 12 hours, diluted with water (10 vols.), and saturated with barium carbonate (Szymanski, Annalen, 230, 44; *v.* also Cahours and Hofmann, Annalen, 102, 293). It forms characteristic salts, a number of which are described by Szymanski (*l.c.*).

Allyl sulphide, *oil of garlic,* (Ger. *Knoblauchöl*) $(C_3H_5)_2S$, occurs in garlic (*Allium sativum*) and other plants. It is prepared from mustard oil and potassium sulphide at 100° (Wertheim, Annalen, 55, 297); or from allyl iodide and potassium sulphide (Hofmann and Cahours, Annalen, 102, 291). It is a liquid boiling at 138·6°, and has sp.gr. 0·88765 at 26·8°/4°. It has a very strong odour of garlic and is only slightly soluble in water.

Allyl thiocarbamide, *allyl thiourea, thiosinamine, 'Rhodallin'* $SC\!<\!\begin{smallmatrix}NH_2\\ NH\cdot C_3H_5\end{smallmatrix}$, is produced by the prolonged action of aqueous ammonia on mustard oil (Dumas and Pelouze, Annalen, 10, 326). It forms clear six-sided tables, which melt at 78·4°, after sintering at 71°. It is insoluble in benzene, sparingly soluble in water, and readily so in alcohol and ether. It combines directly with halogens, cyanogen, ethyl iodide, acids, &c. Deprived of its sulphur by mercuric oxide, or lead oxide, it yields *sinamine* (allyl cyanamide) $C_3H_5\cdot NH\cdot CN$. It has been used in surgery for the removal of scar tissue, being injected as a 10 or 15 p.c. solution in dilute glycerol.

Allyl tribromide, '*Tribromhydrin*' $C_3H_5Br_3$, was obtained by Wurtz by treating allyl iodide with bromine, and by Berthelot and Luca by the action of phosphorus tri- and pentabromides on glycerol. It is a slightly yellow liquid of sp.gr. 2·430 at 15·5°, and boils at 217°. It is a strong sedative and anodyne.

Allyl urea $OC\begin{cases}NH_2\\NH{\cdot}C_3H_5\end{cases}$ crystallizes in needles, melting at 85° (Cahours and Hofmann, Annalen, 102, 299; Andreasch, Monatsh. 5, 36).

J. A. P.

ALMASCA. A soft grey resin soluble in chloroform, ether, and absolute alcohol. Probably derived from the burseraceous *Protium heptaphyllum* (March.) [*Icica heptaphylla* (Aubl.)] (Symes, Pharm. J. [3] 13, 213).

ALMATEIN. Trade name for a condensation product of hæmatoxylin and formaldehyde. Used as an antiseptic.

ALMIRAO. Indian name for *Launœa pinnatifida* (Cass.) *Microrhynchus sarmentosus* (DC) which belongs to the family Compositæ and is used at Goa as a substitute for taraxacum (Dymock, Pharm. J. [3] 6, 730).

ALMOND. The kernel of the fruit of *Prunus amygdalus* or *Amygdalus communis*.

Two principal varieties exist—the sweet and the bitter almond. Both contain amygdalin, but the latter is much richer in this substance (2 to 3 p.c.), and contains an enzyme, *emulsin*, which, in the presence of water, decomposes the amygdalin. yielding glucose, benzaldehyde, and hydrocyanic acid

$$C_{20}H_{27}NO_{11}+2H_2O$$
$$=C_6H_5CHO+HCN+2C_6H_{12}O_6$$

In addition, almonds contain about 50 p.c. of their weight of a fixed oil (mainly oleïn, and liable to become rancid) and smaller quantities of proteïns, sugar, starch, gum, fibre, and ash.

Analyses of almonds made at various stages of growth and ripening, show the percentage of amyloses, glucose, and saccharose to steadily diminish, whilst the proportion of oil increases (Du Sablon, Compt. rend. 1896, 123, 1084).

According to Vallée (Compt. rend. 1903, 136, [2] 114), reducing sugars in the immature almond decrease as the fatty oil increases: sucrose increases until oil-formation begins, then decreases during oil-production, and towards the end again increases. Ripe almonds contain about 3 p.c. of sucrose. According to Osborne and Campbell (J. Amer. Chem. Soc. 1896, 18, 609), the proteïn in almonds is *amandin* and not conglutin or vitellin.

H. I.

ALMOND OIL is obtained from the seeds of *Prunus amygdalus* (Stokes) [*Amygdalus communis* (Linn.)]. The almond tree appears to have been indigenous to Turkestan and Middle Asia, and has been transplanted from there to Greece, Italy, Spain, France, and to Northern Africa. The mean percentage composition of the almond is given by König as follows:—

Oil	41·00	p. c.
Water	27·72	„
Proteins	16·50	„
Extracted matter, free from nitrogen	10·20	„
Crude fibre	2·81	„
Ash	1·77	„

The commercial oil is chiefly expressed from bitter almonds, the seeds of *Prunus amygdalus*, var. *amara*. Bitter almonds contain, besides the oil, amygdalin and emulsin, which give rise to the formation of benzaldehyde, dextrose, and hydrocyanic acid. Hence the press-cakes from almonds find a profitable outlet in the manufacture of genuine 'ethereal bitter almond oil,' which is prepared by triturating the meal with water.

Sweet almonds (from *Prunus amygdalus*, var. *dulcis*) are but rarely used alone for the preparation of almond oil. Mogador bitter almonds, which are chiefly used in this country for the manufacture of almond oil, are always more or less mixed with sweet almonds. Sweet almonds yield from 44 to 55 p.c. of oil, bitter almonds yield less and may contain as low a proportion of oil as 20 p.c. On an average, however, bitter almonds yield from 38 to 45 p.c. of oil.

The oil is pale yellow; it has a very pleasant, mild taste, and is almost free from odour. The specific gravity of the oil varies from 0·915 to 0·9195 at 15°. The oil becomes turbid at −10°, and solidifies at −20°, has the saponification value of the majority of oils which are free from volatile acids, and an iodine value of 93–100. Farnsteiner (Zeitsch. Nahr. Genussm. 1899, 2, 1) separated linolic tetrabromide in a proportion corresponding with 5·97 p.c. of linolic acid, and it is probable that other specimens may contain up to about 10 p.c. of that acid. The other fatty acids consist mainly of oleic acid, with, at most, traces of saturated fatty acids.

Almond oil is chiefly used in pharmaceutical practice. Owing to its high price it is largely adulterated with other oils of the *Prunus* family, chiefly with apricot kernel oil, from *Prunus armeniaca* (Linn.), and with peach kernel oil, from *Prunus persica* (Sieb. et Zucc.). These two oils are very similar to almond oil, but have a less pleasant taste. They are used to such an extent as adulterants that frequently they completely take the place of almond oil; indeed 'foreign' almond oil, or 'oil of sweet almonds, French' (*Oleum amygdalarum gallicum*), is nothing else than a mixture of apricot kernel oil and peach kernel oil. Genuine almond oil is sold in commerce under the name 'almond oil, English.'

The close relationship in which apricot and peach kernel oils stand to almond oil, renders their detection in almond oil a difficult problem. They differ from almond oil in sometimes having a higher iodine value (96–108), and a higher critical temperature of solution (*e.g.* almond oil, 32°–33·5°; apricot kernel oil, 46°–47°; and peach-kernel oil, 41°). Of various colour reactions that of Bieber (Zeitsch. anal. Chem. 1878, 17, 264) is the best known. It depends on the different colourations given by the three oils when shaken with a mixture of strong sulphuric and nitric acids and water. The chromogenic substance in apricot kernel oil is not volatile with steam, and the test is capable of detecting 5 p.c. of that oil in almond oil (Ross and Race, Analyst, 1911, 36, 263).

ALMONDS, BITTER, *Essential oil of* (*v.* BENZALDEHYDE; also OILS, ESSENTIAL).

ALOE. A genus of succulent plants, having

Liliaceæ. (Plants figured, and structure of leaves described, Pennetier, 560, 579.) Of the 85 species 60 are natives of Cape Colony, and the other species are mainly sub-tropical African, though a few occur in the tropics; a number of species have been, however, introduced into the West and East Indies. (For a list of the species and their distribution, *v.* Pharm. J. [3] 11, 746.)

The fibre is used for rope, &c.; experiments made in Paris have shown it to be five times as strong as hemp. The fibre has also been used for paper-making (Nat. 20, 484).

ALOE-EMODIN *v.* RHUBARB.

ALOE RESINS *v.* ALOES OR BITTER ALOES.

ALOES or BITTER ALOES. (*Aloès*, Fr.; *Aloe*, Ger.; *Aloe*, B.P.; U.S.P.). The inspissated juice or extract of the aloe. Slow concentration induces crystallisation and gives an opaque product 'aloe hepatica.' More complete and rapid evaporation yields glassy 'aloe lucida,' which shows no crystals under the microscope. The principal varieties found in the market are:—

1. *Curaçao* (*Barbados*) *Aloes* (from *A. chinensis*, Baker, *A. vera*, L.), formerly produced in Barbados, but now almost exclusively in Curaçao and other Dutch West Indian islands. It is usually opaque ('livery') and from orange to nearly black in colour.

2. *Cape Aloes* (from *A. ferox*, Miller, and other South African species) is vitreous, breaking readily into transparent glassy, reddish, or pale-brown fragments. It is the chief variety used in Germany and adjoining countries; in Britain mostly for veterinary purposes.

3. *Socotrine Aloes* (from *A. Perryi*, Baker). It is generally imported in a moist pasty condition, and is of a dark reddish-brown colour. A variety of Socotrine Aloes from Zanzibar often closely resembles that from Curaçao. Of these, Curaçao Aloes is the only one containing appreciable quantities of *iso*barbaloin, and hence gives Klunge's reaction characteristic for this substance (*see* below). With concentrated nitric acid Curaçao aloes become at once deep red; Socotrine becomes reddish- or yellowish-brown; Cape aloes gradually green. The aqueous solution (1 p.c.) of all varieties shows a green fluorescence on adding 5 p.c. borax solution. Natal aloes is no longer an article of commerce; Uganda aloes (imported from Mossel Bay) is a variety of Cape aloes produced by careful evaporation.

Aloïns. By extracting aloes with water the purgative principles, aloïns, can be obtained. Shenstone (Pharm. J. [3] 13, 461; Chem. Soc. Trans. 44, 480) divides them into two classes: 1. *Nataloïns*, which only yield picric and oxalic acids with nitric acid, and which are not reddened by it, even on heating (Flückiger, Arch. Pharm. [2] 149, 11; Tilden, Chem. Soc. Trans. 25, 153). 2. *Barbaloins*, which yield aloetic acid $C_{14}H_4(NO_2)_4O_2$, chrysammic acid $C_{14}H_2(NO_2)_4(OH)_2O_2$, picric and oxalic acids, and are reddened by nitric acid. *a-Barbaloïns*, from Barbados aloes reddened in the cold by strong nitric acid (Tilden, Pharm. J. [3] 2, 845; Chem. Soc. Trans. 25, 488). *β-Barbaloïns*, from Socotrine, Zanzibar, and Jafferabad aloes, coloured only on heating with ordinary, and in the cold with fuming, nitric acid (Flückiger, *l.c.*; Tilden, Chem. Soc. Trans. 28, 1270; Pharm. J. [3] 4, 208).

Aloïn, official in the B.P. and U.S.P., and obtained chiefly from Curaçao aloes, is a yellow crystalline powder consisting of a mixture of *barbaloïn* and *isobarbaloïn*, which substances, according to Léger (Compt. rend. 1911, 153, 114), are isomeric, having an arabinose group in positions 1 and 8 respectively. Léger (J. Pharm. Chim. 1907, [vi.] 25, 476, 513) further, considers that all the above-mentioned varieties of aloes yield barbaloïn with the exception of the Natal variety, which gives a separate substance, nataloïn. The amount of aloïn in Curaçao aloes has been variously estimated as from 10 to 30 p.c. In addition, there is present an amorphous aloïn (*β-barbaloïn*), which is apparently stereoisomeric with crystalline barbaloïn, and is formed from the latter by heating for three hours to 160°–165°, and partly by acetylation (Léger, Compt. rend. 1914, 158, 1903). Cape aloes contain 5–6 p.c. of crystalline barbaloïn and about three times the amount of β-barbaloïn (Léger, Compt. rend. 1907, 145, 1179).

Tschirch and Pedersen (Arch. Pharm. 236, 200) found in Barbados aloes 12·25 p.c. barbaloïn, 12·65 p.c. resin, 1·75 p.c. ash, 10·5 p.c. amorphous constituents soluble in water, and 0·15 p.c. *aloe emodin* (which is a fission product of barbaloïn, *see* below; its constitution and properties are given under RHUBARB). The resin is the cinnamate of aloeresinotannol $C_{22}H_{24}O_4(OH)_2$(?). According to Tutin and Naunton (Pharm. J. 1914, [iv.] 37, 836) the proportion of aloe emodin is much larger.

Barbaloin may be readily prepared by extracting aloes with two parts of water at 90°–95°; the crystals, which separate on standing for some days, are recrystallised from water, and finally from alcohol. It forms small yellow prismatic needles containing water of crystallisation, and when anhydrous, melting at about 147°.

Barbaloïn has formed the subject of numerous investigations. For a long time its formula was considered to be $C_{16}H_{18}O_7$ (Tilden, Trans. 1872, 25, 204; 1875, 28, 1270; Schmidt, Ber. 1875, 8, 1275), or $C_{16}H_{16}O_7$ (Groenewold, Arch. Pharm. 1890, 228, 115; Léger, Compt. rend. 1897, 125, 185). Aschan (Arch. Pharm. 1903, 241, 341) and Jowett and Potter (Chem. Soc. Trans. 1905, 87, 878) confirmed one or other of these formulæ by molecular weight determinations, as well as by analysis. Against this mass of evidence we must, however, place Léger's observation (Compt. rend. 1902, 134, 1111, 1584), that by the action of sodium peroxide on barbaloïn, there are formed formic acid, *aloe-emodin* $C_{15}H_{10}O_5$ (*see* RHUBARB), and an aldopentose $C_5H_{10}O_5$. He accordingly changed the formula to $C_{21}H_{20}O_9$. Later he showed (Compt. rend. 1910, 150, 983, 1695; 1912, 155, 172) that alcoholic hydrogen chloride also produces aloe-emodin and the sugar, which was confirmed by Oesterle and Riat (Schweiz. Woch. Chem. Pharm. 1909, 717). Finally, Léger identified the sugar with certainty as *d-arabinose*; he considers that in barbaloïn it is attached to the aloe-emodin in position 1, and in *iso*barbaloin in position 8 of the anthraquinone; the sugar is, moreover, attached by one of its hydroxyl groups and not by the aldehyde group as in other glucosides.

Seel and Kelber (Ber. 1916, 49, 2364) have confirmed Léger's formula by molecular weight determinations (*cf.* also Seel, Kelber, and Scharf, Ber. 1917, 50, 759).

The only way of reconciling Léger's results with the C_{16} formula would be to regard barbaloïn as a reduced anthraquinone derivative, which breaks down by two simultaneous but independent reactions to aloe emodin and *d*-arabinose, but it is preferable to attribute the earlier analytical results to the difficulty of purifying the substance.

Barbaloïn, after several crystallisations from alcohol, does not show a sharp melting-point (145°–150°), $[a]_D$ −10·4° in ethylacetate (Léger), −8·3° in 90 p.c. alcohol (Jowett and Potter).

Aloe-emodin $C_{15}H_{10}O_5$, m.p. 224°, is an alcohol, a hydroxymethyl dihydroxyanthraquinone (for constitution and relationships, *see* under RHUBARB). On oxidation with chromic acid barbaloïn gives a mixture of aloe-emodin and the corresponding acid, rhein (Oesterle and Babel, Schweiz. Woch. Chem. Pharm. 1904, 42, 329), which mixture was named by Tilden (Chem. Soc. Trans. 1879, 32, 264, 903) aloexanthin.

Isobarbaloin occurs, according to Léger, in Barbados aloes to the extent of 0·5 p.c.; it gives the same hydrolytic products as barbaloin, and the two are therefore regarded by Léger as stereoisomeric (Compt. rend. 1910, 150, 1695) It gives Klunge's reaction (*see* above), and is not present in Socotrine and Cape aloes.

Nitric acid (D 1·2 at 100°) oxidises both barbaloïn and *iso*barbaloin to tetranitroaloe-emodin $C_{15}H_6O_5(NO_2)_4$ (Léger, Compt. rend. 1910, 151, 1128; 1911, 153, 114), which by boiling nitric acid (D 1·32) is converted into chrysammic acid $C_{14}H_2O_2(OH)_2(NO_2)_2$. In the mother-liquor of the tetranitroaloe-emodin Léger found 2:4:6-trinitro-3 hydroxybenzoic acid, which by loss of carbon dioxide yields picric acid. In addition to picric and chrysammic acids the older observers obtained aloetic acid by the action of nitric acid on aloin; Oesterle and Riat (Schweiz. Woch. Chem. Pharm. 1906, 44, 509) consider aloetic acid to be trinitroaloe-emodin.

Natal aloes contains about 14 p.c. of *nataloin*, m.p. 203°, crystallised from boiling ethyl or methyl alcohol. Among the various formulæ assigned to this substance probably the best established is that of Léger (J. Pharm. Chim. 1903, [vii.] 17, 13), $C_{23}H_{26}O_{10}$, who regards it as the methyl ether of *homonataloin* $C_{22}H_{23}O_9 \cdot OH$, also present in the drug. The latter, and probably also the former, of these aloins, like barbaloin, yield *d*-arabinose on hydrolysis (Léger, Compt. rend. 1912, 155, 172), which is apparently less stably attached than in barbaloin to a *tri*hydroxymethylanthraquinone, *nataloemodin*, orange-red needles, m.p. 220°, and its methyl ether.

Nataloemodin methylether, pale orange-yellow needles, m.p. 238°, is formed by the oxidation of nataloïn with sodium peroxide (Léger, J. Pharm. Chim. 1903, [vii.] 17, 13, 52). Nataloin differs from barbaloïn in its resistance to alkalis, and in not yielding chrysammic acid or aloexanthin on oxidation with nitric acid, but only picric and oxalic acids (Shenstone, Chem. Soc. Trans. 44. 480); further, in not giving Klunge's and Borntraeger's reactions (*see* below). Both nataloïn and its lower homologue give a green colouration with concentrated sulphuric acid and manganese dioxide or potassium dichromate, and a violet colouration in sodium hydroxide solution with ammonium persulphate (Léger). For a general review of the more recent work on the chemistry of the aloins, *see* Léger, Ann. Chim. 1916, [ix.] 6, 318–381.

The resin from Natal aloes yields on hydrolysis *p*-coumaric acid and nataloresinotannol $C_{22}H_{18}O_4(OH)_2$ (?).

Sicaloin is a crystalline substance from aloes of *Aloe vulgaris*, native in Sicily. Condò-Vissicchio has given it the formula $C_{15}H_{20}O_7$, and finds it to contain one methoxy group; it does not fluoresce with borax, and does not give Borntraeger's reaction (below).

The aloins from Curaçao, Cape Socotra, Uganda, and Jafferabad aloes are probably identical with barbaloin. *Zanaloin* from Zanzibar aloes appears to be different (Léger, J. Pharm. 25, [vi.] 513; Tschirch and Hoffbauer, Arch. Pharm. 243, 399). The latter chemists show that Barbados aloes contain but little *iso*aloin, Jafferabad none, whilst that from Curaçao contains a considerable proportion.

Uses.—Chiefly in medicine and as a hop-substitute. In doses of 0·1–0·3 gram aloin causes purgation in 8–20 hours, given by the mouth or hypodermically. In the latter case, it is excreted in the large intestine, where it probably is first oxidised to an active substance. The oxidation is hastened by iron salts, whence the use of *Pilula Aloes et Ferri*. Aloes is the basis of most 'patent' pills.

Various proposals have been made for converting aloin into (insoluble and) tasteless compounds, *e.g.* by condensation with formaldehyde in dilute sulphuric acid solution ('formaloïn' of E. Merck), with carbonyl chloride or ethyl chlorocarbonate in pyridine solution (Ger. Pat. 229191), or with a mixture of formic and acetic acids by means of zinc chloride (Ger. Pat. 233326).

Properties and Reactions.—Pure aloes is soluble in ether and almost completely soluble in water, the solution being coloured dark-brown by alkalis, black by ferric chloride, and grey by lead acetate (Flückiger). By adding a solution of copper sulphate or chloride to a solution of aloes, an intense yellow-coloured solution is obtained, which, warmed with potassium bromide or chloride, turns to a deep-red and reddish-violet tint (Klunge, Ber. 16, 691; Arch Pharm. 1883, 363). This reaction is due to *iso*barbaloin, for barbaloin, recrystallised several times from methyl alcohol, does not give the test (Léger, Compt. rend. 131, 55). Borntraeger (Zeitsch. anal. Chem. 19, 165; Ber. 13, 1040) extracts with twice the volume of benzene, and adds to the clear extract a drop of ammonia, when, on warming and shaking, the solution becomes violet-red; to test for aloes in elixirs, liqueurs, &c., the alcohol is first evaporated. This is a general reaction for hydroxymethyl anthraquinones. Lenz (Zeitsch. anal. Chem. 21, 220) extracts with amyl alcohol, evaporates the extract, treats with nitric acid, and then with potassium cyanide and hydroxide, when a blood-red colouration is obtained. Cripps and Dymond (Pharm. J. [3] 15, 633) test for aloin by dissolving 1 grain in 16 drops of strong sulphuric acid, then adding 4 drops of nitric acid (1·42) and 1 ounce of water, when a deep orange or crimson colour is produced, deepened by ammonia; substances containing chrysophanic acid behave in a similar manner, but their aqueous solution turns pink upon the addition of ammonia. Aschan (Arch. Pharm. 241, 340) gives in tabular form a comparison of the reactions of the chief varieties of aloes. The behaviour towards nitric acid and fluorescence with borax are mentioned above.

Curaçao aloes should be almost entirely soluble in 60 p.c. alcohol, and contain not more than 3 p.c. of ash, 12 p.c. of moisture, and 30 p.c. of substances insoluble in cold water. Cape aloes should dissolve almost completely in 12 parts of boiling water, and completely in 5 parts of warm 90 p.c. alcohol. The moisture should not exceed 5 p.c., the ash 1·5 p.c. At least 60 p.c. is soluble in cold water. According to the U.S.P. the ash of aloes does not exceed 4 p.c.

A process for the estimation of aloin in aloes has been described by Schaefer (J. Pharm. [vi.] 5, 296), and for the non-resinous constituents by Tschirch and Hoffbauer (Arch. Pharm. 1905, 243, 399). The latter process has been modified and used by van Itallie (Pharm. Weekblad, 1905, 42, 553) for the evaluation of aloes, but in the nature of things these processes are not very accurate. G. B.

ALOES, ESSENTIAL OIL OF. A pale-yellow mobile liquid to which the odour of aloes is due. Sp.gr. 0·863, boils at 266°–271°. It exists in small quantities in aloes, and when pure has the taste and odour of peppermint (Pharm. J. [3] 10, 613).

ALOES WOOD. A name applied to the wood of *Aquillaria Agallocha* (Roxb.), a leguminous tree of Cochin China, and to that of *A. malaccensis* (Lam.) of tropical Asia. Both are highly fragrant and aromatic; used in fumigations and pastilles, and occasionally by cabinet-makers and inlayers.

The same name is applied to the resin. Of all perfumes this is said to be the most esteemed by Orientals.

ALOIN *v.* Glucosides.

ALOO BOKHARA, ALPOGADA, PAZHAM. The Bokhara plum (*Prunus insititia* (Linn.) [*P. bokhariensis*], largely imported into Bombay. Used as a laxative. The root is astringent; the gum is used as a substitute for gum arabic under the name of Persian gum (Dymock, Pharm. J. [3] 9, 145).

ALOUCHI RESIN *v. Aluchi resin*, art. Resin.

ALPHOGEN (Alphozone). Trade names for succinyl peroxide.

ALPHOL *v.* Synthetic drugs.

ALPINIA OFFICINARUM *v.* Galanga root.

ALPINIA OIL. An essential oil obtained from the leaves of *Alpinia malaccensis*; sp.gr. 1·02 at 26°, rot. power +6·5°. Consists mainly of methyl cinnamate, together with *d*-pinene (Van Romburgh, Proc. K. Acad. Wetensch. Amsterdam, 1900, 3, 451).

ALPININ *v.* Galanga root.

ALPOGADA *v.* Aloo bokhara.

ALQUIFON. Black lead ore or Potters' ore. A native lead sulphide, used by potters to glaze coarse ware.

ALSOL *v.* Synthetic drugs.

ALSTONIA BARK. The dried bark of *Alstonia scholaris* (R. Br) and *A. constricta* (F. Muell.), an apocynaceous tree growing in Australia. It has a bitter taste, slightly camphorous odour, contains a neutral bitter principle (similar to *cailcedrin* and *tulucumin*), a volatile oil smelling like camphor, an iron-greening tannin, resin, fat, wax, a protein-like substance, oxalic and citric acids (Palm, J. 1863, 615).

Muller and Rummel (Chem. Soc. Trans. 35, 31) obtained a yellow substance to which they gave the name *alstonine*. Oberlin and Schlagdenhauffen (Pharm. J. [3] 10, 1059; Chem. Soc. Abstr. 38, 127) showed that this body consisted of two compounds, *alstonine* and *alstonicine*, the former being soluble in acids with fluorescence, the latter without.

Hesse subsequently (Ber. 14, 264; Annalen, 205, 360) isolated:

Alstonine (chlorogenine) $C_{20}H_{21}N_2O_4$, a brown amorphous mass, a strong base, soluble in chloroform, alcohol, and sparingly soluble in ether, and melting when anhydrous at 195° (uncorr.).

Porphyrine $C_{21}H_{25}N_3O_2$, a white powder melting at 97° (uncorr.), soluble in alcohol, chloroform, ether, and acids, with blue fluorescence.

Porphyrosine, soluble in acetic acid, forming a pink solution.

Alstonidine, colourless needles, melting at 181° (uncorr.), soluble in chloroform, ether, alcohol, and acetone.

Hesse, however, could not find a trace of quinine (Ber. 11, 1546, 1753).

ALSTONIA SPECTABILIS. *Poelé bark.* Contains *alstonamine* (Hesse, Ber. 11, 1548), and the alkaloids of dita bark. It contains six times as much echitammonium hydroxide as dita bark (Hesse, Annalen, 203, 144).

Its physiological action is like that of curare.

ALSTONINE. One of a series of ill-defined alkaloids occurring in *Alstonia* spp. (Hesse, Annalen, 1880, 203, 147; 205, 360), including *alstonamine*, *alstonidine*, *ditaine*, *ditamine*, &c.

ALSTONITE. A rare mineral consisting of barium and calcium carbonate $(Ba,Ca)CO_3$, crystallising in the orthorhombic system. The small crystals have the form of acute six-sided pyramids, and consist of complex twin intergrowths. Found, associated with witherite, in 1834 in a lead- and zinc-mine near Alston in Cumberland, and at Fallowfield in Northumberland; and in 1909 in a coal-mine near Durham. This species is often, but incorrectly, called bromlite (*cf.* Barytocalcite). L. J. S.

ALTHEIN. *See* Anthocyanins. The term *Althein* is used also as syn. for Asparagin.

ALTI. Indian name for a root used at Goa as a substitute for Althæa (Dymock, Pharm. J. [3] 8, 101).

ALUDEL. The aludels of the earlier chemists were pear-shaped pots generally made of earthenware, but sometimes of glass, open at both ends. Each aludel had a short neck at the top and bottom, so that a series of them could be fitted together by means of the necks. The earthenware pear-shaped vessels in which the mercurial vapours are condensed at Almaden in Spain are also known as aludels.

ALUM *v.* ALUMINIUM.

ALUMINATES *v.* ALUMINIUM.

ALUMINIUM. Sym. Al. At. wt. 27·1.

Occurrence.—Aluminium is the most widely distributed element in nature with the exception of oxygen and silicon. It is not found in the metallic state.

As oxide, Al_2O_3, aluminium is found in *corundum*, or, coloured by metallic oxides, in *sapphire*, *ruby*, *emery*, &c. The hydrated oxide Al_2O_3,H_2O occurs as *diaspore*, and, together with ferric oxide, silica, &c., as the important mineral *bauxite*.

Aluminium occurs in combination with oxygen and metals as *aluminates*, in *spinel* $Al_2O_3{\cdot}MgO$, *chrysoberyl* $Al_2O_3{\cdot}BeO$, *gahnite* $Al_2O_3{\cdot}ZnO$. As hydrated sulphate it is found in *aluminite* or *websterite* $Al_2O_3SO_3,9H_2O$, and as *alunogen* $Al_2O_3(SO_3)_3,18H_2O$; as the double sulphate of aluminium, potassium, and sodium in *alumstone* or *alunite*; and, as an efflorescence on aluminous minerals in the form of the alums of potassium, sodium, ammonium, &c.

Aluminium occurs principally, however, as silicate in the various *clays*; as silicate containing silicon fluoride in the *topaz*; and, as double silicate, with iron, magnesia, lime, &c., in *garnets*; with potassium, sodium, magnesium, and calcium in immense quantities in the varieties of *felspar*.

As double fluoride of aluminium and sodium it is found in *cryolite* $Al_2F_6{\cdot}6NaF$; as hydrated phosphate in the *turquoise* and in *wavellite*, and as borate in a crystalline mineral occurring in Siberia.

Although present in such quantities in the soil, aluminium is not usually considered a constituent of the ash of plants except of cryptogams; Yoshida, however (Chem. Soc. Trans. 1887, 748), has found it in a number of phanerogams in Japan.

History.—The name of this metal is derived from *alumen*, a term applied by the Romans to all bodies of an astringent taste. Pott, in 1746, stated that the basis of alum is an argillaceous earth; and in 1754 Marggraf pointed out the distinction between alumina and lime, and its presence in combination with silica in clay.

Davy, in 1807, having isolated the alkali metals by electricity, endeavoured, unsuccessfully, to reduce alumina in the same manner.

Oersted, in 1824, prepared aluminium chloride by passing chlorine over a mixture of alumina and carbon heated to redness. He appears to have reduced the chloride to the metallic condition by heating with potassium amalgam: (Berzelius, Jahresb. 1827, [6] 118). The amalgam produced oxidised rapidly in the air, and left, on volatilising the potassium, a tin-white metal.

Wöhler, in 1827 (Annalen, 1828, 37, 66), having failed to procure the metal by Oersted's method, obtained it by the decomposition of the *anhydrous* chloride with potassium, as a grey powder, which became brilliant under the burnisher.

Bunsen and Deville, in 1854, independently, obtained the metal by electrolysis of the fused chloride. Deville, in the same year, much simplified the manufacture by substituting sodium for the more expensive potassium. In 1854 he was installed in the manufactory of Javel by the Emperor Napoleon III., and supplied with the necessary apparatus for experiments on the large scale. Afterwards his process was removed to Nanterre and finally to Salindres. A description of his method is given in Ann. Chem. Phys. [3] 43, 5–36, and specimens of the metal produced were shown at the Paris Exhibition of 1855.

Shortly after the publication of these results, Messrs. Dick and Smith, under the direction of Dr. Percy, prepared aluminium by the action of sodium on the then newly discovered mineral *cryolite*, some of the product being shown by Faraday at the Royal Institution in March, 1855 (Phil. Mag. 10, 365).

About six months subsequently, Rose, independently, prepared it in the same manner, and published his results in an extended article in P. 96, 152 (Phil. Mag. 10, 233).

Deville at once turned his attention to this process (Ann. Chim. Phys. [3] 46, 451); but on account of the impurity of the metal produced, he preferred the double chloride of aluminium and sodium, using cryolite as a flux only.

The first manufactory in England was started at Battersea, London, in 1859, by F. W. Gerhard. Some of his metal was shown at the Society of Arts Exhibition in 1860. Messrs. Bell, of Newcastle, also prepared aluminium and aluminium bronze in 1863, using Netto's process. A mixture of 200 lbs. of cryolite and an equal weight of common salt was brought to fusion, and 40 lbs. of sodium gradually added. The charge thus contained only 5 p.c. of aluminium, but less than half of this was obtained in the yield.

The manufacture ceased in 1874. In Grabau's process (J. Soc. Chem. Ind. 1891, 433) aluminium fluoride was subjected to the action of metallic sodium. Other modifications were proposed from time to time, but the production of aluminium made no notable advance. Weldon, in 1883, summed up the position of the industry in the statement that 'the only method known for the manufacture of aluminium is Deville's. M. Pechiney has improved and cheapened the modes of working, and the appliances for carrying that method into effect, but this is all the progress which has been made in the manufacture of aluminium during the last five and twenty years.'

When the great stability of the available compounds containing aluminium is considered, it is not to be wondered at that the many attempts that have been made to prepare the metal by the action of the usual reducing agents, such as carbon, hydrogen, or hydrocarbons, have met with so little success. The heat of formation of these compounds is an index to their stability, and may be taken as a measure of the energy requisite for the isolation of the aluminium. The operation is not likely to succeed unless the elements which become separated from the aluminium enter into new combinations of still greater stability. The nature of the changes that might be expected to take place may be expressed in the following equations:—

$$\begin{array}{rrcl} & 2Al_2O_3 + 3C & = & 4Al + 3CO_2 \\ \text{or} & Al_2O_3 + 3C & = & 2Al + 3CO \\ & Al_2O_3 + 6H & = & 2Al + 3H_2O \\ & Al_2O_3 + 6Na & = & 2Al + 3Na_2O \\ & Al_2Cl_6 + 6H & = & 2Al + 6HCl \\ & Al_2Cl_6 + 6Na & = & 2Al + 6NaCl \\ & Al_2F_6 + 6Na & = & 2Al + 6NaF. \end{array}$$

In order that there may be a likelihood of these reactions occurring, the heat arising from the formation of the compounds on the right hand should exceed the heat concerned in the decomposition of the aluminium compounds on the left. The following table will show how far this is the case:—

	Calories		For amount equivalent to 2Al
Al_2O_3	391,600	$\frac{3}{2}CO_2$	145,500
		3CO	86,400
		$3H_2O$	174,900
		$3Na_2O$	302,700
Al_2Cl_6	323,600	6HCl	132,000
		6NaCl	587,400
Al_2F_6	558,000	6NaF	604,200

It will be seen that only the last two reactions will be at all likely to take place, and these heat values indicate that sodium is a much more favourable reagent than carbon or hydrogen, and that the highest excess of heat evolved over that absorbed occurs in the case of the aluminium chloride in presence of sodium.

The following analyses, taken from Hoffmann's Ber. Entwick. Chem. Ind. (1) 603, show the composition of commercial aluminium as produced under Deville's process:—

	1	2	3	4	5	6	7	8	9	10

Sodium . .	—	trace	trace	—	—	—	—	—	—	—

Moissan has shown (Compt. rend. 121, 851) that it contained also from 0·1 to 0·5 p.c. of sodium; 0·3 to 0·4 p.c. of carbon and other impurities. These impurities would have a very considerable effect on the properties of the metal, and statements based on observations with such metal, or even metal now being made, must be accepted with due regard to these impurities.

The production even in 1885 was small and did not exceed 2½ tons at Salindres and 2½ cwt. in the United States.

According to Mallet, pure aluminium may be prepared by the method adopted by him in his determination of the atomic weight of that element (Phil. Trans. 171, 1018). Ordinary commercial aluminium is converted into bromide by the direct action of bromine. On account of the violence of the action, the metal should be immersed only for a short time, at intervals, until dissolved, or should be added in very small pieces. The bromide so produced is freed from bromine by distillation and fractionally distilled, that portion boiling uniformly at 263·3° being reserved. This portion is colourless, entirely soluble in water, and consists of the pure bromide.

It is heated with sodium (which has been carefully freed from oil and well scraped) in a crucible made of a mixture of pure alumina and sodium aluminate. The amount of sodium used should not be sufficient to reduce the whole of the bromide, or the aluminium is liable to contain sodium. The globules of metal are fused together before the blowpipe on a bed of alumina, immersed for a short time in hydrochloric acid, washed and dried. Pure aluminium might also be produced by the electrolysis of the pure bromide or chloride.

The purification from metallic impurities on the large scale involves many difficulties. The only method of obtaining satisfactory metal is to ensure as high a state of purity as possible in the first instance by making use of selected materials and avoiding contamination in the process of manufacture.

By the establishment of Deville's process the price of aluminium had been brought down from 18*l.* per lb. to 1*l.*, at which it stood till 1887.

The double chloride of sodium and aluminium used contained only 14 p.c. of aluminium, and the working of large charges with a small yield together with the high cost of sodium and fuel stood in the way of any prospect of reduction in the price of the metal.

The introduction of Castner's process, by which sodium could be produced much more cheaply, led to the establishment of the Aluminium Company's works at Oldbury, and effected some reduction in the price of aluminium. Meanwhile Messrs. Cowles (Patents Aug. 18, 1885, and Jan. 26, 1886) brought electrical heating into operation, and, though their process was not adapted to the production of aluminium, it was capable of furnishing alloys of aluminium with copper and other metals. These could be made at one-tenth the price which had ruled for aluminium, and the valuable properties of aluminium bronze, Hercules metal, and other alloys were soon recognised. Moreover, the discovery of the effect of the addition of minute amounts of aluminium to iron and steel gave a further stimulus to the production of aluminium. C. W. Siemens had already described an electric furnace (1881) capable of giving very high temperatures, and the type of furnace patented by Messrs Cowles Bros. was based on similar lines.

The furnace is a rectangular box, one foot wide, five feet long, and fifteen inches deep, all inside measures. Two carbon electrodes pass through pipes in the ends; they are three inches in diameter and thirty inches long; this size could not be exceeded, as larger carbons disintegrated under the intense heat. For a non-conducting furnace lining, fine particles of charcoal are washed in lime-water, exposed to the air and dried. They thus become coated with lime and are of good insulating power. At the high temperature produced, ordinary charcoal becomes converted into graphite and forms a good conductor. The two electrodes being within a few inches of one another, the charge of twenty-five parts of corundum, twelve parts of carbon, and fifty parts of granulated copper is placed around and between them, covered with small lumps of charcoal, and the whole covered with an iron top lined with fire-brick. The current from a powerful dynamo is then passed, and the electrodes moved if necessary to produce the requisite resistance. In about ten minutes, the copper having melted between the electrodes, the distance between them is increased while the current is raised to 300 amperes of fifty volts E.M.F. and the yield 1 lb. per E.P.H. hour. As the resistance is increased, the temperature rises, the alumina is reduced to the metallic condition and alloys with the copper, while its oxygen forms carbon monoxide and burns at the openings in the cover with a white flame. After about five hours the operation is completed The alloy produced is brittle, consisting of copper and 15 p.c. or upwards of aluminium. When boron or silicon oxides have been added, the bronzes produced contain these elements. It is melted, cast into ingots, the percentage of aluminium determined, and sufficient copper added to produce 'aluminium bronze,' or the required alloy.

When other metals, such as iron, nickel, silver, &c., are substituted for copper, corresponding alloys are produced.

The slag produced is hard and compact, but soon falls to a fine alkaline powder; it contains alumina, calcium aluminate, with traces of copper, silicon, &c.

Pure aluminium cannot be produced satisfactorily by this method, as it remains, to a great extent, mingled with the carbon.

See further, W. P. Thompson (J. Soc. Chem. Ind. 1886, 206); Mabery (Amer. J. Sci. 308, and Amer. Chem. J. 1887, 11).

The Electrical Process.—A new principle was, however, introduced into metallurgy, and the application of electricity for purposes of heating and reduction of metals has made rapid progress in recent years. Its full development had not, however, been reached in the process just described. It had been shown that, though the fusion of a substance like alumina could not be economically effected owing to its high resistance, the addition of copper and other metals enabled the furnace charge to conduct the current. If a suitable solvent could be found for alumina then the electrolytic action of the current could be brought into play. When this was accomplished the chemical method of decomposition would give place to the electrolytic method, and the isolation of aluminium become a question of a sufficient current at the necessary voltage. This voltage can readily be calculated from the heat of formation of the compound in question by dividing the number of calories per equivalent by 23,250. We thus obtain for alumina 2·81 volts, for aluminium chloride 2·32 volts, for aluminium fluoride 4·00 volts, for aluminium sulphide 0·9 volt.

A suitable solvent is found in native cryolite $3NaF{\cdot}AlF_3$, which may be brought to fusion below 1000°, and will dissolve 15 to 20 p.c. of its weight of alumina, and in this condition, also owing to high temperature, the voltage is lower—in the case of alumina about 2·3 volts.

In the year 1886 the Héroult process was patented and soon came into use at Neuhausen, and at the Société Electrométallurgique at Froges, near Grenoble. In this process the anodes consisted of carbon and the cathode was the carbon lining of the furnace, the distance between the anode and cathode being capable of adjustment by raising or lowering the anode. The cryolite was first melted in the bath by utilising the heat generated by the resistance to the electric current, and then alumina was added, and the additions continued from time to time as the bath became exhausted. The metallic aluminium settled at the bottom of the bath in the neighbourhood of the cathode, and was tapped every 24 hours.

The purity of the metal at first was 97–99 p.c. There were at disposal 360 kilowatts at Froges, and just over 1000 kilowatts at Neuhausen (J. Soc. Chem. Ind. 1892, 910); the yield usually obtained was about 1½ lbs. of aluminium per kilowatt-day, an efficiency of less than 25 p.c. To-day 35 p.c. efficiency is reached.

The Hall process, brought out in the United States about the same time, only differed from Héroult's in matters of detail, the anodes being rods of carbon 3 inches in diameter, or of larger dimensions in sections banded together, the electrolyte being alumina dissolved in mixed fluorides of calcium and aluminium or $AlF_3{\cdot}NaF$.

Minet (Compt. rend. 112, 231) used a bath composed of 62·5 p.c. of common salt and 37·5 p.c. of cryolite, but his metal seems to have contained 2 to 3 p.c. of impurity, which was chiefly silicon, owing largely to the impurity of the alumina used by him. Aluminium so prepared was liable to contain sodium, owing to the fact that the voltage necessary for the decomposition of aluminium fluoride differed so little from that required to decompose sodium fluoride—viz. 4·7 as against 4.

There was added to the bath as the operation proceeded, a mixture of hydrated alumina, cryolite, and alumina dissolved in cryolite.

Kleiner invented a furnace for the decomposition of cryolite, and carried on the production of aluminium at Tyldesley in Lancashire; a plant was also operated on the lines of the Héroult system at Patricroft near Manchester.

In this case the dynamos were run by steam power, and it soon became manifest that this could not compete with advantageous supplies of water power which began to be called into requisition wherever such power was available.

Mention should also be made of the method of Bucherer, D. R. P. 63995 (1892), who prepared aluminium by electrolysing the double sulphide of aluminium and an alkali or alkaline earth, the chief obstacle to success being the expense and difficulty attending the production of the sulphide.

It soon became evident that the Hall and

Héroult process must hold the field, and that coal could not compete with cheap water power in this industry, and rapid expansions of the industry were made. The price had by 1891 been brought down to one-fifth of that which had ruled under Deville's process, and the production had increased to over 300 tons per annum. The accompanying statement is the cost of production at this period, as given by A. E. Hunt (Eng. and Mining Journ. 1891, 280). For 1 lb. of aluminium there was requisite

2 lbs. alumina	costing 6 cents
1 lb. carbon electrode	„ 2 „
Chemicals, pots, &c.	„ 1 „
22 E.H.P one hour	„ 5 „
Labour, interest, repairs	„ 5 „

making 19 cents in all.

The following firms were at this period manufacturing either aluminium or its alloys:—

In England—
- Cowles Syndicate (Cowles process).
- Reduction Syndicate (Hall process).

In the United States—
- Pittsburg Reduction Company.
- Cowles Electric Smelting Company.
- United States Aluminium Metal Co.

On the Continent—
- Société Electrométallurgique at Froges.
- Aluminium Industrie Actien-Gesellschaft at Neuhausen.

Further progress was mainly in the direction of increasing the yield and bringing down the cost of production whilst perfecting the various details of the process so that a purer product could be made.

We shall now describe the further development of the industry and the manufacture as it stands to-day after over 20 years of experience; and in doing so it will be well to consider in greater detail (*a*) the production of alumina, (*b*) the making of the carbon electrodes, (*c*) the nature and arrangement of plant, including the reduction furnaces.

Development of the Aluminium Industry—The first factory established on electrical lines was that started in 1888, at New Kensington, by the Pittsburg Company, which is now known as the Aluminium Company of America, and conducts operations at the Niagara Falls, the Shawinigan Falls, and at Massena.

Amongst the pioneers of the industry were also (1) Aluminium Industrie Aktien-Gesellschaft, who control works at Neuhausen, Rheinfelden, and Lend Gastein; (2) the British Aluminium Company, with reduction works operating in 1896 at Foyers and now at Kinlochleven (Argyllshire), and branch works at Larne, Burntisland, Warrington and Milton (Staffordshire),—this company is also associated with reduction works at Stangfiord and Vigelands Brug (Norway), and projected works at Orsières (Switzerland); (3) Société Electrométallurgique Française at Froges, La Praz, and St. Michael, and the Cie. des Produits Chimiques d'Alais et de la Carmargue.

There were formerly works on a smaller scale under the Aluminium Corporation at Wallsend, now in operation at Dolgarrog (N. Wales), and developments in Italy at Bussi. The cost of production of the metal to-day is said to be 61*l.* per ton as a minimum, though at most works it would reach 80*l.* (Mining World, June 26, 1909). For the past five years costs have been much higher.

The market price of aluminium ingots in 1902-4 was 120*l.* per ton, but it rose to 200*l.* in 1906, and has since then fallen to 65*l.* (1909), though it is now again advancing. Since 1902 no trustworthy record has been made of the world's output of aluminium. It remained, however, fairly stationary in the neighbourhood of 8000 tons from 1900 to 1905 inclusive, and since then has grown steadily, and may be estimated for 1909 at 30,000 tons. In the United States Geological Survey publications (Metallic Products) for 1908 there may be found the estimated consumption of metal in the United States, from which it appears that in 1907 this amounted to nearly 7700 tons, and in 1908 to nearly 5000 tons.

The following is a statement of the production of aluminium in metric tons from 1889 to 1913, (*a*) in the United States and Canada, (*b*) total output:—

	a	*b*
1889	22	93
1890	28	193
1891	68	302
1892	118	505
1893	154	870
1894	250	1491
1895	417	1835
1896	591	2250
1897	1814	5220
1898	2359	6860
1899	2948	8950
1910	17400	43800
1911	20500	45000
1912	29200	63000
1913	32300	68000

During the period of the war, 1914 to 1918, the data available are incomplete and hardly to be depended upon. Considerably increased outputs are, however, recorded. In 1917 there appear to have been about 79,500 tons manufactured in the United States and Canada with 168,000 tons as total output. France in that year produced about 20,500 tons; Germany, who in 1913 produced only 800 tons, put down during the war large instalments of plant sufficing for 40,000 tons; the British production was 13,000 tons and that of the other European countries 15,000 tons. Switzerland is stated to have exported nearly 10,000 tons per annum into Germany. Norway made large extensions in reduction works which did not become effective owing to lack of raw materials. In other directions her efforts in electrochemical developments have been such as to command 125,000 kilowatts in 1917 as compared with 9000 kilowatts in 1904.

The Production of Alumina.—The raw material from which the alumina is usually made is bauxite, deposits of which occur at Beaux and in the Var (S. France), at Feistritz (Austria), Wochein (Styria), Irish Hill (Ireland), Georgia, Arkansas, Alabama, Tennessee (United States), British Guiana, and in New South Wales. The physical condition of the bauxite varies considerably, so that some kinds are more readily acted upon for the production of alumina than others. In the aluminium industry a low content of iron and silica is desired,

especially the latter; it is therefore usually found advantageous to employ the red bauxites, the white bauxites being used preferably in the manufacture of sulphate of alumina. The following table gives the composition of typical samples :—

Locality .	Beaux		Var		Wochein		Feistritz			Irish	Georgia
			Red	White	Dark coloured	Light coloured	Reddish brown	Yellow	White	Raw	
Al_2O_3 .	60	75	50–62	65–74	63·16	72·87	44·4	54·1	64·6	35·0	60·5
Fe_2O_3 .	25	12	24–28	0·3–3	23·55	13·49	30·3	10·4	2·0	38·0	1·9
SiO_2 .	3	1	1–7	12–18	4·15	4·25	15·0	12·0	7·5	3·5	3·3
H_2O .	12	12	12–13	14	8·34	8·50	9·7	21·9	24·7	21·5	32·1
TiO_2 .	—	—	0·1–4	—	trace	trace	—	—	—	2·0	2·2

The following analyses by Leop. Mayer and O. Wagner (Dingl. poly. J. 248, 213) show that the appearance of bauxite cannot be relied on as a criterion of its value. The origin of the samples is not given :—

	Appearance	Hygroscopic moisture	Combined water	Al_2O_3	Fe_2O_3	SiO_2	MnO_2	CaO	MgO	P_2O_5
1	Pure white .	2·33	13·86	29 80	3·67	44·76	—	2·75	0·84	1·47
2	Yellow . .	1·03	27·85	43·22	14·39	10·43	—	1·61	—	1·13
3	„ . .	1·30	27·70	50·38	11·68	8·34	trace	trace	trace	0·61
4	Red . .	1·34	23·12	33·86	25·69	12·41	2·42	trace	—	0·53
5	„ . .	1·31	23·81	46·18	22·05	4·82	—	0·89	—	0·66
6	„ . .	0·95	20·83	62·10	6·11	5·06	2·01	3·20	trace	trace
7	„ . .	1·17	4·75	21·80	3·75	60·10	—	6·06	2·49	trace

The amount of bauxite mined in 1907 was 260,000 tons, three-fifths of which was produced in France. In 1913 the production was 533,000 tons distributed as follows: United States 210,000, France 309,000, Great Britain 6000, other countries 8000. During the period 1914–1918 no reliable returns are available, but it is certain that the output was much larger. That for the United States alone was 569,400 tons in 1917, and British production 15,000 tons. New deposits were opened up in Dalmatia and Hungary, the latter country contributing 59,000 tons in 1915. Increased production of aluminium and aluminium salts account for 457,000 tons. The more recent applications of bauxite to the production of alundum, abrasives and refractory materials for bricks and furnace linings took up 112,400 tons.

For the manufacture of the purest form of alumina the bauxite is first roughly powdered and calcined to get rid of water and any organic matters. It is then more finely ground and introduced gradually with agitation into kiers containing caustic soda solution of 1·45 sp.gr. The kiers are now closed and the charge heated for some hours under high-pressure steam—about 70–80 lbs. The contents of the kiers are then transferred to the filter presses, and the filtrate further cleared through wood pulp in lead-lined vats. The liquor contains sodium aluminate $NaAlO_2$, which may be decomposed by passing carbon dioxide into it, but it is now more usual to adopt the Bayer method of precipitating the alumina. This method depends on the fact that the addition of alumina effects the decomposition of the aluminate and throws down some 70 p.c. of the alumina. The dissolved liquor now contains alumina and soda in the proportion $Al_2O_3 : Na_2O :: 1 : 6$. The precipitated hydrate of alumina is allowed to settle, and the liquor with its undecomposed portion is run off into weak-liquor tanks. The hydrate is filter-pressed, sufficent being left in the vat to serve as precipitant for the next charge. The weak liquor may, after concentration, be used over again for reacting upon a further amount of bauxite.

The press cake containing the impurities removed in the treatment of bauxite constitutes usually over 30 p.c. of the bauxite, whether the wet process of extraction or the dry fusion process with sodium carbonate be used. In the latter case, the residue has been successfully applied in the removal of sulphuretted hydrogen from coal—or from exit gases of other products. The residue from the wet process is, however, inactive in this respect, but may be transformed into a condition in which it is very effective.

The hydrate of alumina so obtained ought to contain less than 0·5 p.c. of mineral impurity, iron and silicon being the more objectionable impurities. To bring it into a suitable physical condition for use in the reduction furnaces it must be calcined at 1100°–1200°, so that it shows no tendency to give up moisture when used in the furnace or to absorb moisture when exposed to air.

The alumina of to-day is superior to that of twenty years ago, and the cost of production less than one-half. It constitutes, however, about one-fifth of the whole cost of manufacture of aluminium, and many processes have been brought forward with a view to improve or cheapen the product. Of these may be mentioned the patents of Peniakoff (Eng. Pat. Nov. 19, 1895, Mar. 18 and May 13, 1896, &c.). Endeavours have been made to obtain alumina of sufficient purity from bauxite, clay, felspar, or kaolin by electrically heating them with iron (or its oxide), carbon and cryolite, thus separating ferrosilicon from alumina; Moldenhauer (J. Soc. Chem. Ind. 1909, 148), Sinding-Larsen (*ibid.* 1908, 409), Tone (Electrochem. and Metallurg. Ind. 1909, 35), Hall (J. Soc. Chem. Ind. 1902, 49). Recently Serpek has proposed to prepare alumina by forming the carbide and acting upon this with producer gas consisting of 77 p.c. nitrogen, 23 p.c. carbon monoxide, and a little carbon dioxide. He claims that a tolerably pure nitride of aluminium is formed, and this decomposed by steam yields alumina and ammonia (Journal du Four Electrique, 315, 1; J. Soc. Chem. Ind. 1911, 26; Fr. Pat. 405712 and 418059). Many other patents have been taken out with the object of producing alumina or nitride with the use of clay or other crude materials in place of the purified alumina, or as means of procuring alumina. Amongst these may be mentioned Cowles' process (Journal du Four Electrique, 1913, 176), Child's process (Met. and Chem. Eng. 1913, 231), Peacock's proposal to use felspar (*l.c.*), the Badische patent (Chem. Trade Journ. April, 1911), as well as methods of extraction from alunite with the recovery of alkaline salts (Waggaman and Cullen, J. Soc. Chem. Ind. 1916, 1217), and Hershmann (U.S. Pat. 1915 and 1916). Serpek's process has also undergone considerable developments in operations on the large scale at St. Jean de Maurienne. *See* also J. Soc. Chem. Ind. 1913, 509; Met. and Chem. Eng. 1913, 137.

The Making of Carbon Electrodes.—Bituminous coal, anthracite, retort carbon, natural or artificial graphites, soot and oil-coke are all materials which have from time to time been used in the production of carbon electrodes. In deciding which of these materials should be used, account must be taken of: (*a*) Supply and cost of raw material; (*b*) ash content; (*c*) amount of volatile matter and sulphur; (*d*) conductivity for electricity and heat. It must also be understood that electrodes used for the production of aluminium differ in character from those used for lighting or for the production of calcium carbide and many other purposes where graphitisation of the carbon is an advantage and the presence of mineral matter is quite permissible and even necessary. The graphitisation of amorphous carbon, which must contain mineral impurities, is indeed effected by exposing it to a high temperature under electrical heating.

It is said that at the temperature employed the iron volatilises. Be this as it may, the ash of such carbon contains a considerable amount of oxide of iron. Aluminium, boron, silicon, and other elements which form carbides can be used as graphitising agents, as also to some extent the oxides of these elements.

Graphite or graphitised electrodes have at 1000° C. about 5 times the electrical conductivity of coke blocks and 8 to 10 times the thermal conductivity, but it is now recognised that these properties, advantageous in some respects, are not, however, favourable to the efficient working of reduction furnaces.

It may be taken that, so far as it is capable of reduction in the aluminium furnace, the mineral ash contained in the carbon alloys itself with the aluminium, as also the foreign matter present in the alumina. The amount of alumina used should be about double that of the aluminium resulting therefrom, and the electrode consumption about one-half of the aluminium, so that an estimate may be made of the impurity as silicon contained in the metal. Assuming the silica in the alumina and in the electrode together as 0·4 p.c., in each case, the amount of silicon in the metal will be very nearly 0·2 p.c.

Similar considerations apply to the iron content of the metal, though this may, by reason of operations, much exceed the amount of iron contributed by the alumina and electrodes.

The electrical resistance is in microhms per cubic inch of

	0°	1000°
Amorphous carbon (pressed)	1·63	1·45
Graphite carbon . . .	0·42	0·25
Electrodes for aluminium .	3·00	2·60

The resistance per cubic centimetre would be 2·54 times these values. (For further detail, The Electric Furnace, Stansfield, or the pamphlet issued by the Acheson Graphite Co., may be consulted; also Met. and Chem. Eng. 1915, 23.) In addition to low resistance to the electrical current, it is desirable that electrodes should be of low conductivity for heat, that they should be sufficiently hard and resistant to superficial oxidation, of low porosity and of as even character as possible throughout their whole mass.

To produce electrodes having these qualities the material (oil coke, pitch coke, and anthracite, used separately or mixed) must be carefully selected, ground, calcined, and subjected to high pressure with the admixture of tar or other material to act as binder. The blocks are baked at a temperature of about 1200° to 1300° in a kiln, in principle resembling a pottery kiln, the surface of the blocks being protected from oxidation by being embedded in carbon. The permissible current-density for good electrodes of this type is in the neighbourhood of 8 amperes per square inch of transverse section. For further details and description of Mendheim and other kilns suitable for baking the blocks, reference may be made to Die Künstlichen Kohlen, by Julius Zellner. Also to Chem. and Met. Engineering, vol. xix. 179, where an illustration of a more modern type of kiln known as the Meiser Kiln is shown. Various types of tunnel furnaces are also in use for this purpose (and for baking pottery and bricks). The connection of the carbon blocks with the anode beam carrying the current may be effected by means of an iron claw let into the block or a copper hanger fitted into it by a screw contact or by other devices.

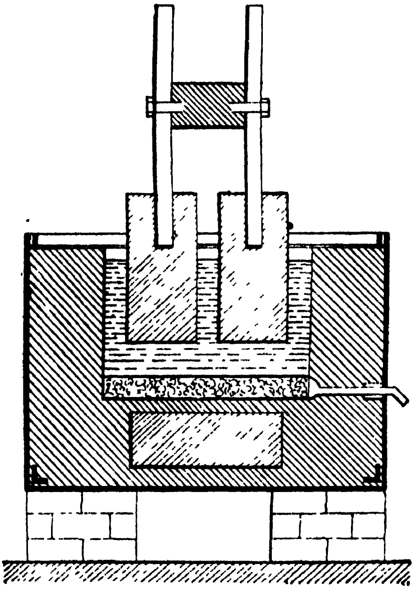
The Reduction Furnaces.—These consist essentially of an iron casing lined with carbon, the general character and arrangement of which is shown in transverse section below. The electrodes vary in size and form in different works, and are not necessarily arranged in two rows as indicated in the figure. Their total sectional area is, however, always adapted to the current to be used and good electrodes will act satisfactorily under a current-density of about 8 amperes to the square inch. The lower part of the carbon body serves as the cathode, or a special form of cathode is let into the carbon at the base of the furnace. In starting a furnace it is usual to introduce first the cryolite, which is brought to a state of fusion by electrical heating. Alumina is then fed in gradually at the surface of the cryolite, and as it dissolves the resistance gradually falls to about 5 or 6 volts, and the temperature of the bath will be generally 1000°. The electrolytic action brings about a decomposition, which has been usually taken to result in the formation of carbon monoxide, according to the equation

$$Al_2O_3 + 3C = 2Al + 3CO$$

but there is little doubt that primarily carbon dioxide is formed, and the change should be expressed as

$$2Al_2O_3 + 3C = 4Al + 3CO_2$$

In the former case the carbon used would be two-thirds of the weight of the aluminium produced, whilst in the latter it would be one-third. In practice the ratio of carbon to aluminium lies between these extremes.



The production of aluminium is discontinuous, for about 2 hours after the proper charge of alumina has been added the voltage of the furnace rises rapidly and affords an indication that more alumina must be added. The aluminium collects at the bottom of the bath of electrolyte, and is tapped off at stated periods, either every day or at longer intervals. The reduction of alumina by electrolytic methods on a laboratory scale is beset with difficulties; an account of experiences in this direction is given in papers by Neumann and Olsen (Met. and Chem. Engineering, 1910, 185), and Tucker (*ibid.* 1909, 315). The metal is subsequently re-melted and cast into notch bar slabs or blocks. The blocks are broken down in heavy rolls and further brought down into sheet. Metal which has been subject to much cold work in rolling is in a stressed condition. To render it homogeneous it is exposed to an annealing process at about 400°. The resulting sheet is ultimately obtained according to details of treatment in soft, medium, or hard condition. The metal may also be drawn into wire or extruded in large masses either in solid sections or in tube.

Physical Properties.—Commercial aluminium is a metal with the whiteness of tin. It has been obtained in crystals resembling octahedra, and is very slightly magnetic.

Its specific heat is, at

−100°	0·1893	300°	0·2434
0°	0·2098	500°	0·2739
100°	0·2236	650°	0·3200

(Schmitz, Proc. Roy. Soc. 72, 177).

The total heat required to bring a kilogramme of aluminium from 0° to 625° is 239,400 cals., and its latent heat of fusion is usually taken as 80 calories per gram. Laschtschenko (J. Chem. Soc. 1913, Abst. 427) found for metal of 99 p.c. purity the value 71. It melts at 654·5° (Heycock and Neville), 657·3° (Holborn and Day), the melting-point being dependent (as are other physical properties) on its purity. Small amounts of silicon and iron, which are always present, have a considerable effect on its behaviour, both physically and in contact with reagents. Lorenz found its conductivity for heat at 0° 0·3435, at 100° 0·3619; whilst Jaeger and Dresselhorst for metal containing 0·5 p.c. iron and 0·4 p.c. copper, found 0·4923 at 100°. Similarly the electrical conductivity of aluminium, taking copper as 100, is as follows: 98·5 p.c. purity, 55; 99 p.c., 59; 99·5 p.c., 61; specific resistance, 2·7–2·8 microhms increasing to 3·6 at 100°.

Its elasticity modulus (*i.e.* load in kilogrammes per square millimetre, divided by its alteration in length) is 7462 as compared with 11,350 for copper, and the torsion moduli of these metals are 3350 and 4450 respectively.

The specific gravity of the molten metal is 2·54, and of the cast metal is about 2·66; this may be increased by rolling. Its thermal expansion is given by the formula $l_t = l_0[1 + 22 \cdot 9t + 0 \cdot 009t^2)10^{-6}]$ (Jaeger and Scheel). It expands on fusion to the extent of 4·8 p.c. (Toepler). The metal expands in volume from 0°C. to melting point 6·1 p.c., after fusion reaches 10·9 p.c., and at 800° C. 12·4 p.c. In hardness it resembles silver, and the pure metal is softer than the impure. It becomes more elastic and also harder by hammering and rolling, and is capable of being drawn down to a wire of $\frac{1}{250}$ inch in thickness, or rolled into plate or beaten into foil to $\frac{1}{2500}$ inch thick. It can also be finely granulated, or prepared in the form of powder (Guillet, J. Soc. Chem. Ind. 1912, 339), which is largely employed as 'thermite,' or as aluminium paint. The tensile strength of aluminium is 12 to 13 tons on the square inch, but this varies with the temper of the metal between 6½ and 15½ tons on the square inch, the elongation varying in the inverse manner from 23 p.c. to 1½ p.c. 6-mm. wires have a tensile strength of 13 kg./mm.² and 3-mm. wires a strength of 17 kg./mm.². Aluminium has been largely used for overhead electrical transmission and it possesses many advantages for such purposes owing to its lightness. Its specific gravity being only $\frac{3}{10}$ of that of copper, and conductivity over 60 p.c., it follows that an aluminium cable has double the efficiency of a copper cable of the same weight as a means of conveying current. The tensile strength of aluminium is affected, of course, by its form, method of casting and mechanical treatment. Its ultimate strength in tons per square inch is in castings 5 tons, in sheet 8 to 9 tons, and in wire from 13 to 29 tons. On annealing its strength is reduced about 50 p.c. and its ductility much increased, the elongation being 4 to 8 times greater than when it is in the hard-rolled form.

Although corroded in the atmosphere of some large towns, it is not more so than other metals used for cables, and under ordinary circumstances it merely becomes coated with a thin film of oxide which acts protectively (Kershaw, J. Soc. Chem. Ind. 1901, 133; E. Wilson, J. Soc. Chem. Ind. 1902, 1283; 1903, 1093). A protective coating for insulation purposes can also be produced (Mott, J. Soc. Chem. Ind. 1904, 509; Skinner and Chubb, J. Soc. Chem. Ind. 1915, 360; also Eng. Pat. 9941, April 24, 1911).

There has been great difficulty in finding a wholly satisfactory solder for the metal, and one that shall resist corrosion. Dagger (J. Chem. Soc. Ind. 1891, 436) quotes as useful for heavy soldering Al 12 pts. Cu 8 pts. Zn 80 pts., and for light soldering Al 6 pts. Cu 4 pts. Zn 90 pts. A satisfactory flux for soldering consists of $NaCl$ 30 grams, KCl 45 grams, $LiCl$ 15 grams, KF 7 grams, $NaHSO_4$ 3 grams (J. du Four Electrique, 1914, 868). Joints can, however, be made by autogenous welding with an oxyhydrogen or acetylene flame or electrically. Butt and other joints may be effected by various mechanical devices with the aid of fusion at the surfaces or by a casting of metal around the junctions.

Applications of Aluminium in the Industries.—*Castings* or extrusions of the metal or its alloys are used in the construction of railroad cars, motor-cars, air-ships, and aeroplanes; for collector bows, field coils, and other details in electrical traction, also for various mechanical appliances, such as pulleys, &c. *Sheet* is largely employed for spinning, pressing, or stamping into forms suitable for cooking vessels, trays, drawers, beakers, and similar articles of domestic use, or in works operations. *Wire* and extruded metal is employed in the distribution of electrical current either by means of solid or stranded cable, for feeder connections or bus-bars. In America, on the Continent, and in Canada and other Colonies aluminium is used for overhead high-tension currents running to over 100,000 volts. In Great Britain its use is confined to lower-tension currents either over or underground.

Granules and Notch Bar are cast in this form for convenient addition to molten steel during casting with the object of securing greater purity and density of the steel. In the form of *powder*, or as finely *granulated* metal, aluminium finds application in the thermite welding process, as paint, and for the manufacture of high explosives, such as ammonal. In consequence of the very large number of chemical products which have practically no action upon aluminium, the metal is now being used with advantage in a large number of chemical industries. The following may be quoted as processes or branch industries, in which already wide applications in the construction of plant are being found for the metal:—

Manufacture of nitric acid and guncotton, &c.; oils, fats, soap, glycerine, organic acids; fine chemicals, such as formaldehyde, hydrogen peroxide, ether, extracts, essences, and syrups; foodstuffs, gelatin, jams, etc.

Also in the canning industry, sugar refining, varnish making, brewing, dyeing, rubber, paper, lithography, and printing.

Chemical Properties.—Aluminium absorbs about its own volume of hydrogen (Delachanal and Dumas, J. Soc. Chem. Ind. 1909, 368), which is, however, expelled on heating or *in vacuô*. In the course of its production and treatment aluminium takes up gases (chiefly hydrogen and nitrogen) usually in such quantity that their total volume is from 7 to 20 p.c. of that of the metal. Good metal tapped from the reduction furnaces yields 5 to 10 p.c. of its volume of hydrogen and about 3 to 4 p.c. of nitrogen. After re-melting, especially under unsuitable conditions, it is found to contain more hydrogen and also carbonic oxide and hydrocarbons. An ingot of metal, which had been melted and allowed to cool in the furnace *very* slowly, was highly crystalline and found to contain of its volume an extraordinary amount, viz. 85 p.c. hydrogen, 7·5 p.c. nitrogen, and 4 p.c. carbonic oxide and hydrocarbons. It is practically unacted upon by oxygen at ordinary temperatures, but if finely divided it undergoes considerable oxidation at 400°, or even, though less rapidly, at lower temperatures. If sufficiently pure, water has slight action upon it, though if sodium is present in the metal a somewhat greater action occurs. This is accentuated if copper, brass, or other metals are in contact with it. A recent use to which the metal has been put is for the treatment of hard waters, which by intimate contact with the metal, are said to be softened and become less liable to form incrustation on the shell of the boiler. The halogen elements or acids readily act upon aluminium, and the chemical activity of the metal is such that a large amount of heat is generated on combination with these elements.

The very great affinity which aluminium possesses for oxygen has been made use of in the application of 'thermite' as a means of reducing oxides. Goldschmidt, D. R. P. 96317 (1895), has thus used the finely divided metal in the production of iron, manganese, chromium, nickel, cobalt, titanium, boron, molybdenum, tungsten, vanadium, and other metals.

Reagents which readily part with the halogens, such as $SiCl_4$ and PCl_3, also attack it, and carbon or the oxides of carbon at high temperatures convert it into the carbide, Al_4C_3. Mallet (Chem. Soc. Trans. 1876, 340) found that molten aluminium is acted upon by nitrogen with the formation of nitride, indeed it burns vigorously in an atmosphere of nitrogen.

If brought into intimate contact with mercury in presence of moisture, aluminium is readily converted into the hydroxide, and when exposed to the vapour of mercury with access of air, it undergoes rapid oxidation.

Perspiration, being acid, has no apparent effect; saliva, on account of its slight alkalinity, acts very slowly. Aluminium tubes have been used for insertion in the human body where much purulent matter was present, without perceptible corrosion.

Aluminium when fused with potash or soda is unaffected even at a dull red heat, but the superficial silicon is removed; metal so treated takes a good 'matt.'

For burnishing and engraving aluminium, the ordinary media are unsuitable. According to Mourey and others, an emulsion of equal parts of rum and olive oil is most satisfactory. The finish of manufactured articles is improved by a frosted appearance. This is produced by plunging the article momentarily into caustic alkali, washing well, and immersing in dilute nitric acid.

Action on metallic solutions.—Aluminium, especially in the form of foil, has a considerable action on many salts in solution. The action of sulphates and nitrates is usually very slow. All chlorides, except those of the alkalis and alkaline earths, are readily decomposed, even *aluminium chloride* solution dissolves the metal with evolution of hydrogen. Bromides and iodides have corresponding effects. The presence of chlorides in solutions of other salts much facilitates their action.

From a neutral or feebly acid solution of silver nitrate, silver is precipitated slowly; from an ammoniacal solution of the chloride, silver is rapidly precipitated as a crystalline powder.

From the nitrate or sulphate of copper, precipitation is slow, from the acetate quicker, and from the chloride or other salt in presence of sodium chloride, rapid and complete.

Salts of mercury are decomposed with formation of an amalgam. Lead and zinc are readily precipitated (*v.* also Cossa, Zeitsch. f. Chem. [2] 6, 380 and 443; Nicolardot, J. Soc. Chem. Ind. 1912, 438).

Action of dry salts and oxides.—The action of aluminium, when heated with certain salts and oxides, is peculiar, and shows, especially at high temperatures, the tendency of this metal to form aluminates.

It is not affected by potassium nitrate except above a red heat; it is then rapidly oxidised with formation of potassium aluminate. With alkaline carbonates combination takes place at a red heat with separation of carbon, and with alkaline sulphate combination takes place suddenly at redness with explosive violence; in both cases aluminates are formed.

When finely divided aluminium is mixed with oxide of copper, lead, or iron, combination takes place at a *white* heat only, with such violence as frequently to shatter the crucible. In the case of lead and copper oxides, aluminates are produced, and with iron an alloy of iron and aluminium (Tissier).

When heated with silicates or borates, aluminium liberates silicon or boron, forming an aluminate with the base. Fused silver chloride is reduced to metal; zinc is reduced from its fused chloride, whilst magnesium chloride is not affected (Flavitzky, Ber. 6, 195). The vapour of mercuric chloride is reduced with such energy by heated aluminium that the metal fuses.

Corrosion of aluminium.—The question of corrosion is one which is of the highest importance in the application of metals, but in none more so than in the case of aluminium (Bailey, J. Inst. Metals, ix. 79, and xxi., 234).

This arises not only from the considerable extent of the usage of this metal for culinary operations, but also because of its large and extending use in the chemical industries and for constructional work where atmospheric and other agencies are to be reckoned with.

Speaking generally, with the exception of alkalis and salts with an alkaline reaction, solutions containing less than 5 p.c. of the reagent have very little action.

It is also noteworthy that concentrated mineral acids or organic acids, and with few exceptions the salts of these react very slowly with aluminium. The most important exceptions are hydrochloric acid and the halogen acids generally.

It is essential, however, to add that whilst this general statement holds good at ordinary temperatures, action is very greatly accelerated by a rise in temperature, and especially when the reagent approaches its point of ebullition. The extent to which aluminium is corroded is also largely dependent on its purity, especially where this is lower than that of good commercial metal, say 99·2 p.c., or, of course (though in practice this is frequently overlooked), aluminium is in contact with other metals. In the notes which follow, some information is given as to the corrosive effects of those reagents which are already associated with the use of aluminium in the industries, and references are given to details.

The numbers stated in parentheses, in respect of any of these reagents, express the milligrams of metal removed per 100 square centimetres of surface for an exposure at ordinary temperatures of 24 hours, when the concentration is approximately 5 p.c., except where otherwise stated.

Acetic acid (0·6) (Lunge, J. Soc. Chem. Ind. 1895, 592; Seligmann and Williams, J. Soc. Chem. Ind. 1916, 88, and 1917, 409).

Acetone (Pikes, Zeitsch. angew. Chem. 1914, 52).

Alcohol, wines, and *spirits* (Lunge, *l.c.*; Rüdiger and Karpinski, J. Soc. Chem. Ind. 1913, 41).

Ammonium hydroxide (reaches maximum with 2 p.c. at 375) (E. K. Davis, Metal. Ind. 1910, 109).

Barium hydroxide (370 for centinormal solutions).

Beer (Schönfeld and Himmelfarb, J. Soc. Chem. Ind. 1912, 789; Chapman, *l.c.* 1912, 87; Bleisch, *l.c.* 1912, 199; Zikes, *l.c.* 1913, 248; Trillat, *l.c.* 1915, 883).

Boric acid (0·3) (Lunge, *l.c.*).

Bromine acts vigorously on aluminium, also *chlorine* and *iodine*.

Butyric acid (0·2) (Lunge, *l.c.*; Seligmann and Williams, *l.c.*).

Calcium hydroxide (285 for a centinormal solution).

Citric acid (0·3) (Lunge, *l.c.*).

Formic acid (Seligmann and Williams, *l.c.*).

Hydrochloric acid (7).

Lactic acid (0·8) (Lunge, *l.c.*).

Nitric acid (5) (Seligmann and Williams, J. Soc. Chem. Ind. 1916, 665).

Oxalic acid (6) (Carpenter and Edwards, 9th Report of Alloys Research Committee).

Potassium hydroxide (205 for a centinormal solution).

Potassium iodide (1·3).

Propionic acid (Seligmann and Williams, J. Soc. Chem. Ind. 1916, 88).

Salicylic acid (1·1) (Lunge, *l.c.*).

Sodium chloride (2).

Sea water (13) (Carpenter and Edwards, *l.c.*).

Sodium hydroxide (460 for a centinormal solution).

Sodium carbonate (reaches maximum with 0·5 p.c. at 140).

Sodium bicarbonate (little or no action).

Sulphuric acid (7).

Tartaric acid (0·3) (Lunge, *l.c.*).

It should be realised that corrosion measured, especially in the cold and over short exposures, shows in many cases, a much higher value than would be the case for prolonged exposure, owing to the formation of a protective coating. This applies particularly to weathering, action of ammonia, and certain hydrates and salts, and more commonly in hot solutions.

With the fixed alkalis the activity is progressive with increased concentration, and also in a very rapid degree with hydrochloric acid; but with ammonia, sodium carbonate, and with sulphuric, nitric, and acetic acid the activity rises to a maximum, and ultimately falls off rapidly, so that with the highest concentration the action is slight. Many of the results given above have been confirmed by the author of this article or are the results of unpublished determinations by him. It only remains to add that the following bodies have practically no action on aluminium: Acetone; acetylene; benzol; tea and other similar beverages; borax; chlorides; sulphates and nitrates of the alkalis; carbolic acid; ether; fats, oils, and fatty acids; formaldehyde; gallic acid; gelatin; glycerine; hydrogen peroxide; hydrogen sulphide; soap; sulphur; sulphur dioxide; chlorine.

Potable waters, if free from common salt and alkalis, have very slight effect.

Detection.—Compounds of aluminium, when heated, moistened with solution of cobalt nitrate, and again strongly heated produce a fine sky-blue colour (*Thenard's blue*, *q.v.*, art. COBALT).

Aluminium compounds are usually colourless. Silicates and other compounds insoluble in acids require to be finely powdered, mixed with 4 parts of sodium carbonate or fusion mixture, and heated strongly in a platinum crucible The aluminium, having thus become converted into sodium aluminate, is dissolved out with hydrochloric acid, evaporated to dryness to render any dissolved silica insoluble, and treated with dilute hydrochloric acid. The aluminium is then present as chloride.

Aluminous solutions, on addition of an alkali, give a white gelatinous precipitate of hydrate, soluble in excess of the precipitant and in acids. Ammonia produces the same precipitate, which is only slightly soluble in excess, and is entirely reprecipitated on boiling off the excess of ammonia if sufficient ammonium chloride be present, or it may be precipitated by CO_2.

Estimation.—Aluminium is usually precipitated as the hydrated oxide $Al_2O_3,3H_2O$.

For this purpose the solution, which, in presence of alkalis or alkaline earths, is mixed with excess of ammonium chloride, is treated with a *slight* excess of ammonia, and the solution boiled until the free ammonia is expelled. The hydrate, having thus become totally precipitated, is filtered, well washed, dried and heated in a platinum crucible, the heat being finally raised to bright redness to constant weight over the blowpipe. The weighed residue consists of anhydrous oxide, Al_2O_3, and contains 53 p.c. of aluminium. The separation from other metals is not difficult. The heavy metals may be precipitated from the *acid* solution by sulphuretted hydrogen, leaving the aluminium in solution, whilst the precipitation in presence of ammonium chloride in excess separates it from the alkalis and alkaline earths. From chromium and iron the separation is less simple. Chromium may be separated as follows:—The precipitated oxides are dried, mixed with 2 parts potassium nitrate and 4 sodium carbonate and fused in a platinum crucible. Alkaline chromate and aluminate are thus produced. The mass is digested with water and a small quantity of potassium chlorate and of hydrochloric acid are then added, and the solution is evaporated to a syrup, with occasional addition of potassium chlorate to destroy the excess of hydrochloric acid and prevent its reducing action on the chromate. The aluminium in the diluted solution is precipitated as above by ammonia, leaving the chromate in solution.

For the separation from iron, the precipitated hydrated oxides are dissolved in the minimum quantity of hydrochloric acid and treated with an excess of *pure* strong potassium hydroxide solution, boiled for a few minutes, diluted, filtered, and well washed. The ferric oxide is thus precipitated and separated from the soluble alumina. The solution and washings are acidified with hydrochloric acid and precipitated by ammonia. On account of its solvent action upon glass, the treatment with potash should be performed in a porcelain dish, which is much less attacked, or, preferably, in one of silver.

Commercial Analysis of Aluminium.—The direct determination of aluminium, constituting as it does usually over 99 p.c. of the metal under examination, presents many difficulties. It has been proposed to estimate the aluminium by ascertaining the volume of hydrogen evolved on dissolving it in hydrochloric acid or the amount of chloride formed, but the errors to which such a determination is liable are too great to admit of sufficient accuracy; moreover, the impurities usually present give rise to corrections which detract from the simplicity of the method and complicate the result. The solution in caustic soda is preferable to this, the iron and copper remaining as a black residue, but the silicon, in part, at least, reacts with caustic soda, so that even in this case the hydrogen evolved cannot be taken as a measure of the aluminium present. In these circumstances it is customary to determine the impurities and arrive at the amount of aluminium by difference.

The impurities generally present in quantity are iron, silicon, and sometimes copper. Minute amounts of sodium, carbon, and nitrogen are also contained in the metal, but these should not greatly affect the result unless when dealing with specially impure metal. Commercially, therefore, iron and silicon alone are usually estimated. For the *iron*, the metal is dissolved in caustic soda, and this solution on acidulation with sulphuric acid yields sulphates of alumina and iron which redissolve in the acid, whilst the presence of copper is indicated by the appearance of a black residue. The amount of iron is finally determined by titration with potassium permanganate. For the *silicon*, the metal is digested with hydrochloric acid in presence of nitric acid (to avoid volatilisation of any silicon as chloride) forming a turbid solution owing to the separation of the silica. This is then boiled down with sulphuric acid until white fumes of this acid appear. The aluminium and iron salts are thus converted into sulphate, and redissolve on digestion with water, the silica being left in suspension.

After filtration and washing, the silica is strongly heated and weighed. *Copper* may be estimated as sulphide, or the black residue above mentioned may be dissolved and the copper estimated colorimetrically. If the amount of *sodium* is to be found, the metal must be dissolved in nitric acid, boiling acid of 60 p.c. strength being used. The solution is boiled down to dryness and exposed to a dull red heat so long as red fumes appear. The residue is extracted with water, care being taken finally to remove all alumina or other metals precipitated by the ordinary reagents. Ultimately the sodium salt remaining may be converted into sulphate and weighed as such. For fuller details a paper by Seligmann and Willott may be consulted (Journ. Inst. Metals, vol. iii. p. 138).

For general analytical details, the following sources of information may be consulted: Moissan (Compt. rend. 121, 851); Gouthière (Analyst, 21, 270); Jean (Rev. Chim. Indust. 8, 5); Withey (Journ. Inst. Metals, xv. 207). The better qualities of commercial metal should not contain more than 0·5 p.c. of iron and silicon together, nor more than 0·05 p.c. of sodium. It is, however, very doubtful whether sodium is present in the metallic form.

Alloys.—The addition of quite small quantities of aluminium to certain metals (*e.g.* copper and iron) has a profound effect in modifying the properties of these metals. Likewise the addition of small quantities of certain metals (*e.g.* Fe, Mn, Si, &c.) to aluminium effects considerable change in the properties of this metal. The addition of 0·1 p.c. of aluminium to copper brings down its conductivity 23 p.c.; the addition of zinc, copper, nickel, iron, or manganese to aluminium is accompanied by considerable augmentation of the tensile strength. The alloys of aluminium may be classified into bronzes, casting alloys, and rolling alloys, according to their properties. The *true bronzes* consist of copper and aluminium alone, but there are many binary (and ternary) alloys which contain metals other than copper and yet sufficiently resemble bronze to be classed along with it. The bronzes proper chiefly employed are gold bronze, containing 3 to 5 p.c. of aluminium; steel bronze, with 8·5 p.c. Al and some silicon; acid bronze, with 10 p.c. Al. The copper bronzes, with 90, 92·5, 95 and 97·5 p.c. of copper, are all good alloys, showing homogeneity and freedom from crystallisation. They are of great hardness and high tensile strength.

Such alloys possess very valuable properties, the ultimate stress of the 90 p.c. alloy being 38 tons to the sq. inch, and they have the further valuable property of being practically noncorrodible by sea-water; this property is also shown very markedly by bronzes containing manganese. These bronzes in hardness and tensile strength compare favourably with the best steel, and are similarly affected by tempering. The alloys high in aluminium and low in copper are also of great commercial value; a bronze with 4 p.c. copper by rolling and drawing showed a steady increase in tensile strength from 9·6 tons to 20 tons to the sq. inch.

A small percentage of manganese increases the tensile strength of aluminium without affecting its ductility, but large proportions of manganese increase the strength and lessen the ductility.

For further information reference may be made to the eighth report of the Alloys Research Committee of the Inst. Mech. Engineers (Carpenter and Edwards), and to the ninth report (Rosenhain and Lantsberry), and tenth report (Rosenhain and Archbutt), also to The Metal Industry, 1909, 186 (Hiorns); Schirmeister, J. Soc. Chem. Ind. 1916, 894; also J. du Four Electrique, 1914, 700. The composition of other bronzes used industrially is given in the following table:—

	Al	Cu	Zn	Sn	Ni	Cr	Mg
Hercules bronze .	2	65	33	—	—	—	—
Chromium bronze .	95·75	4	—	—	—	0·25	—
Duralum .	79	10*	—	—	—	—	11
Partinium .	88·7	6·8	4·5	—	—	—	—
Grossmann's alloy . .	87	8	—	5	—	—	—
Argentan .	7	70	—	—	23	—	—
Hercules metal (No. 3)	1·5	61	37·5	—	—	—	—

* Phosphorised copper.

The aluminium alloy containing 20–50 p.c. of copper or nickel is brittle, as is the alloy with 35 p.c. of manganese.

Rolling Alloys.—Aluminium alloys, containing 3 to 4 p.c. of copper or 1·5 to 5 p.c. of nickel, roll well, as do many other alloys containing copper and zinc, the former in small quantity, amounting to from 1 to 3 p.c., and the latter 10 to 12 p.c., or even more.

Magnalium consists of aluminium alloyed with 2 to 10 p.c. of magnesium. This alloy is lighter than aluminium, and in strength and workability equal to good brass. *Duralumin* is a very important alloy containing 3·5 to 5·5 p.c. Cu, 0·5 to 0·8 p.c. of Mn, and 0·5 p.c. Mg. An account of this alloy is to be found in the discussion on Tenth Report of the Alloys Research Committee; also Met. Industry, 1910, 393 and 413; and Met. and Chem. Eng. 1910, 547.

Casting alloys are also largely used, consisting most frequently of aluminium, zinc, and copper in varying proportions (Richards, Eng. and Mining Journ. 1908, 715). Magnalium admits of introduction with advantage of small quantities of copper and nickel without unduly raising its specific gravity. The tensile strength and hardness of these alloys are considerable, and they are said to be resistant to atmospheric corrosion (Barnett, J. Soc. Chem. Ind. 1905, 832). Taps, tuyères, and the like are made from an alloy composed of aluminium, to which 12 p.c. Cd, 6 p.c. Cu, 5 p.c. Sn, 2 p.c. Ni are added. Pedestals are also made of aluminium, containing 14 p.c. Sb, 1·2 p.c. Cu, 12 p.c. Sn, 37 p.c. Zn, and 0·8 p.c. Pb; copper, with 10 p.c. Al and 1 p.c. Mn, is an excellent hard alloy for bearing metal or tool steel; horse-shoes are made from a ternary alloy of aluminium containing either 12 p.c. Cu and 10 p.c. Zn, or 5 p.c. Cu and 10 p.c. Sn. Many alloys of aluminium resist acid corrosion to a remarkable degree, and even if cooking utensils are made from an aluminium copper alloy, Carpenter and Edwards have shown that when corrosion does occur the copper is not dissolved out, and hence there is no danger of poisoning in using such vessels, since the salts of aluminium have no toxic action.

An improvement is effected by the addition of aluminium to *brass*. An alloy containing aluminium 2·5 p.c., copper 70 p.c., and zinc 27·5 p.c., is said to show nearly double the tenacity and considerably more than double the elongation of ordinary cast brass.

The presence of *tin* in aluminium renders it more fusible and brittle. According to Bourbouze (Compt. rend. 102, 1317), an alloy of aluminium 100 and tin 10 is strong, easily worked, may be soldered as easily as brass, is whiter and less affected by reagents than aluminium, and is very suitable for parts of optical instruments. Its sp.gr. is 2·85. The addition of aluminium to tin increases its hardness and tenacity. The alloys containing 5, 7, and 9 p.c. of aluminium are all easily worked and soldered. A larger proportion of aluminium is liable to separate out on melting.

Aluminium combines in all proportions with *cadmium*, forming malleable fusible alloys.

Small quantities of *silver* increase the hardness and elasticity and lower the melting-point without rendering aluminium brittle. The alloy containing 4 p.c. silver has been used for the beams of delicate chemical balances. When the addition exceeds 5 or 6 p.c. the metal becomes brittle; the 50 p.c. alloy is as hard as bronze, but very brittle. '*Tiers argent*' consists of 1 part silver and 2 parts aluminium; it is of considerable hardness, and is used for table-spoons, &c. The addition of 5 p.c. of aluminium to silver renders it as hard as standard silver and very permanent.

The presence of aluminium in *gold* considerably alters its properties. The addition of 0·186 p.c. of aluminium to *pure* gold increases the tensile strength from 7 tons to 8·87 tons per square inch, a greater increase than is produced by the same amount of any other metal (Roberts-Austen, Roy. Soc. Rep. April, 1888; Chem. News, 1888, v. 57, p. 133). With 1 p.c. aluminium the gold has the colour of 'green gold,' is hard but easy to work; with 5 p.c. aluminium it is white and extremely brittle, and with 10 p.c. white, brittle, and crystalline. Aluminium containing 10 p.c. of gold is white and hard.

The malleability of aluminium is not much impaired by the addition of gold, silver, or tin, but the presence of excessive amounts of iron, and especially of silicon, is very injurious.

The alloys of aluminium and *silicon* appear to form a simple eutectiferous series, the silicon branch of the curve exhibiting no singularity whatever (Fraenkel, Zeitsch. anorg. Chem. 1908, 58, 154). These results have been confirmed by Roberts (Chem. Soc. Trans. 1914, 105, 1383). That no compound is formed is supported by the fact that no silicon hydride can be detected when the alloys are dissolved in acids; the silicon, as appears from a microscopic study of the structure of the alloys, crystallises in plates arranged in five- or six-rayed stars.

The presence of silicon renders aluminium brittle and much less permanent.

With *iron* the alloys are of especial interest. The presence of a quantity of iron is very injurious; it renders the aluminium crystalline, and raises the melting-point. The alloy containing 5 p.c. of iron is hard and brittle; with 8 p.c. the alloy crystallises in needles, and on heating separates into a more liquid alloy containing but little iron and a skeleton very rich in that metal. Michel (Annalen, 115, 102) has prepared an alloy which crystallises in six-sided prisms, corresponding to Al_2Fe. A beautifully crystalline substance having the composition Al_4Fe is often found in the neighbourhood of the cathode of a reduction furnace.

The valuable properties imparted to iron and steel by the presence of a small quantity of aluminium have long been known; Faraday (Quarterly Journ. Roy. Inst. 1819, 290) found from 0·013 to 0·069 p.c. of aluminium in certain samples of Bombay wootz, though it has been shown by Henry and others that this metal is not always present. About the same time S. B. Rogers showed the presence of aluminium in some of the best quality of pig-iron made in South Wales, and found that a steel to which 0·8 p.c. of aluminium had been added in the form of an alloy with iron, was rendered harder and stronger and resembled the best wootz (Rogers, Metallurgy, 1858, 14). A superior steel was prepared by Sir Charles Knowles, which was stated to owe its value to the use of *kaolin* and consequent introduction of aluminium into the metal in its preparation (Mining Journal, 1859, 118).

Messrs. Cowles Bros. have exhibited a Siemens-Martin basic steel containing 0·2 p.c. aluminium, which welds with iron and shows no mark at the junction.

The addition of aluminium to iron or steel for the production of 'mitis castings' has been patented by P. Ostberg (Engineering, 1886, 360). Iron and steel, especially at temperatures far above the melting-point, absorb considerable quantities of gas, which impairs the value of the castings. The addition of 0·05 or 0·1 p.c. of aluminium to the fused iron or steel lowers the melting-point, prevents the absorption of gas, and considerably increases the fluidity. The metal can then be easily cast.

Nickel and aluminium combine with incandescence when heated together. The presence of under 3 p.c. of nickel lowers the melting-point and increases the hardness and elasticity.

Pure aluminium combines with mercury, although not readily, when the metals are heated together in an inert gas such as carbonic anhydride. The two metals combine rapidly in presence of alkalis. The amalgam may also be produced by electrolysis of mercuric nitrate, using a negative plate of aluminium dipping in mercury. When aluminium is rubbed with wash leather impregnated with mercury, combination occurs; the surface rapidly oxidises and becomes heated, with formation of concretions of alumina (Jehn and Hinze, Ber. 7, 1498).

Alloys of *bismuth* with aluminium are hard and brittle. With *antimony* and *lead* aluminium does not unite, although traces of lead are frequently present in commercial aluminium.

Sodium unites readily with aluminium. The last traces of sodium are difficult to remove, especially, it is said, when the metal has been reduced from cryolite. The alloys are easily attacked by moisture, and burn in the air, with oxidation both of the aluminium and sodium; that containing 2 p.c. of sodium decomposes water with ease. The necessity of avoiding the presence of sodium in the preparation of aluminium is therefore obvious.

Aluminium also unites with *manganese*; with *platinum* it unites easily, forming fusible alloys. With *boron* aluminium combines in varying proportions. The so-called 'adamantine' and 'graphitic' boron appear to be borides of aluminium (Hampe, Annalen, 1876, 75; and Deville and Wöhler, *ibid.* 1867, 268) (*v.* BORON).

Mallet (Chem. Soc. Trans. 1876, ii. 350) has prepared a nitride of aluminium in small crystals hard enough to scratch glass. It may be obtained in colourless hexagonal needles of the composition AlN by direct union of its elements at 820°. It forms ammonia when fused with potassium hydroxide, or by heating with sulphuric acid. Alcohol forms triethylamine at 230°. Fichter and Spengel (Zeitsch. anorg. Chem. 1913, 82, 192). It dissociates in nitrogen at atmospheric pressure at about 1850°. When heated in nitrogen at a pressure of 4·3 atmos. it melts at 2150°–2200° (Wolff, Zeitsch. anorg. Chem. 1914, 87, 120).

For further information, *see* J. W. Richards, Aluminium and its Alloys, London.

Aluminium oxide, *Alumina*, Al_2O_3.

Aluminium forms only one oxide, Al_2O_3, corresponding to and isomorphous with the sesquioxides of iron and chromium.

This oxide occurs native, colourless as *hyaline, corundum*; or coloured by metallic oxides, as *ruby, sapphire, oriental topaz*, &c. (*q.v.*). Very impure, dark, and usually associated with magnetite and *hæmatite*, it occurs in large boulders in many districts, and is used as a grinding and polishing material in the form of *emery* (*q.v.*). The native oxide crystallises in the rhombohedral system; in hardness it comes next to the diamond. The finely coloured specimens are used as gems. It occurs almost pure in considerable quantities in the Alleghanies in Northern Georgia.

It may be prepared by the ignition of aluminium foil in air or oxygen; the oxide so produced is fused and as hard as corundum.

Alundum is fused alumina, a product made up into electrical furnace cores, crucibles, bricks and tubes where high refractory properties are of value. It withstands 2000°, and has a linear expansion of 0·0000078, a specific heat of 0·195; at high temperatures (over 1500°) it has a low electrical resistance. It is, however, inapplicable to use in some directions owing to its porosity.

Amorphous alumina may be produced by ignition of the precipitated hydrate, pure aluminium sulphate or ammonia alum; in either case alumina alone is left.

It is white and soft, but becomes hard on strong ignition. According to H. Rose (Pogg. Ann. 74, 430) the sp.gr. of the oxide after heating over a spirit-lamp is 3·725; its density may be raised to 4, just about that of corundum by heating in a porcelain furnace, but it still remains amorphous. It is remarkable that though the density of the artificially prepared alumina is nearly 4, its bulk density may be less than one-fifth of this. With a somewhat lower density the bulk density is higher, but is still such that it occupies a larger bulk than the same weight of water.

When heated by the oxyhydrogen blow-pipe, alumina melts at 2050° and crystallises; the addition of chromium oxide or a chromate imparts a ruby colour to the crystals.

Fremy and Verneuil (Compt. rend. 1888, 566) have prepared artificial rubies by heating to redness a mixture of barium fluoride and alumina containing a trace of potassium dichromate. The heat requires careful management. Fine rubies are thus formed in a friable matrix which may be separated by agitation with water. By former methods the matrix was hard and difficult to remove (Fremy and Feil, Compt. rend. 1877, 1029, and 1887, 737). The crystals contain no barium, easily scratch the topaz, and possess the form and properties of natural rubies; their crystalline form has been determined by Descloiseaux (Compt. rend. 1888, 567). By the addition of a little cobalt oxide before the fusion, sapphires may be produced.

Alumina is soluble, when strongly heated, in boric acid; the latter may be driven off at a very high temperature, leaving crystalline alumina. By the addition of the proper oxide the corresponding spinels may be produced, coloured by cobalt oxide (blue), chromium oxide (red), iron oxide (black), (Ebelmen, Ann. Chim. Phys. 3, 22, 211 and 33, 34). Only two *hydroxides* of aluminium are known, viz.: Al_2O_3,H_2O and $Al_2O_3,3H_2O$. By Graham's method an aqueous solution of the hydroxide may be obtained.

When the hydroxide is freshly precipitated it dissolves readily in dilute acids, but on standing, or after filtration, solution is more difficult, and is best achieved by a mixture of 8 parts of sulphuric acid and 3 parts of water. When heated, the hydroxide loses its water, undergoing a contraction of about 30 p.c. in bulk as it passes into the form of the anhydrous oxide.

When boiled with water containing a drop of a 1 p.c. solution of alizarin, the hydroxide assumes a bright red colour, not removed by a weak solution of acetic acid.

This test easily distinguishes it from gelatinous silica. Aluminium hydroxide possesses a powerful affinity for many organic substances, and enters into association with a large number of colouring matters, precipitating them entirely as *lakes*. On this property depends the use of alum mordants (red liquor, &c.). They precipitate the hydroxide upon the fibre of the goods to be dyed, and this constitutes the *mordant* or fixing agent which retains the colour.

Sodium aluminate $Al_2O_3 \cdot 3Na_2O$ or $Al_2(NaO)_6$. This salt is now prepared on a large scale, both to be used as such and as an intermediate product in the preparation of the sulphate and other salts of aluminium.

Its formation depends upon the property possessed by alumina of acting as an acid in presence of a powerful base.

Its preparation from bauxite has already been described It may also be produced by passing a current of steam through a heated mixture of bauxite and common salt, and by strongly heating a mixture of bauxite, sodium sulphate, and carbon, but in the latter case its purification from the sodium sulphide simultaneously produced is difficult. It is also formed in the preparation of soda from *cryolite*. According to Thomsen's method, powdered cryolite is heated to redness with chalk, forming sodium aluminate and calcium fluoride :—

$$Al_2F_6 \cdot 6NaF+6CaCO_3=Al_2(NaO)_6+6CaF_2+6CO_2$$

The mass produced is lixiviated with water and filtered. From this aluminate the hydroxide is precipitated by carbon dioxide with formation of sodium carbonate :—

$$Al_2(NaO)_6+3CO_2+3H_2O=Al_2(OH)_6+3Na_2CO_3.$$

The hydroxide is usually made into aluminium sulphate by solution in sulphuric acid, or it is converted into alum.

An entirely different process has been introduced by Sauerwein. The finely powdered cryolite is boiled with milk of lime forming aluminate as before :—

$$Al_2F_6 \cdot 6NaF+6CaO=Al_2(NaO)_6+6CaF_2.$$

For the conversion of the aluminate into oxide Sauerwein applies a peculiar property possessed by that salt, which shows the readiness with which alumina loses its acid properties and again becomes basic. Sodium aluminate, when mixed in equivalent proportions with any haloid salt of aluminium, is decomposed ; the sodium combines with the halogen, while the whole of the aluminium is precipitated as hydroxide. On the large scale the haloid salt used is cryolite. The finely powdered mineral is stirred into the clear liquid from the previous operation, and the alumina precipitated as hydroxide :—

$$Al_2(NaO)_6+Al_2F_6 \cdot 6NaF+6H_2O$$
$$=2Al_2(OH)_6+12NaF.$$

Sodium aluminate is a white, infusible, amorphous solid, easily soluble in both cold and hot water. The concentrated solution rapidly deposits alumina, leaving in solution a basic aluminate, which on evaporation is obtained as a fusible and hygroscopic mass. The addition of any acid at once decomposes it with precipitation of alumina. This alumina is pure and free from alkali, which is never the case when alkaline precipitants have been used. It may be employed as a mordant in dyeing and calico-printing, in an acid and not, as in the case of alum, an alkaline bath. For the production of *lakes* the colouring matter is mixed with the aluminate solution and precipitated by the addition of sulphuric acid. According to Morin these lakes are richer than those obtained from alum and are produced at about one half the cost.

Potassium aluminate $Al_2O_3 \cdot 3K_2O$ or $Al_2(KO)_6$ is obtained in hard glistening crystals when alumina is fused with potash, the mass boiled in water and the solution evaporated *in vacuô*.

Aluminium chloride Al_2Cl_6. This compound was first prepared in 1824 by Oersted, by passing chlorine over a mixture of alumina and charcoal heated to redness. The method and apparatus resemble that used in the preparation of the double chloride, omitting the sodium chloride.

According to P. Curie (Chem. News, 28, 307) it may be easily prepared as follows :—Anhydrous alumina, or, less satisfactorily, clay, is strongly heated in a tube and subjected to a current of hydrochloric acid impregnated with carbon disulphide by bubbling through that liquid. Aluminium sulphide appears to be formed and at once decomposed by the hydrochloric acid, yielding aluminium chloride and sulphuretted hydrogen. The condensed chloride may be freed from sulphur by distillation with iron filings.

A solution of the chloride may be obtained by dissolving the hydroxide in hydrochloric acid.

The pure anhydrous chloride is a white, waxy, crystalline solid ; in presence of a trace of iron it becomes yellowish. On heating, it volatilises without fusion. If large pieces be quickly heated they fuse and boil at 180° to 185° (Liebig). It is very hygroscopic, and evolves hydrochloric acid on exposure to the air ; is easily soluble in water ; soluble in alcohol and ether. When deposited from a solution in hydrochloric acid, it forms crystals of the formula $Al_2Cl_6,12H_2O$.

It absorbs ammonia and combines with many metallic chlorides, forming double chlorides, the most important being that with sodium. Aluminium chloride has been recommended by Filsinger (Chem. Zentr. 10, 1270) for the preservation of wood, and by Saget (Chem. News. 45, 113) and others (J. Soc. Chem. Ind. 1882, 185 and 230) for the production of a discharge on indigo blue. An impure chloride containing calcium and sodium salts is stated to be largely used as a disinfectant under the name 'Chloralum.'

Double chloride of aluminium and sodium $Al_2Cl_6,2NaCl$. This compound may be produced by fusing together the proper proportions of aluminium and sodium chlorides. It is a colourless crystalline solid, melting at 185° (Deville) and volatilising at a red heat. It is slightly hygroscopic, but much less so than aluminium chloride ; it is also more stable and more satisfactory in use than that substance, and gives up nearly the whole of its aluminium when reduced by sodium.

Aluminium bromide Al_2Br_6 is most readily prepared by the action of bromine on metallic aluminium. The action is violent, and the metal should only be added gradually. A lump of aluminium weighing twenty grams becomes strongly heated and even fused on being placed in cold bromine (Mallet, Phil. Trans. 171, 1018).

It may also be prepared by the action of bromine on a strongly heated mixture of alumina and carbon, and, in solution, by dissolving the hydroxide in hydrobromic acid. It crystallises in colourless shining laminæ, which melt at 93° (Deville and Troost) and boil at 263·3° (at 747 mm.) (Mallet).

Like the chloride, it forms a double bromide, $Al_2Br_6,2KBr$.

Aluminium iodide Al_2I_6 may be prepared by heating aluminium with iodine in a closed tube. It melts at about 185° (Weber) and boils at 350° (Deville and Troost); its vapour is combustible. It dissolves in water, alcohol, and carbon disulphide.

Aluminium fluoride Al_2F_6, may be prepared by the action of gaseous silicon fluoride, or of hydrofluoric acid upon aluminium. It forms transparent rhombohedra, volatile at a red heat, insoluble in water and unacted upon by acids. In solution in hydrofluoric acid, it appears to form the compound $Al_2F_6{\cdot}6HF$, the acid corresponding to the double fluoride of aluminium and sodium.

Cryolite $Al_2F_6{\cdot}6NaF$. This important compound may be prepared artificially, and attempts have been made to produce it as a substitute for the natural cryolite, it being claimed that the artificial cryolite possesses the advantage of being lighter and melting at a lower temperature (J. Soc. Chem. Ind. 1890, 945). In recent years, however, artificial cryolite has been put on the market which presents no essential difference either in composition or properties from natural cryolite. Natural cryolite occurs in quantity only in one locality, in a large vein in the gneiss at Ivigtut in Greenland. Greenland cryolite has the following composition: Al 13·2, Na 32·7, F 54·2, and small quantities of silica. The melting-point of mixtures of cryolite and alumina is said to be—

Cryolite	1000°
With 3 p.c. Al_2O_3 . .	974°
,, 6 p.c. ,, . .	960°
,, 10 p.c. ,, . .	980°
,, 15 p.c. ,, . .	994°
,, 20 p.c. ,, . .	1015°

(Chem. Soc. Abst. 1907, 469; also Chem. Soc. Abst. 1913, 508).

It is a semi-transparent, white, crystalline, brittle solid, which melts at the edges in a candle flame. Its hardness is 2·5 to 3; its sp.gr. 2·95, but 2·21 in the fused state. When impure it is frequently yellowish-red or even black (*v.* CRYOLITE).

Cryolite is used as a flux in the manufacture of aluminium; formerly for making salts of sodium and aluminium; and for the manufacture of an opaque, porcelain-like glass. It is also used for enamelling pans and as a glaze for pots as replacing lead glaze. (*See* further, Benzon, Hoffmann's Ber. Entw. Chem. Ind. [1] 660).)

Aluminium sulphide Al_2S_3, may be prepared by strongly heating a mixture of aluminium and sulphur, or by heating alumina to bright redness in the vapour of carbon disulphide. It forms a yellow, glassy mass, which fuses at 1100°, and burns in air with production of alumina and sulphur dioxide. It may be purified by sublimation in a vacuum at 1100°–1250°, and then forms white needles resembling asbestos of sp.gr. 2·02 13°/13° (Biltz and Caspari, Zeitsch. anorg. Chem. 1911, 71, 182). It is readily hydrolysed by water. Houdard (Compt. rend. 1907, 801) found that by heating aluminium turnings and sulphides of manganese iron and chromium in a carbon boat, sulphides related to the spinels are formed, of which he prepared

$$MnS,Al_2S_3,\ FeS,Al_2S_3,\ CrS,Al_2S_3$$

Aluminium carbide Al_4C_3 may be obtained by the action of carbon or the oxides of carbon on alumina at very high temperatures, and often occurs in small quantity contaminated with nitride in the neighbourhood of the cathode of aluminium reduction furnaces in the form of a yellow powder; it is formed when a mixture of alumina and carbon is submitted to a current of 300 amperes at 65 volts. It possesses the remarkable property of being stable at high temperatures, and yet undergoing decomposition at a dull red heat. It reacts, though somewhat slowly, with water or dilute acids with the production of methane. The formation of carbide and ultimately its decomposition has been proposed as a means of preparing alumina from clay or other crude materials. Pring (Chem. Soc. Trans. 1905, 1530) found that up to 1400° C. the carbide acts as a reducing agent on metallic oxides,

$$Al_4C_3+12MO=2Al_2O_3+3CO_2+12M$$

but at higher temperatures alloys of aluminium and the metal are produced, only carbon being oxidised,

$$Al_4C_3+3CuO=Al_4Cu_3+3CO$$

owing to the fact that alumina can be reduced by carbon at very high temperatures; at lower temperatures the aluminium is oxidised by carbonic oxide as observed by Moissan,

$$6Al+3CO=Al_4C_3+Al_2O_3$$

the reaction being reversed at the higher temperatures.

Aluminium sulphate $Al_2O_3(SO_3)_3,18H_2O$ or $Al_2(SO_4)_3,18H_2O$. Aluminium sulphate occurs naturally in considerable quantities. As the hydrated salt of the above composition, it forms the chief constituent of the mineral *alunogen, halotrichite, feather alum,* or *hair salt,* which is found in volcanic districts, at Bilin in Bohemia, Copiapo in Chile, &c. It also occurs in pyritic shale. A sample of feather alum from Friesdorf, Bonn, was found by Rose to contain Al_2O_3 14·9 p.c., SO_3 37·4 p.c., FeO 2·5 p.c., H_2O 45·2 p.c., with traces of K, Na, Mg, and SiO_2.

Aluminite or websterite, a hydrated basic salt of the composition $Al_2O_3SO_3,9H_2O$, has been found at Auteuil, Halle, Muhlhausen, &c.

In combination with potassium sulphate, the basic salt occurs also in *alunite, alumstone,* or *alum rock* $K_2SO_4,3Al_2O_3(SO_3),6H_2O$, a mineral which is found in large quantities at La Tolfa near Civita Vecchia, in Hungary, at Puy-de-Sancy and Madriat in Auvergne, New South Wales, Kyoquot Sound (Canada), and in many other localities. It usually occurs in fibrous compact masses in trachyte, of colour varying from white to red or brown, being produced by the action of sulphurous gases upon trachytic rocks rich in felspar.

The alunite from La Tolfa contains from

35 p.c. to 17·5 p.c. alumina; the average composition of the mineral is Al_2O_3 27·6 p.c., SO_3 29·74 p.c., K_2O 7·55 p.c., Fe_2O_3 1·2[illegible] p.c., SiO_2 22·7 p.c., H_2O 11·2 p.c.

Aluminium sulphate may be produced by dissolving either the hydrated oxide or the silicate in sulphuric acid. Of the raw materials available for its manufacture, the two which are of the greatest importance at the present time are china clay (kaolin) and bauxite. China clay is a very pure variety of clay, resulting from the natural decomposition of felspar, and approximating in composition to the formula $Al_2O_3,2SiO_2,2H_2O$. It is of comparatively rare occurrence, being found chiefly in Devon and Cornwall in England; at St. Yrieix near Limoges, and in the departments of Allier, Puy-de-Dome, and Brittany, in France; at Seilitz in Saxony; and at Nassau in Bavaria.

Bauxite is an impure aluminium hydroxide $Al_2O_3,2H_2O$, containing widely varying quantities of silica and ferric oxide. It is found in Ireland, in the south of France, and in Austria, Calabria, Senegal, &c. (*v.* BAUXITE).

The composition of typical commercial grades of the two minerals is given in the following table, the analyses having been made on material dried at 100°:—

Source	China clay		Bauxite	
	St.Stephen's	St. Austell	Antrim	France
Al_2O_3	40·15	41·10	41·08	64·18
Fe_2O_3	0·35	0·20	3·21	3·47
SiO_2	45·00	46·20	33·17	18·96
TiO_2	—	—		
K_2O+Na_2O	0·80	trace	—	—
H_2O (comb.)	13·70	12·50	22·54	13·39
Total	100·00	100·00	100·00	100·00

Production of aluminium sulphate from china clay.—At the present time the manufacture of aluminium sulphate from china clay is carried out on an extensive scale by a process based upon the original patent of Pochin (Pat. 1855, 14656). The clay, containing about 40 p.c. alumina, is obtained from Cornwall, and is selected as free as possible from grit and oxide of iron. It is reduced by milling and sifting to the finest possible state of division, and after a preliminary drying by exposure to a warm atmosphere, is calcined at a dull-red heat in a reverberatory furnace. The furnace is provided with three working doors, the material being introduced by the door which is most remote from the firegrate, and gradually raked forward until it reaches the hottest part of the hearth. During the calcination the clay suffers a loss in weight amounting to from 20 to 25 p.c., due to the expulsion of the whole of the moisture present (10 to 15 p.c.) and of the greater part of the water of hydration.

The calcined clay, which still contains about 3 p.c. of water, is transferred by means of iron tubs to a lead-lined wooden vat containing the requisite quantity of sulphuric acid, heated to a temperature of 85°, and having a strength at this temperature of 96° Tw. A vigorous reaction immediately takes place, and after the lapse of 15 minutes, during which period the contents of the vat are kept well agitated, the product is run into lead-lined wooden waggons (with removable sides), in which the reaction continues for a considerable time and the pasty mass gradually solidifies. Finally the solid block is brought under a heavy mechanical knife, and by a combined cutting and crushing action is reduced to the state of a coarse powder.

The product, which is brought on the market under the name of 'alum cake,' contains the whole of the silica, iron, and other impurities present in the clay, its average composition being: Al_2O_3 (soluble) 12·25 to 13·0 p.c., Fe_2O_3 0·12 to 0·22 p.c.; combined SO_3 29·5 to 31·8 p.c., free SO_3 0·4 to 1·0 p.c.; insoluble matter 20·0 to 26·5 p c.

About 60 p.c. of the alumina present in the china clay is converted into sulphate.

The commercial 'white sulphate of alumina' is prepared from alum cake in the following manner: The coarsely crushed alum cake is lixiviated with water (or with weak liquors from previous extractions) in lead-lined vats heated by live steam; after settling, the clear solution is decanted by means of a hinged pipe, and run into lead-lined evaporators, heated by steam coils, where it is concentrated to a strength of 112°Tw. at the boiling-point (about 115°). The syrupy liquid is then run into a series of shallow tiled troughs, where it solidifies on cooling. Before solidification occurs, a number of leaden partitions are inserted in the troughs, and the product is thus obtained in the form of rectangular blocks of uniform size (24″×9″×6″). 'White sulphate of alumina,' prepared by the above process, contains on an average about 14 p.c. of alumina and 0·25 p.c. of ferric oxide, and is practically free from insoluble matter. Another grade of the material is prepared containing 17·5 p.c. alumina.

Preparation of aluminium sulphate from bauxite.—The substitution of bauxite for china clay in the manufacture of aluminium sulphate was proposed by Lechatelier in 1858, and its treatment forms the subject-matter of numerous patents. Bauxite has the advantage over china clay that it is more readily soluble in acid, and needs no preliminary calcination, the chief drawback to its use being the presence of a comparatively large amount of iron.

The treatment of bauxite for the preparation of 'alumino-ferric cake,' as patented by Messrs. P. and F. M. Spence (1875), is as follows:—The mineral is digested with dilute sulphuric acid with the aid of steam until the acid is neutralised; the insoluble matter allowed to subside, and the solution evaporated to 116°Tw. and run into shallow-partitioned lead coolers. It there solidifies, and is removed in blocks 18 or 20 inches square, each weighing about 1 cwt. It is yellowish-green in colour, contains much alumina, and a small proportion of iron and free acid. It is used in the preparation of all but the finest papers, in the precipitation of sewage and refuse liquids, and in the clarification and decolourisation of water supplies. The following analysis shows its general composition: Al_2O_3 14·26 p.c. (corresponding to $Al_2O_3 3SO_3$ 47·61 p.c.), Fe_2O_3 0·28 p.c., FeO 0·32 p.c., SO_3 (combined) 35·36 p.c., SO_3 (free) 0·45 p.c. Insoluble 0·06 p.c.

The commercial sulphate of alumina which is sold under the names of 'concentrated alum' and 'alferite,' resembles alumino-ferric in composition, and is prepared by a similar process. The following details concerning its manufacture will serve to exemplify modern practice.

As raw material, it is usual to employ a mixture of Irish and French bauxites, reduced by means of disintegrators to the state of a coarse powder. The powdered mineral is conveyed by means of an elevator to a lead-lined vat containing sulphuric acid, heated to its boiling-point (about 125°), and having a strength, at this temperature, of 70°Tw. The mixture of acid and bauxite is boiled vigorously for 6 hours, after which it is diluted with weak liquors to 70°Tw. (measured at the boiling-point) and allowed to settle. The clear liquor is decanted and evaporated in lead-lined vessels until its density reaches 112°Tw. (boiling). It is then run into partitioned coolers where it solidifies, forming blocks or slabs, containing on an average 13·8 p.c. alumina, 0·7 p.c. ferric oxide, and 0·1 p.c. insoluble matter.

If French bauxite be used alone in the above process, great difficulty is experienced in the clarification of the liquor; with a mixture of Irish and French bauxites, however, rapid settling occurs, and a perfectly clear liquor is readily obtained. It is of importance also, in this connection, that the liquor should retain a small amount of free acid, as the fully neutralised solution settles very slowly.

Sulphate of alumina prepared by any of the above processes always contains appreciable quantities of iron, and the removal of this impurity is a problem of considerable importance, and one which has received the attention of many chemists. Numerous processes have been devised for the purpose, but it is doubtful if any of these is satisfactory in works' practice.

Newlands (Eng. Pat. 1880, 5287) evaporates a crude solution of the sulphate to a density of 67°Tw. (at 200°F.) and cools for twenty-four hours in leaden tanks.

About 60 p.c. of the sulphate thus crystallises out. The liquid is drained off, and the residue pumped or forced into lead-lined filter presses, the plates of which are covered with thick felt, and separated by metal rings. Here it is subjected to a pressure of about 200 lbs. to the square inch. The hard cake so produced contains about 67 p.c. of the total aluminium sulphate, and 0·05 to 0·1 p.c. of iron. The mother liquor, evaporated and similarly treated, yields a second and third crop of crystals containing increasing quantities of iron.

Chadwick and Kynaston have patented a method for the removal of iron from bauxite before converting the latter into aluminium sulphate. The powdered mineral is mixed to a thick cream with water, and treated with 5 to 10 p.c. of oxalic acid and sufficient hydrochloric acid to prevent the formation of insoluble oxalates. After seven to ten days the mass is washed, and a large proportion of the iron (together with some of the alumina) is thus removed as oxalate.

Condy, in 1877, proposed the reduction of the iron by reducing agents, or its conversion into sulphide by sulphuretted hydrogen, and the removal of the metal or sulphide by dilute acid. The proportion of iron may thus be reduced to one-third.

Weismann suggested the precipitation of the iron from aluminium sulphate liquors by means of potassium ferrocyanide. The method is by no means satisfactory, as the precipitate contains much alumina and subsides very slowly.

Kynaston precipitates the bulk of the iron as ferric arsenite, removing the last portions with calcium ferrocyanide, followed by the addition of copper or zinc sulphate.

According to Fahlberg and Semper (Eng. Pat. 1881, 5579), both ferrous and ferric salts may be precipitated from aluminium sulphate by agitation in the cold for about thirty minutes with lead peroxide, ferrous salts being first oxidised and then precipitated. No lead passes into solution unless chlorides be present. The composition of the precipitate is not known, but the peroxide may be regenerated by digestion in cold nitric acid. P. and F. M. Spence (Eng. Pat. 1882, 3835) use manganese dioxide for the same purpose. In presence of reducing agents such as ferrous salts, &c., manganese passes into solution, and requires to be reprecipitated by addition of chlorine or a hypochlorite.

The use of metantimonic acid and metastannic acid (Hood and Salamon) has also been proposed for the precipitation of iron. The iron is first oxidised by the addition of bleaching powder, and the liquid is neutralised with chalk and agitated with the precipitant. Both substances may be regenerated by digesting the precipitate with sulphuric acid.

According to H. Spence, W. B. Llewellyn, and P. Spence and Sons (Eng. Pats. 23036, 1904; 3805, 1912; 9148, 1914), the crude liquor, which must be basic and have all the iron in the ferric state, is treated with potassium sulphate and agitated for several hours at from 60° to 80° until most of the iron is precipitated as insoluble basic ferric sulphate. J. Boulton (Eng. Pat. 20227, 1914) proposes to neutralise the free acid in and remove iron and other impurities from crude aluminium sulphate by immersing in the liquor a framework of magnetised steel wire with cross wires of copper holding zinc rods in suspension. The process is carried out for six hours at 38°.

(For further information regarding these processes, *see* Beveridge, J. Soc. Chem. Ind. 1886, 16–22; B. E. R. Newlands, *ibid.* 1882, 124; Kynaston, Chem. News, 40, 191 and 202.)

Most of the above-mentioned processes for the purification of aluminium sulphate from iron possess little or no commercial significance at the present time. 'Pure aluminium sulphate' is prepared directly from *pure* alumina, which is obtained from French red bauxite by the 'alkali fusion' process. The bauxite, after a preliminary roasting, is reduced to a fine powder, and mixed with soda ash in such proportions that for every molecule of Al_2O_3 present there are 1 to 1·5 molecules of Na_2O. The mixture is strongly heated in a reverberatory furnace, with frequent stirring, for a period of five hours. Carbon dioxide is evolved and the alumina and ferric oxide are converted into sodium aluminate and sodium ferrite respectively. The mass is lixiviated by successive extractions, first with weak liquor from previous batches, and finally with pure water. The sodium aluminate dissolves as such, whilst the sodium ferrite is decomposed, forming insoluble ferric oxide which remains in the exhausted residue, and caustic soda which passes into solution. The clear liquor is run into a boiler and saturated with carbon dioxide produced by the combustion of coke or by the decomposition of limestone. During the passage of the gas the contents of the boiler are heated to 70° C. and kept thoroughly stirred by means of an agitator. When the precipitation of the alumina is complete, the liquid is allowed to settle and the clear liquor decanted and concentrated for the recovery of the dissolved sodium carbonate, whilst the alumina is drained in a hydro-extractor.

A cheaper process for obtaining the alumina from the sodium aluminate has been devised by Bayer, as already described.

The alumina prepared by either of the above processes yields by treatment with sulphuric acid, a very pure quality of aluminium sulphate. Two grades of the latter are commonly prepared for the English market—the one, sold in the form of slabs or blocks, contains 14·0 p.c. of alumina and 0·0025 p.c. of ferric oxide, the other, sold in powder, contains 17·0–18·0 p.c. of alumina and 0·0040 p.c. of ferric oxide.

Aluminium sulphate crystallises with difficulty in thin, six-sided nacreous plates, containing 18 molecules of water and having a density of 1·6913 at 17° C. (Dewar). The following table of solubilities is given by Poggiale (Ann. Chim. Phys. [3] 8, 467) for the crystalline and anhydrous salts :—

Temp. °C.	Solubility in 100 parts of water	
	$Al_2(SO_4)_3$	$Al_2(SO_4)_3,18H_2O$
0	31·3	86·8
10	33·5	95·8
20	36·1	107·3
30	40·4	127·6
40	45·7	167·6
50	52·1	201·4
60	59·1	262·6
70	66·2	348·2
80	73·1	467·3
90	80·8	678·8
100	89·1	1132·0

The addition of alcohol, in which aluminium sulphate is almost insoluble, to aqueous solutions of aluminium sulphate, facilitates the crystallisation of the salt (Persoz).

When heated, aluminium sulphate melts in its water of crystallisation, swells up, and gradually forms a white porous mass of the anhydrous sulphate, which only dissolves slowly in water. At a red heat oxides of sulphur are expelled and a residue of pure alumina remains.

Aluminium sulphate combines readily with the sulphates of the alkali metals, forming crystalline double sulphates, known as alums, which are, as a rule, considerably less soluble than aluminium sulphate itself. According to Reuss (Ber. 17, 2888), the addition of 1 p.c. of potassium sulphate to a solution containing 7 p.c. or upwards of aluminium sulphate, at once produces a crystalline precipitate of alum.

The general industrial uses of aluminium sulphate are the same as those of ordinary alum. It is largely used in paper-making, water purification, and in the preparation of red liquor as a mordant. The coarser preparations are employed for the precipitation of sewage.

Karl Reuss (Ber. 17, 2888) gives the density of solutions of pure anhydrous aluminium sulphate as follows :—

Percentage	Density at 15°C.	Percentage	Density at 15°C.
1	1·017	14	1·1467
2	1·027	15	1·1574
3	1·037	16	1·1668
4	1·047	17	1·1770
5	1·0569	18	1·1876
6	1·0670	19	1·1971
7	1·0768	20	1·2074
8	1·0870	21	1·2168
9	1·0968	22	1·2274
10	1·1071	23	1·2375
11	1.1171	24	1·2473
12	1·1270	25	1·2572
13	1·1369		

Percentage	Density at 25°C.	Density at 35°C.	Density at 45°C.
5	1·0503	1·0450	1·0356
10	1·1022	1·0960	1·0850
15	1·1522	1·1460	1·1346
20	1·2004	1·1920	1·1801
25	1·2483	1·2407	1·2295

For further particulars regarding the manufacture of aluminium sulphate, *see* The Mineral Industry, iii. 25; and Manufacture of Alum and other Salts of Alumina, by L. Geschwind, Scott, Greenwood and Co., London.

The production of aluminium sulphate, alum cake, alums and other aluminium compounds is carried out in large quantities in the United States. The total output of these products in 1912 approached 160,000 tons, and rose steadily to 296,000 tons in 1917.

For the detection of free acid in aluminium sulphate, a dilute solution of Congo red is useful, becoming blue in presence of free acid, but is not affected by the pure salt.

For the estimation of the free acid, a weighed quantity (20 to 50 grams) of the sample is dissolved in 40 to 100 c.c. of water, the solution heated to boiling, and titrated with normal caustic soda until a drop of the liquid, taken out with a glass rod, fails to yield a blue colour when mixed with six drops of Congo red solution (prepared by dissolving 0·067 gram of Congo red in 100 c.c. of boiling water and diluting to a litre). The presence of iron salts interferes with this method as ferric sulphate, for example, reacts acid towards Congo red.

T. J. I. Craig (J. Soc. Chem. Ind. 1911, 184) proposes to determine the free acid in aluminium sulphate by treating the latter with excess of neutral potassium fluoride, whereby the double salt $AlF_3 \cdot 3KF$ is formed together with potassium sulphate. As these products are neutral to phenolphthaleïn, the free acid present may be directly titrated with a standard solution of potassium hydroxide.

Iron, in the ferrous condition, is estimated by titration with decinormal potassium permanganate, and total iron by means of standard titanous chloride solution (*v.* Knecht and Hibbert, New Reduction Methods in Volumetric Analysis; and Ber. 1903, 1550). If the quantity of iron present be very small, it is determined colorimetrically (*v.* ALUMS).

Several basic aluminium sulphates have been prepared. The compound $Al_2O_3,2SO_3,12H_2O$ is obtained by heating a solution of aluminium sulphate with zinc, or by dissolving in it the calculated quantity of aluminium hydrate. Spence and Sons, Limited (D. R. P. 1903, 167419), prepared a basic sulphate of similar composition by heating sulphuric acid under pressure with 15 to 30 p.c. more alumina than is required for the formation of the normal salt. The solution is then treated with sufficient chalk or lime to raise the basicity by 20 to 28 p.c. The strongly basic solution is rapidly filtered and concentrated *in vacuô* until its density reaches 1·45. On cooling with agitation, a magma of crystals is formed and is separated by suitable means from the mother-liquor which contains normal aluminium sulphate (*cf.* also Eng. Pat. 1902, 25683, and Fr. Pat. 1903, 331836).

Aluminium sulphite $Al_2O_3(SO_2)_3$.

The bisulphite has been used by Becker (Dingl. poly. J. 257, 300), Suchomel (J. Soc. Chem. Ind. 1887, 143) and others, for the purification of beet sugars. Becker prepares for this purpose a solution of sp.gr. 1·167 containing 4·37 p.c. alumina and 13·9 p.c. sulphurous oxide, by dissolving the hydrated oxide in sulphurous acid.

Aluminium phosphates. As hydrated phosphate, aluminium occurs in the *turquoise*, and enters into the composition of *wavellite*, *lazulite* and *gibbsite*. It is found in considerable quantity in mineral phosphates, as in the Redonda phosphates which have been used for the preparation of alum and for fertilisers (*v.* ALUMS; MANURES). A massive stony variety is found on the island of Anguilla in the West Indies.

Aluminium thiocyanate or **sulphocyanate** has been proposed as a substitute for aluminium acetate for alizarin, steam reds, &c.; the colours produced are said to be especially permanent (*v.* Storch and Ströbel, Dingl. poly. J. 241, 464; and Gottlieb Stein, Dingl. poly. J. 250, 36).

Lauber and Haussmann (Dingl. poly. J. 245, 306) recommend the following method of preparation: 5 kilos aluminium sulphate are dissolved in 5 litres boiling water, 250 grams of chalk are added, followed by 11·5 litres of crude calcium thiocyanate solution of 30° Tw., and the whole well stirred and allowed to settle. The clear liquid is ready for use.

Aluminium permanganate *v.* MANGANESE.

Aluminium silicates. These compounds are exceedingly numerous and important. As an anhydrous silicate, with silicate of iron, calcium, magnesium, &c., aluminium occurs in the varieties of *garnet*, crystallising in the regular system. As silicate of aluminium, calcium, and sodium it is found in *lapis-lazuli*, which was formerly used as *ultramarine*. It is now replaced by artificial ultramarine (*v.* ULTRAMARINE). As silicate of aluminium, combined with potassium, iron, and magnesium, it occurs in the *micas*. As double silicate of aluminium, potassium, sodium, magnesium, or calcium, it forms the varieties of *felspar* which occur in immense quantities in eruptive rocks. By the decomposition of felspar by the carbonic acid in the atmosphere and in rain or spring water, the alkaline compounds are removed, leaving kaolin or clay of more or less purity (*v.* CLAY), which, under pressure, becomes hardened and laminated, forming *shale*, and finally *slate* (*q.v.*). Many of the silicates of aluminium are of great importance, and of the widest application. The more important of them are specially considered under their applications (*v.* POTTERY; PORCELAIN).

Aluminium acetate. *Red liquor* (*v. Aluminium acetates*, art. ACETIC ACID).

Aluminium ethoxide is prepared by treating anhydrous alcohol with aluminium in presence of a small quantity of mercuric chloride (as a catalyst) and iodine or alkyl haloids. The mixture is distilled under reduced pressure when a distillate free from mercury is obtained (Farbwerke vorm. Meister Lucius and Brüning, D. R. P. 286596; J. Soc. Chem. Ind. 1915, 34, 1168).

Aluminium oleate is a soft white, putty-like substance, of great tenacity, insoluble in water, soluble in ether and petroleum. A mixture of oleate, palmitate, and other fatty salts is produced from whale, cotton-seed, and similar oils by saponification with soda and addition of the sodium salt so produced to a solution of alum. The gummy precipitate is known as 'oil pulp,' and is dissolved in 4 or 5 parts of mineral oil to form a 'thickener' for addition to the lubricator. A sample of oil pulp resembling thick gelatin had a sp.gr. of 0·921, and contained 6 p.c. alumina combined with 30 p.c. fatty acids, together with 15 p.c. lard oil, and 48 p.c. paraffin oil (Oil and Colourman's Journ. 4, 403).

Aluminium palmitate is a constituent of oil pulp. It may be prepared in the same manner as the oleate, from palm oil. It forms a resinous, elastic, inodorous, neutral substance, insoluble in water, but readily soluble in petroleum and turpentine. K. Lieber (Dingl. poly. J. 246, 155) recommends the use of the latter solution as a varnish. It imparts a glossy appearance to paper, leather, &c., and renders them waterproof without affecting their elasticity.

The compounds of aluminium with the higher fatty acids are used for increasing the viscosity of mineral lubricating oils, under the names 'oil pulp' and 'fluid gelatin' (L. Marquardt, Zeitsch. anal. Chem. 25, 159). G. H. B.

ALUMINIUM BRONZE *v.* ALUMINIUM.

ALUMINIUM FOIL AND POWDER, *Manufacture of.* The following is an account of the processes conducted at La Praz and Charleville-sur-Audelle by the Société française de Couleurs métalliques, for the manufacture of aluminium foil and powder. In the manufacture of aluminium foil the metal, delivered to the works in the form of ingots, 700 × 320 × 120 mm. (cast at 750°–775° C.) is first hot-rolled at 420° C. to a thickness of 3·5 m. and then cut into strips 8 cm. wide, which, after being annealed at 420° C., are cold-rolled to 0·04 mm. in six stages, further reduction in thickness being then effected by continued rolling or by hammering. In the former case the metal bands are first greased, then rolled in pairs to 0·02 mm., and subsequently in fours to the desired thickness of 0·01 mm., the foil thus being obtained in lengths of about 16 m. In the latter case, the bands are made into packets of 500 each and beaten by pneumatic hammers, each packet being placed between two thin sheets of zinc; when the thickness of the metal reaches 0·03 mm. the packets are hammered in pairs to 0·02 mm.. and then in fours to 0·01 mm. The wastage in either case is very considerable, only about 33–35 p.c. of the 0·04 mm. metal employed being obtained as good foil, one square inch of which weighs about 27 grams; the waste foil is used for the production of aluminium powder. Before being finally trimmed and cut to size, the sheets of foil are either mechanically separated, or embossed by means of suitable rolls, since—in the absence of the layers of air thus introduced between the sheets—the metal is liable to become autogenously soldered at the cut edges. In the manufacture of aluminium powder it has been found necessary to employ the foil as the raw material, the powder yielded by other forms of the metal being of too granular a character for use in the preparation of paint. The comminution of the foil is conducted in a series of stamp mills, in each of which the closed mortar-box is provided with a circle of twelve stamps actuated from a central shaft, to the lower end of which a scraper or plough is attached. Caking of the metal is prevented by the scraper, which also causes the charge to be periodically thrown against the screen inserted in the side of the mortar; the screen is provided with an exterior sliding box for collecting the metal passing through. After further classification, the finer portion of this product is mixed with about 2 p.c. of stearine (to prevent agglomeration and autogenous soldering of the particles during the fine grinding) and passed to a second series of stamp mills, the product from which is screened through silk bolting cloth (No. 200). The powder passing through the latter is then classified by a kind of winnowing process in 'elevators,' each comprising a vertical brass cylinder, 2 m. high and 0·80 m. in diameter, in which a central vertical spindle—to which horizontal wings or paddles are attached—is adapted to rotate, and provided with receptacles arranged at different levels upon a helical rail attached to the inner wall. The powder is fed through a tube into the lower part of the cylinder, the rotation of the spindle being so adjusted that the lighter particles or flakes become suspended in the air, and are deposited in the peripheral receptacles at levels corresponding to their weight and physical condition; the coarser particles remaining at the bottom of the cylinder are returned to the fine-grinding mills. The product from the 'elevators' is finally treated for ten hours in polishing machines, consisting of horizontal, rotatory cylinders of striated steel, 1·20 m. long and 0·60 m. in diameter. The polishing of the metallic powder is effected by means of brushes attached to the axis and bearing upon the interior wall of the cylinder through the whole of its length. Since conditions favourable to ignition or explosion are liable to be developed within the fine-grinding mills, elevators and polishing machines, the various units are of relatively small capacity, and are so disposed, both in relation to each other and to the other portion of the works, as to localise any damage that may arise from this cause (Guillet, Rev. Mét. 1912, 9, 147; J. Soc. Chem. Ind. 1912, 31, 339).

ALUMNOLE. $[C_{10}H_5OH(SO_3)_2]_3Al_2$ Trade name for aluminium naphthol sulphonate. Produced by the action of aluminium sulphate on the barium salt of β-naphthol disulphonic acid R. Used as an antiseptic.

ALUMS. This generic name is given to an important group of double salts of the general type $R_2SO_4,R'_2O_3(SO_3)_3,24H_2O$, where R is a monovalent metal or basic radical such as potassium, sodium, ammonium, &c., and R'_2O_3 is a sesquioxide such as that of aluminium, iron, chromium, or manganese. They are all soluble in water, and crystallise therefrom with twenty-four molecules of water, in forms belonging to the regular system, usually octahedra or cubes.

The alums which contain the sesquioxide of alumina will alone be considered here, and of these the most important are the potassium, sodium, and ammonium compounds.

'Selenic alums' have been prepared, in which sulphuric acid is replaced by selenic acid.

Potassium alum, *Potash alum*

$$K_2SO_4,Al_2O_3(SO_3)_3,24H_2O.$$

This salt is found in nature as *kalinite*, in the form of fibrous crystals or as an efflorescence on aluminous minerals, and occasionally also in octahedra, at Whitby, Campsie, &c. In the Solfatara near Naples, and the islands of Volcano and Milo, it occurs in larger quantities, being formed by the action of volcanic gases upon felspathic trachyte.

Of greater importance is the mineral *alunite* or *alumstone*, which is a double salt of potassium sulphate and basic aluminium sulphate, having the composition $K_2SO_4,Al_2(SO_4)_3,2Al_2(OH)_6$; it is found at La Tolfa near Civita Vecchia; at Montioni in the Duchy of Piombino; at Mursaly, Munkact, and Tokay in Hungary; in the islands of Milo, Argentino, and Nipoglio (Grecian Archipelago); at Puy-de-Sancy and Madriat (Auvergne); at Samsoun in Asia Minor; and in Australia. An 'alum mountain,' composed of this mineral, is reported to exist in China, and is stated to be nearly 1900 feet high and to have a circumference at its base of about ten miles (U. S. Cons. Report, 1903).

The manufacture of alum is of great antiquity. In the time of Pliny alum was in use as a mordant for the production of bright colours, and was even tested by means of the *tannin* in pomegranate juice to ascertain its purity. It was prepared in the thirteenth century at Smyrna from alum rock, and since the fifteenth century has been largely produced at La Tolfa from the same substance.

Its preparation from pyritic shale has long been known, together with the fact that the presence of an alkali was necessary to induce crystallisation, but, until proved in 1797 by Chaptal and Vauquelin, the essential presence of alkali in the crystals was not recognised.

Very pure alum is prepared in small quantities at Solfatara. The natural alum found there is digested with water in large wooden vats under cover, and maintained at about 40° by the natural heat of the soil. The solution is decanted and crystallised. A second crystallisation produces extremely pure alum.

Production of alum from alunite.—The preparation of alum from alunite is an industry which dates from very early times. Of Oriental origin, it appears to have been introduced into Europe in the thirteenth century, and during the fifteenth century several alum works were established. Amongst these may be mentioned the celebrated works at La Tolfa near Civita Vecchia, a district in which alum manufacture still ranks as an important industry.

The outline of the La Tolfa process given below is of historical interest. The mineral, broken into lumps of moderate size, is calcined at a low red heat, either in heaps or in kilns. The operation requires to be carefully performed, and is stopped as soon as the mineral begins to evolve acid fumes. The calcination occupies about six hours and results in a loss in weight amounting to about 33 p.c., chiefly due to the expulsion of water; at the same time the basic sulphate is decomposed, yielding alum and insoluble alumina. The roasted mass is transferred to brickwork bins and exposed to the air for several months, during which time it is occasionally moistened. The resulting sludge is lixiviated with water at 70°, and the clear decanted liquor concentrated. The crystals of alum which separate on cooling are cubic and have a reddish tinge owing to the presence of suspended ferric oxide; this may be removed by recrystallisation. The amount of soluble iron present is stated to be less than 0·005 p.c. The product, known as Roman alum, was in former times highly valued on account of its great purity.

In the modern process, employed on the Continent, the alunite is calcined at a higher temperature and the product treated with sulphuric acid, whereby aluminium sulphate is formed from the excess of alumina, and passes into solution together with the alum. The latter is either crystallised out, and the more soluble aluminium sulphate recovered as such from the mother liquors, or sufficient potassium sulphate is added to convert the whole of the aluminium sulphate into alum.

According to C. Schwartz (Ber. 17, 2887), the best temperature for the roasting is 500°, and the acid used should have a density between 1·297 and 1·530. L. Geschwind (Manufacture of Alum and the Sulphates of Alumina and Iron, 1901), however, states that in France a temperature of about 1000° is employed.

Formerly, the greater portion of the alum manufactured in England was prepared from alum shale (alum ore), alum schist, and similar minerals, which occur in large quantities at Whitby in Yorkshire, Hurlet and Campsie in Scotland, in Sweden, Norway, Belgium, and in several parts of Thuringia, Westphalia, &c. These minerals are mixtures of aluminium silicate, iron pyrites, and bituminous substances; the iron pyrites is principally present in the aluminous schists as a fine black powder, disseminated throughout the mass, and not distinguishable to the eye. The rapid oxidation of these minerals under atmospheric influences or heat is due to this state of fine division.

Aluminous earths are dark brown, friable, porous masses without structure, and contain less silica than the schists. They usually occur in layers with lignite.

Production of alum from aluminous shale.—The more earthy shales are porous, and if piled in heaps in the open air and occasionally moistened undergo spontaneous oxidation, with the formation of sulphates of iron and aluminium. Usually they require roasting, and when not sufficiently bituminous for combustion, are first mixed with fuel.

The coarsely broken shale is built up with alternate layers of coal into heaps, which are ignited. As the mass burns, fresh quantities of the mineral are added, until a sufficient mass of material has been accumulated. By pumping water over the surface at intervals the temperature is regulated to a degree suitable for rendering the decomposition as complete as possible. Too high a temperature is to be avoided, as it results in the loss of sulphur dioxide and the formation of a slag. During the combustion of the shale the pyrites is decomposed, giving up a portion of its sulphur, which is converted by burning into sulphur dioxide, and this in conjunction with atmospheric oxygen attacks the clay, forming aluminium sulphate. The calcined mass is allowed to remain exposed to the air for a considerable period, during which a further absorption of oxygen takes place, resulting in the conversion of the lower sulphide of iron into ferrous sulphate and ferric oxide.

Lixiviation.—This operation is carried out in large lead-lined boxes with perforated bottoms, the filtering bed being formed of timber topped with brushwood. A layer of the roasted mineral about 13 inches deep, is introduced and its extraction is effected, first with the mother liquor from the alum crystallising pans, and later with pure water, the liquid in each case being left overnight in contact with the material.

The exhausted mineral still contains a considerable amount of alumina and sulphuric acid. The liquors, which have a density of 1·09 to 1·15, are run into settling tanks and allowed to deposit calcium sulphate, ferric oxide, and other suspended impurities, and are then removed for concentration. The method adopted for this purpose varies according to the nature of the mineral under treatment. In the case of shales from Hurlet and Campsie the concentration is effected by surface evaporation in a reverberatory furnace.

The bed is of stone, coated with well-rammed clay, 4 or 6 feet wide, 2 or 3 feet deep, 30 or 40 feet long. It is filled to the brim with strong liquor, and the flame and hot air from the fire carried over it. As evaporation proceeds, more liquor is added until the proper concentration is reached. It is then run into leaden pans, concentrated to about 1·4 sp.gr. and conveyed to a precipitating cistern containing the requisite quantity of dry potassium chloride; the liquid is well agitated and the chloride soon dissolves.

In about 5 days the liquor is drained from the large crystals, which are washed and recrystallised.

The Whitby shales differ from those at Hurlet, in that they contain a considerable quantity of magnesia which passes into the extract in the form of magnesium sulphate. In this case surface evaporation is not satisfactory on account of the formation of a crust of this salt which retards evaporation. The evaporation of the liquor is carried out, therefore, in leaden vessels, until a sp.gr. of 1·125 to 1·137 is reached, after which the solution is allowed to stand until clear. The concentration is continued up to sp.gr. 1·25, at which stage a sample of the liquor is withdrawn and the percentage content of aluminium sulphate determined. After further evaporation to a density of 1·4 to 1·5, the hot liquor is run into a precipitating tank and mixed with a saturated solution of the calculated quantity of potassium chloride or sulphate, the whole being kept in constant agitation to induce the formation of small crystals (alum meal).

When much ferric sulphate is present in the solution, the addition of potassium sulphate would produce iron alum, isomorphous with ordinary alum, which would crystallise out and contaminate the product. The use of potassium chloride prevents this, by producing the easily soluble ferric chloride, while ferrous salts are converted into the equally soluble ferrous chloride, an equivalent amount of potassium sulphate being formed at the same time. Chloride of potassium is generally employed in preference to the sulphate, whenever sufficient iron sulphate is present to supply the requisite amount of sulphuric acid for the formation of alum; its greater solubility is also in its favour. Too much chloride should be carefully avoided, for after the iron sulphates have been decomposed, the aluminium sulphate is itself attacked, with the production of the very soluble chloride, which is lost.

The *alum meal*, consisting of small brownish crystals, is drained and washed twice with cold water. The adhering mother liquor, containing much iron, is thus removed, and the meal is left nearly pure. The final purification is effected by dissolving in a minimum quantity of boiling water and allowing the solution to stand for about eight days in casks furnished with movable staves. At the end of this period the staves are removed, and after two or three weeks further standing, the block of crystals is pierced, the mother liquor drained off and employed for dissolving fresh quantities of meal.

The mother liquor from the alum meal has a sp.gr. of about 1·4; it contains sulphate or chloride of iron, magnesium sulphate, &c., and will yield more alum on evaporation. In a final evaporation it yields ferrous sulphate in fine green crystals. When iron is present in large quantity, the liquors are evaporated and the ferrous sulphate crystallised out before the addition of the potassium salt. In this case the iron salt is less pure and less soluble, but the alum subsequently produced contains less iron.

Formerly, potassium alum was alone produced. In 1845, however, the potassium sulphate was replaced by the ammonium sulphate produced from the then waste liquors from gas works, yielding ammonium alum. This great improvement was introduced by the late Peter Spence; his method was soon generally adopted both in England and on the Continent.

Another great advance was made by Spence in 1845 in the manufacture, by the treatment of the refuse shale underlying the coal-seams of South Lancashire. This shale contains from 5 to 10 p.c. of carbonaceous matter. It is piled upon rows of loosely placed bricks (to allow a free passage to the air) in heaps 4 or 5 feet high and 20 feet long. The combustion is started with a little fuel, but the shale contains sufficient combustible matter to continue burning. The calcination is performed slowly at a heat below redness. In about 10 days the roasting is completed, and the material has become soft, porous, and light-red, whilst the alumina contained in it has become anhydrous and soluble in sulphuric acid. Too high a temperature, however, partially vitrifies it, in which case it is only slowly attacked by acid. Charges of 20 tons are placed in large covered pans 40 feet long, 10 feet wide, and 3 feet deep, lined with lead, and are digested for about 48 hours with sulphuric acid (of sp.gr. 1·35) at 110°, the temperature being maintained by fires beneath the boilers. Formerly ammonia was forced into the liquid from a boiler containing gas liquor; ammonium sulphate was thus produced, with considerable rise of temperature, and combined with the aluminium sulphate forming ammonium alum. The solution of alum so produced is run into cisterns 29 feet by 17 feet, and 1½ feet deep, in which it is kept in constant agitation. In about 14 hours the small crystals so formed are drained, washed with some mother liquor from 'block alum,' and dissolved by a process known as 'rocking' for the production of pure block alum. For this purpose they are introduced into a hopper, at the bottom of which they encounter a current of steam at a pressure of 20 lbs. per sq. inch, both steam and crystals being supplied in such proportions that all the crystals are dissolved, while no steam is wasted. In this manner 4 tons of crystals may be dissolved in 30 or 40 minutes. The solution is run into a leaden tank, and, after a time, treated with a small quantity of size, which precipitates a quantity of insoluble matter. The clear liquid is next run into tubs about 6 feet high and 6 feet wide, tapering upwards, with movable lead-lined staves. After some days the staves are removed and a hole is bored in the mass of crystals for the removal of the liquor. Each block weighs about 3 tons, while the mother liquor contains about 1 ton.

To produce 1 ton of ammonium alum by this method on an average about 15 cwts. of the shale is required.

A great advantage of this process is the speed with which the crude material is converted into marketable alum. By the old process twelve months was required for this conversion, whilst by Spence's process the whole operation is performed in one month. For this process Spence was awarded the medal for alum manufacture at the Exhibition of 1862, at which date he manufactured 150 tons of alum weekly, over one-half the total production of England (*v.* Hofmann's Report on Chemical Processes at the Exhibition of 1862, p. 62, and J. Carter Bell, Chem. News, 12, 2[illegible]

Alum is also produced by the addition of potassium sulphate to aluminium sulphate, prepared by any of the processes already described. It is prepared in great purity from the sulphate produced from cryolite; 1 ton of cryolite produces 3 tons of alum (*v. Sodium aluminate*).

Many other processes have been proposed and used for the preparation of alum.

Spence, in 1870 (Eng. Pat. 1676), patented a method of preparing alum from mineral phosphates, especially that from Redonda near Antigua, which contains 26·1 p.c. of alumina as phosphate with ferric oxide and silica. It is calcined at a red heat to render it porous, powdered, and digested with sulphuric acid of sp.gr. 1·6 in quantity proportional to the amount of alumina, in lead-lined vessels, heated by steam. The liquid is concentrated to a density of 1·45, and treated with the requisite amount of potassium sulphate to convert the whole of the alumina into alum. Phosphate containing 20 p.c. of alumina yields about 1½ times its weight of alum, from which, however, the last traces of phosphoric acid are removed with difficulty. The phosphoric acid in the mother liquors is valuable as a manure.

Methods have frequently been proposed for the preparation of alum from felspar. Ordinary felspar contains both potassium and aluminium combined with silica in larger proportions than are contained in alum; the problem to be solved is the substitution of sulphuric acid for silica. A method adopted by Turner, said to have been originated by Sprengel, consisted in the ignition of a mixture of one part of the powdered mineral with one part of potassium bisulphate until fused; one part of sodium carbonate was then added, and the whole again fused. The mass was boiled with water and the insoluble double silicate remaining was decomposed by hot sulphuric acid of sp.gr. 1·20, and the alum crystallised out. On account of the high temperature required, this process was not successful.

At the present time the bulk of the alum manufactured in England is prepared either from shale or alunite or from the aluminium sulphate derived from bauxite or china clay.

For the more delicate dyes the alum used must be of extreme purity. Samples containing even less than 0·001 p.c. of iron may be unsuitable for certain purposes. The percentage of iron in alum or in aluminium sulphate is usually determined by means of a solution of ammonium thiocyanate standardised with iron alum. Many precautions are necessary in performing the analysis (*v.* Tatlock, J. Soc. Chem. Ind. 1887, 276; G. Lunge, Mon. Sci. 1897, 160).

Potash alum crystallises with 24 molecules of water, in crystals belonging to the cubic system, usually in large colourless octahedra of sp.gr. 1·751 (Retgers, Zeitsch. physikal. Chem. 3, 289; J. B. 1889, 148).

De Boisbaudran has also obtained it crystallised with hemihedral faces of the tetrahedron. The crystalline form is affected by the presence of other substances in solution, and by the temperature. When formed at ordinary temperatures in the presence of basic alum, the crystals are cubes, frequently dull on the surface from the presence of the basic salt; for this reason Roman alum usually forms cubes. At 40° C., even in presence of basic salts, octahedra are produced.

Potash alum possesses the property of crystallising with hydrogen peroxide (Willstatter, Ber. 36, [1903] 1828).

According to Poggiale (Ann. Chim. Phys. [3] 8, 467), the solubility of potash alum and of ammonia alum is as follows:—

100 parts water dissolve:

°C.	Crystallised Potash alum.	Crystallised Ammonia alum.
0	3·9	5·2
10	9·5	9·1
20	15·1	13·6
30	22·0	19·3
40	30·9	27·3
50	44·1	36·5
60	66·6	51·3
70	90·7	72·0
80	134·5	103·0
90	209·3	187·8
100	357·5	421·9

Conductivity determinations, made on alum solutions of different concentrations, indicate that even at moderate dilutions the alum is resolved into its component salts.

Potash alum possesses a sweetish astringent taste and a strongly acid reaction. The aqueous solution decomposes when heated with precipitation of a basic alum, especially when dilute. For this reason a small quantity, not sufficient to be distinguished by taste, is frequently added to impure water. The gelatinous precipitate carries with it the colouring matter and most of the organic impurities, producing a slimy deposit.

Alum is almost insoluble in a saturated solution of aluminium sulphate, and is quite insoluble in alcohol. On exposure to air, the crystals become white on the surface. This change is due, not to the loss of water, but to the absorption of ammonia from the air, with formation of a basic salt. Below 30° C. they lose no water; at 42° C. they evolve 11 molecules (Juttke, Chem. Zentr. 18, 777). In a closed vessel over sulphuric acid they lose 18 molecules at 61° C. (Graham) and become slowly anhydrous at 100° C., more rapidly in a current of air. Alum melts in its water of crystallisation at 92·5° C., and when heated to dull redness is converted into a porous friable mass, slowly soluble in water, known as 'burnt alum.' At a white heat alumina and potassium sulphate alone remain.

When burnt alum is mixed with one-third its weight of carbon and heated to redness, the residue is spontaneously inflammable on account of the presence of finely divided potassium sulphide, and is known as Homberg's pyrophorus. By fusing alumina with potassium bisulphate and digesting the mass in warm water, anhydrous potassium alum may be obtained in crystals of which 5 parts are soluble in 100 of water at 10° C. and 74·5 parts at 100° C. (Salm-Horstmar, J. pr. Chem. 52, 319).

On the addition of caustic soda or sodium carbonate to a solution of alum until the precipitate at first produced is only just redissolved on agitation, *i.e.* when two-thirds of the acid has been neutralised, the solution contains a neutral basic alum, known as *neutral alum*, together with sodium sulphate. This solution, on account of the ease with which it gives up its excess of alumina to the fabric, is used by dyers as a mordant. Commercial potash alum is frequently mixed with ammonia alum.

Alum is extensively used as a mordant in the dyeing industries, and in the production of other aluminium mordants such as the acetate, sulphoacetate, &c., employed in dyeing and printing and for shower-proofing fabrics. The alum used for dyeing with alizarin red must be free from iron, otherwise dull shades are produced. It is also employed in the manufacture of lake pigments, in the dressing of skins ('tawing') to produce white leather, in sizing paper, and in the production of fireproofing materials. In most of its applications, however, it is being replaced by aluminium sulphate, the use of which is considerably more economical.

Sodium alum, *Soda alum*

$$Na_2SO_4,Al_2O_3(SO_3)_3,24H_2O$$

occurs as *mendozite* in S. America and in Japan (Divers, Chem. News, 44, 218).

This alum was prepared by Zellner in 1816, by the spontaneous evaporation of a solution containing sodium and aluminium sulphates. Its existence, disputed by Ostwald, has been established by Wadmore (Chem. Soc. Proc. 21, 150; C.-B. 1905, 11, 18), who from a solution of the mixed sulphates obtained octahedral crystals having the above composition. From a hot concentrated solution it is deposited on cooling as a pasty mass which slowly becomes crystalline. Contrary to the statement frequently made, the crystals do not appreciably effloresce in the air.

Technically, soda alum may be prepared in the following manner:—To a solution of aluminium sulphate containing 675 grams of the crystalline salt per litre, and maintained at a temperature of 50° C. to 60° C., is added a solution of sodium sulphate containing 146 grams of the anhydrous salt per litre, until the liquid attains a density of 1·35; crystals of soda alum separate on cooling. The crystallisation should be effected at a temperature between 10° C. and 25° C.; at 28° C. the formation of crystals proceeds very slowly, whilst below 10° C. separation of sodium sulphate occurs (Augé, D. R. P. 1899, 50323; J. 1890, 2635).

Messrs. F. M., D. D., and H. Spence (Eng. Pat. 1900, 5644) prepare a solution of sodium sulphate saturated at 40° C. to 50° C., which is allowed to cool during agitation until a considerable proportion of decahydrated crystals have separated. The mixture of liquid and crystals is then run into a solution of aluminium sulphate containing the solid salt in suspension. There is thus obtained a large crop of well-defined soda alum crystals. Alternatively, the solid aluminium sulphate may be added to a suitable solution of sodium sulphate or chloride, in which either salt may be suspended in the solid state.

Soda alum is much more soluble at ordinary temperatures than potassium or ammonium alum, in consequence of which it is more difficult to purify from iron. On account of the lower cost of sodium salts, it would be largely used in place of other and more expensive alums, if it could be easily purified by crystallisation (*see* Eng. Pat. 1881, 5650).

Soda alum crystallises with 24 molecules of water in regular octahedra, having a sp.gr. of 1·667 (Soret). At 10·6° C. 100 parts of water dissolve 107·11 parts of the alum (Wadmore); according to Ure, the solution saturated at 15·5° C. contains 110 parts of the alum in 100 of water, and has a density of 1·296. Soda alum is insoluble in alcohol.

Ammonium alum, *Ammonia alum*

$$(NH_4)_2SO_4,Al_2O_3(SO_3)_3,24H_2O$$

occurs as *Tschermigite* in Bohemia, and in the crater of Mount Etna.

Its preparation is analogous to that of potash alum, a solution of aluminium sulphate, prepared by any of the methods already described, being treated with the equivalent quantity of ammonium sulphate, and the alum separated and purified by crystallisation.

Ammonia alum crystallises with 24 molecules of water in regular octahedra, having a conchoidal fracture and a density of 1·631 (Soret). At ordinary temperatures it is less soluble in water than potassium alum (*v.* Table of solubilities, under Potassium alum). The saturated solution boils at 110·6° C., and contains 207·7 parts of the alum to 100 parts of water (Mulder). When heated the crystals swell up and form a porous mass, losing water and sulphuric acid; at a high temperature alumina alone remains. This serves as a useful method for the production of very pure alumina.

In its general properties and uses, ammonia alum closely resembles the corresponding potassium compound. G. H. B.

ALUMNOL *v.* SYNTHETIC DRUGS.

ALUM-SHALE. A kind of shale or slate containing disseminated iron-pyrites, which, on prolonged exposure to the weather, gives aluminium sulphate, owing to the action of sulphuric acid (from the decomposition of the iron-pyrites) on the clayey material. The heaps of weathered shale are leached with water, and to the solution of aluminium sulphate and sulphuric acid so obtained potashes are added. The alum obtained by the evaporation of this solution is purified by recrystallisation. The alum-shales of Liassic age on the coast of Yorkshire, in the neighbourhood of Whitby, have been largely worked by this method since the time of Queen Elizabeth, but now the industry has become extinct. At Alum Bay in the Isle of Wight clays of Tertiary age were formerly used in the manufacture of alum, as early as 1579; and in the early part of the eighteenth century the Kimmeridge clay in Kimmeridge Bay, Dorsetshire, was also so used. Pyritous shales of Carboniferous age were formerly worked at Hurlet in Renfrewshire, large works for the extraction of alum having been erected here about the year 1800. Alum-shales in the coal-measures of the West Riding of Yorkshire are, however, still worked to a small extent near Rotherham, Barnsley, and Darton. Here the iron-pyrites is more efficiently and quickly oxidised by roasting the shale, which is afterwards steeped in shallow pits, and the concentrated liquor treated with potassium chloride.

Reference.—Special Reports on the Mineral

Resources of Great Britain, vol. v. Mem. Geol. Survey, London, 1916. *V. Alums*, art. ALUMINIUM. L. J. S.

ALUNDUM. A form of fused alumina manufactured as a refractory material and abrasive. As used in the preparation of refractory articles it is a white crystalline product containing less than 1 p.c. of impurities (oxides of iron, titanium, and silicon); it melts at 2050°-2100°, and its coefficient of linear expansion is 0·0000078. A less pure form containing 6-8 p.c. of impurities and of a reddish-brown colour is also employed; it melts at about 50° lower than the white variety, and its coefficient of expansion is 0·0000085. Alundum does not soften when within 100° of its melting-point; sp.gr. 3·93-4·0; hardness 9-10 (Moh's scale). Thermal conductivity 3-4 times that of most fire-clays. Not attacked by aqueous acids and alkalis, and only very slightly by fused alkali carbonates. Dissolved with difficulty by fused slags both acid and basic, more readily by the former. For the preparation of shaped articles it is mixed with a refractory binding agent, moulded, and fired in a ceramic kiln; the articles are usually more refractory than amorphous alumina. When treated with sulphuric or hydrochloric acid they lose up to 0·03 p.c. of their weight but are then quite unaffected. The articles are porous, and cannot be used where gas-tight vessels are required, or as protecting tubes for pyrometers. The melting-point of the bonded articles is never below 1950°, and they possess great strength, both tensile and compressive; electrical resistance 476×10^6 ohms. at 535°, 49×10^6 at 721°, 24×10^6 at 908°, and $7·5 \times 10^6$ at 1040°. Alundum muffles last 4-5 times as long as clay muffles, and are more refractory and have a higher tensile strength than quartz. Crucibles of alundum can be used for melting metals, even platinum. On account of their porosity they cannot be used for melting slags or salts, but this quality makes them specially suitable as a substitute for Gooch crucibles; no asbestos filler-layer is required, and the porosity can be so controlled that the finest precipitates may be collected in them. Alundum extraction thimbles can be cleaned by simple ignition. An alundum cement is made for lining crucibles and furnaces; it does not melt or combine with carbon below 1950°. Alundum bricks have been used in place of silica for the roofs of electric furnaces (Saunders, Amer. Electrochem. Soc. 1911; Met. and Chem. Eng. 1911, 9, 258; J. Soc. Chem. Ind. 1911, 30, 686).

ALUNITE or **ALUM-STONE.** Hydrated basic sulphate of aluminium and potassium $KAl_3(SO_4)_2(OH)_6$, containing theoretically 11·4 p.c. of potash. The potash may, however, be replaced isomorphously by soda with a passage from 'kalioalunite' to 'natroalunite' (Analysis, VI). Further, the material is often impure owing to admixture with silica and clayey matter. The mineral is usually found as white, grey, or pinkish, compact and granular masses, somewhat resembling chalk, limestone, or marble in appearance. Sp.gr. 2·58-2·75. Occasionally, minute glistening crystals, which belong to the rhombohedral system, are found in cavities in the massive material. The following analyses are of material from I and II Bullahdelah, New South Wales (I pale pink, and II chalky white, containing more silica); III and IV, Marysvale, Utah (III of selected clear pink, translucent, coarsely granular material, and IV of compact, fine-grained, porcelain-like material); V, 'calafatite' from Benahadaux, Almeria, Spain; VI, white, chalky 'natroalunite' from Funeral Range, Death Valley, California.

The mineral mostly occurs in connection with volcanic rocks, having been formed by the action of solfataric vapours on such rocks. In some cases, however, it may have been formed by the action of decomposing iron-pyrites on clay. Extensive deposits have long been known at Tolfa near Rome, Montioni in Tuscany, and Musaz and Bereghszasz in Hungary. An important deposit, forming wide veins in volcanic rock (andesite or dacite), has been discovered and mined near Marysvale in Utah. A detailed description of this, together with a *résumé* of the published descriptions of other deposits of commercial importance, has been given by B. S. Butler and H. S. Gale (Bull. U.S. Geol. Survey, 1912, No. 511, pp. 1-64). Other localities are in Colorado, Nevada, California, and Arizona; Kyuquot Sound, Vancouver Island, British Columbia; Bullahdelah, 60 miles north of Newcastle, New South Wales; Carrickalinga Head, on St. Vincent Gulf, 40 miles south of Adelaide, South Australia; Warnertown, near Port Pirie, South Australia; and near Sunbury, Victoria. (On the Australian deposits, *see* E. F. Pittman, The Mineral Resources of New South Wales, Dept. of Mines, N.S.W., 1901. The Alunite Deposits of Australia and their Utilisation, Advisory Council of Science and Industry, Commonwealth of Australia, Bull. No. 3, Melbourne, 1917.) Extensive deposits have also been found near Benahadaux, 10 km. from the port of Almeria in Spain (S. Calderón, Los minerales de España, 1910, ii. p. 205).

Since the fifteenth century this mineral has been exploited at Tolfa near Rome, for the manufacture of potash-alum; and the harder and more compact varieties from Hungary have been used for millstones. Now, however, the mineral is of considerable importance as a source of potash. When ignited, it gives off all its water and three-quarters of its sulphuric acid, there remaining alumina and potassium sulphate, 92 p.c. of the whole of the latter being capable of extraction in solution by this method. When roasted at a lower temperature, aluminium and potassium sulphates can be extracted by lixiviation and crystallised as potash-alum. Details of the methods of treating the mineral as practised in Australia and Utah are given in the Bulletins quoted above. The mineral may be used directly as an artificial manure; but, since the potash is not present in a soluble form, better results are obtained by first roasting.

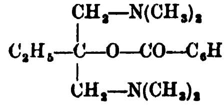
L. J. S.

ALUNOGEN. Hydrated aluminium sulphate $Al_2(SO_4)_3,18H_2O$, occurring as a white, delicately fibrous efflorescence on shale and other rocks. It has been formed by the action on the aluminous rock of the products of decomposition of iron-pyrites. A trace of iron sulphate is often present, imparting a yellowish or reddish colour to the mineral. L. J. S.

ALVA or **ALFA** *v.* ESPARTO.

ALVELOS. A name applied to the *Euphorbia heterodoxa* (Muell.), growing in Brazil, the juice of which has been used as a cure for cancer (Pharm. J. [3] 15, 614).

ALYPINE. Trade name for *benzoyltetramethyldiaminoethyldimethylcarbinol hydrochloride.*



$$\begin{array}{c} CH_2\text{—}N(CH_3)_2 \\ | \\ C_2H_5\text{—}C\text{—}O\text{—}CO\text{—}C_6H_5 \\ | \\ CH_2\text{—}N(CH_3)_2 \end{array}$$

Employed in place of cocaine and stovaine as an anæsthetic and as a remedy for vomiting and in the treatment of diseases of the upper respiratory passages and of the organ of hearing. Used also in veterinary practice in place of cocaine.

It occurs in crystals, m.p. 169°, sol. in water, forming a neutral solution. Aqueous solutions may be sterilised without undergoing decomposition by boiling from 5 to 10 minutes (Neustatter, Pharm. J. 1905, 869).

(For distinctive reactions, *v.* Lemaire, Rep. Pharm. 1906, 18, 385.) (*v.* SYNTHETIC DRUGS.)

AMADOU or **GERMAN TINDER.** (*Amadou*, Fr.; *Zunderschwamm*, Ger.). A spongy combustible substance, prepared from a species of fungus, *Fomes* (*Polyporus*) *igniarius*, the 'false' tinder-fungus, which grows on the trunks of the oak, but also on alder, willow, and various other trees. It must be plucked in the months of August and September. It may also be prepared from *Fomes* (*Polyporus*) *fomentarius*, the true tinder-fungus, also indigenous, found especially on the beech, elm, and various fruit trees. It was formerly used in surgery, and has hence been called surgeons' agaric. Amadou is prepared by removing the outer rind and carefully separating the yellow-brown spongy substance which lies within it. This substance is cut into thin slices, and beaten with a mallet to soften it, till it can be easily pulled asunder between the fingers. In this state it is useful in surgery. To convert it into tinder, it is boiled in a strong solution of nitre, dried, beaten anew, and put a second time into the solution. Sometimes, to render it very inflammable, it is imbued with gunpowder, whence the distinction of 'black' and 'brown' amadou.

AMALGAM. An alloy of mercury with some other metal or metals.

There are four general methods for preparing amalgams.

1. Metallic mercury is brought into contact with the other metal, either in the solid or in a finely divided state at the ordinary or at a higher temperature. In this way amalgams of antimony, arsenic, bismuth, cadmium, magnesium, potassium, silver, sodium, tellurium, thorium, tin, zinc, and lead may be obtained.

2. Mercury is brought into contact with a saturated solution of a salt of the metal, when part of the mercury goes into solution and the remainder combines with the liberated metal; or better still, zinc or sodium amalgam is employed, when the zinc or sodium displaces the metal in the solution. By this method amalgams of bismuth, calcium, chromium, iridium, iron, magnesium, manganese, osmium, palladium, and strontium may be prepared by using sodium amalgam, and cobalt and nickel by using zinc amalgam (Moissan, Compt. rend. 1879; Chem. News, 39, 84).

3. The metal to be amalgamated is placed in a solution of a mercury salt; copper may be amalgamated by this process.

4. The metal is placed in contact with mercury and dilute acid; this is the method usually employed in amalgamating zinc. Iron, aluminium, palladium, nickel, and cobalt may be made to combine with mercury by this process if they be placed in contact with a stick of zinc (Casamajor, Chem. News, 34, 36; Arch. Pharm. [3] 11, 64; Chem. Soc. Trans. [2] 34, 474).

Amalgams are also formed when mercury is used as the cathode in the electrolysis of salt solutions; a number of metals can thus be obtained as amalgams, although they cannot be obtained directly in the free state by the electrolysis of aqueous solutions.

The combination of sodium with mercury by method 1 takes place with great energy, heat and light being produced. The preparation is best carried out by combining a small portion of the mercury with the sodium, and then adding the remainder to the amalgam.

Native amalgams are found in various parts of the world. The table on next page contains the analyses of a few.

Gold and silver in the metallic state can be extracted from their ores by grinding the ores and making them pass through mercury, although this process is now largely replaced by the modern cyaniding methods. (For details, *v.* these metals; and May, J. Soc. Chem. Ind. 4, 352; Moon, *id.* 4, 678; Miller, *id.* 4, 122; Whitehead, *id.* 4, 503; Fisher and Waber, *id.* 4, 351; Barker, Dingl. poly. J. 251, 32; Body, *id.* 252, 33; Molloy, *id.* 254, 210; Bonnet, *id.* 254, 297; Cassel, *id.* 257, 286; Jordan, *id.* 258, 163; Hollick, *id.* 258, 168.) When the mercury has taken up a quantity of gold, the amalgam is squeezed through chamois leather, when the greater portion of the gold is left, combined with a little mercury, as a pasty mass. Kazantseff (Bull. Soc. chim. [2] 30, 20; Chem. Soc. Trans. [2] 34, 937) finds that the mercury which escapes contains at ordinary temperatures 0·126 p.c. of gold, at 0° 0·110 p.c., and at 100° 0·650 p.c., thus behaving like an aqueous solution.

Berthelot found that the solution of definite amalgams in different quantities of mercury, like the solution of salts in water, absorbs a constant amount of heat; thus the heat of solution of an amalgam of which the composition corresponds with the formula $Hg_{24}K$ in four times its weight of mercury is —8·0 kil. deg. of heat, and in twenty times —9·0 kil. deg. (Compt. rend. 89, 465; Chem. Soc. Abstr. 38, 1).

According to Berthelot, the maximum heats of formation for amalgams of potassium and sodium are 34·2 and 21·1, corresponding with crystalline amalgams containing 1·6 p.c. of potassium, and 2 p.c. of sodium respectively. In these amalgams the relative affinities of the free alkali metals are inverted: this explains Kraut's and Popp's observation that sodium displaces potassium when potassium hydroxide is treated with sodium amalgam, the final result being the formation of an amalgam of composition $Hg_{24}Na$ (Compt. rend. 88, 1335).

The views formerly held on the constitution of amalgams and particularly on the existence of definite amalgams of the nature of chemical compounds of mercury and the alloyed metal, have been profoundly modified by the study of those bodies by the methods of metallography (*v.* METALLOGRAPHY). The amalgams are found to be strictly analogous to other alloys, but their peculiar behaviour arises from the fact that they are frequently met with in a range of temperature which lies between the commencement of solidification and final complete crystallisation. It has been shown that a number of supposed compounds, of which the existence had been assumed on the ground that amalgams representing them took the form of homogeneous crystalline bodies, are not true compounds, whilst definite compounds of different composition have been found. Thus, in the case of sodium and potassium amalgams, the compounds Hg_4Na, Hg_2Na, $HgNa$, Hg_2Na_3, Hg_2Na_5, $HgNa_3$, and Hg_2K, HgK, Hg_3K, Hg_9K_2, and Hg_9K, have been recognised (Schüller, Zeitsch. anorg. Chem. 1904, 40, 385; Kurnakoff, *ibid.* 1900, 23, 439; Jaenecke, Zeitsch. physical. Chem. 1907, 58, 245).

The amalgams of bismuth, zinc, tin, and thallium are found not to contain any definite compounds (Pushin, Zeitsch. anorg. Chem. 1903, 36, 201; Heteren, *ibid.* 1904, 42, 129; Kurnakoff and Pushin, *ibid.* 1903, 30, 86).

'Ammonium amalgam' is prepared by acting on a saturated solution of ammonium chloride with sodium amalgam; the amalgam thus obtained soon breaks up into mercury, and ammonia and hydrogen gases. According to Wetherill (Amer. J. Sci. [2] 50, 160), this compound is not a true amalgam, as when an ammoniacal solution is electrolysed, the negative pole being a spongy plate impregnated with mercury, no amalgam is formed. Landolt (Zeitsch. f. Chem. [2] 5, 429) draws attention to the fact that ammonium amalgam does not reduce solutions of silver nitrate, ferric chloride, or cupric sulphate, as do sodium and potassium amalgams.

Seeley (Chem. News, 21, 265) has shown that on submitting ammonium amalgam to pressure, its volume diminishes in the same way as does that of a gas, and hence he considers that the ammonia and hydrogen exist in the amalgam as gas, and that the spongy mass is only a froth of mercury enclosing these gases.

Gellatlin (Zeitsch. f. Chem. [2] 5, 607) asserts that when ammonium amalgam, free from sodium, is placed in contact with phosphorus, phosphoretted hydrogen is evolved, and he infers that the hydrogen must be in the nascent state.

Pfeil and Lippmann (Compt. rend. 62, 426) state that trimethylamine hydrochloride also forms a spongy amalgam which quickly decomposes with evolution of hydrogen and formation of trimethylamine; saturated solutions of the hydrochlorides of aniline, conine, morphine, and quinine give off hydrogen only.

Electrical amalgam is made by melting together 1 part of zinc and 1 part of tin, and then adding 3 parts of mercury. An amalgam of cadmium is used in the construction of the cadmium standard cell; this amalgam and its electrical behaviour have been studied by F. E. Smith (Phil. Mag. February, 1910).

Silvering amalgams. For metals, 1 part of silver to 8 parts of mercury; for glass, 1 part each of lead and tin, 2 parts bismuth, and 4 parts mercury. The use of amalgams for silvering has been almost completely superseded by the use—in the case of glass—of chemically deposited silver, and in the case of metals by electro-plating.

Teeth fillings. 1. Copper precipitated from copper sulphate solution with zinc, washed with sulphuric acid containing a small quantity of mercuric nitrate, and amalgamated with twice its weight of mercury (Fletcher), has the property of softening with heat and hardening again after a few hours. It is a permanent filling, as the copper salts penetrate and preserve the tooth substance. It has the objection of staining the tooth, and is only used in posterior teeth. 2. A palladium amalgam is sometimes employed, but its rapidity of setting, intense black colour, and cost are against its general use. 3. An alloy of silver 68·5, tin 25·5, gold 5, and zinc 1 p.c. (Black); or silver 69·5, tin 25·5, gold 4, and zinc 1 p.c. (Tulloch), amalgamated with mercury, is extensively employed, as it has a good edge strength, and suffers little, if any, shrinkage. The shrinkage is the greatest difficulty to overcome in order to render alloys of permanent use for teeth filling, the object being to secure such a proportion of metals that the shrinkage of one may be overcome by the expansion of another, and so obtain a watertight plug. W. R.

AMALIC ACID *v.* ALLOXANTIN.

AMANITA MUSCARIA. *Fly agaric.* A poisonous fungus, used in Kamtschatka and Siberia as a narcotic and intoxicant, and, when steeped in milk, as a fly-poison. A narcotic organic base, *muscarine* $C_5H_{15}NO_3$, which is the hydrated aldehyde of betaine, has been isolated from it (Schmiedeberg and Harnack, J. 1876, 804).

The natural muscarine is like the artificial product in crystalline form, solubility, and composition of its platino- and auro-chlorides, and to a large extent in its physiological action, but unlike the artificial muscarine it does not induce paralysis of the intermuscular nerve-terminations in the frog, and myosis in the pupils of the eyes of birds (Nothnagel, Ber. 26, 801). It differs both in constitution and properties from anhydro- and *iso*-muscarine.

A green and red dye of composition $C_{29}H_{20}O_{10}$, and $C_{19}H_{18}O_6$ respectively, have also been isolated from it (Griffiths, Compt. rend. 130, 42).

AMARANTH *v.* AZO- COLOURING MATTERS.

AMARIN. Trade name for triphenyldihydroglyoxaline.

AMATOL. A mixture of 80 parts of ammonium nitrate with 20 parts of trinitrotoluene (T.N.T.). Used as an explosive. *See* EXPLOSIVES.

AMAZON-STONE. A bright-green variety of the potash-felspar microcline ($KAlSi_3O_8$). It is found in granitic rocks near Lake Ilmen in the Ural Mountains, at Pike's Peak in Colorado, and of very good quality in Madagascar. It is used to a limited extent as a gem-stone, and for making various small ornamental objects (*v.* FELSPAR). L. J. S.

AMBAR LIQUID *v.* BALSAMS.

AMBATOARINITE *v.* ANCYLITE.

AMBER or **SUCCINITE.** (*Bernstein*, Ger.) A fossil resin derived from the extinct conifer *Pinites succinifer* (Göppert), and found as irregular nodules in strata of Tertiary age, principally on the Prussian coast of the Baltic. The amber-bearing stratum lies partly below sea-level, and the amber washed out by the action of the waves is picked up on the sea-shore or won by dredging. Such 'strand-amber' was formerly collected farther west, as far as the coast of Holland, and isolated specimens are picked up on the east coast of England (Norfolk, Suffolk, and Essex). At the present time the bulk of Prussian or Baltic amber is obtained from pits and mines in the 'blue earth' in Samland, East Prussia. Here the production in 1907 amounted to 404,300 kilos. and in addition about 20,000 kilos was collected on the sea-shore.

Baltic amber differs from other fossil resins in containing succinic acid, which is present to the extent of 3 to 4 p.c. in perfectly transparent specimens, but reaching 8 p.c. in cloudy ('frothy') amber. It is therefore distinguished by the mineralogical name *succinite*, and in the trade the tendency is to apply the name 'amber' exclusively to Baltic amber. The composition is somewhat variable, averaging C, 79 p.c.; O, 10·5 p.c.; H, 10·5 p.c.; and corresponding approximately with the formula $C_{10}H_{16}O$. Sulphur is also present (0·26 to 0·42 p.c.), and some ash, usually about 0·2 p.c., but increasing in amount if the material encloses foreign matter. Amber is, however, not a simple resin; when heated, it gives oil of amber (*q.v.*) and other products, and by the action of solvents at least four different kinds of resin can be extracted from it. According to O. Helm, Baltic amber contains 17 to 22 p.c. of a resin (m.p. 105°) soluble in alcohol; 5 to 6 p.c. of a resin (m.p. 145°) insoluble in alcohol, but soluble in ether; 7 to 9 p.c. of a resin (m.p. 175°) insoluble in alcohol and ether, but dissolving in caustic potash; and 44 to 60 p.c. of insoluble bitumen.

Baltic amber is usually pale yellow, ranging to brown or reddish-brown in colour, and it varies from perfect transparency to opacity. The varying degrees of turbidity are due to the presence of vast numbers of microscopic air-bubbles. The enclosure of insects and fragments of wood and dirt in amber is well known, and points at once to the mode of origin of the material. According to differences in colour and transparency, various trade names are applied, such as 'clear,' 'flohmig,' 'cloudy,' 'bastard,' 'osseous' or 'bone,' and 'frothy.' The sp.gr. ranges from 1·05 to 1·10 (varying with the porosity); and the hardness is 2½, being rather higher than that of most other resins, which latter can be scratched with the finger-nail. The material is brittle and breaks with a conchoidal fracture. When cut with a knife, parings are not obtained, but only powder. It can be turned on the lathe and takes a good polish, being worked with whiting and water or rotten-stone and oil, and finished by friction with a flannel. When heated, amber begins to soften at about 150°, giving a characteristic odour; it melts at 350°–375°, that is, at a higher temperature than other resins, giving dense white fumes with a peculiar aromatic odour, and causing violent coughing. When rubbed it becomes negatively electrified (from the ancient name *electron*, for amber, the word 'electricity' is derived); and when rubbed vigorously it emits an aromatic odour, but does not become sticky like other resins. These characters serve to distinguish true amber from the more abundant copal; the latter is further usually clearer, lighter in colour, and more gummy in appearance.

In the trade the material is sorted into many grades suited for various purposes. The larger pieces of better quality ('work-stone') are cut into beads and other small personal ornaments, and are largely used for making the mouth-pieces of tobacco-pipes and cigar- and cigarette-holders. Smaller and impure fragments ('varnish') are melted down for the manufacture of amber varnish and lac; but in recent years such material is largely converted by the application of heat and hydraulic pressure into blocks of *pressed amber* or 'ambroid.' About 35,000 kilos of pressed amber is now produced annually from three times the amount of rough amber; it is cut for ornaments and smokers' mouth-pieces. Prices (current in 1908) for rough 'work-stone' vary, according to size and quality, from 11*l.* to 10*s.* per kilo, and for smaller, inferior material ('varnish') about 5*s.* per kilo. Pressed amber fetches 4*l.* to 5*l.* per kilo. The production and the trade in amber, as well as the literature of the subject, is almost exclusively German, though the finished articles are largely made in Vienna.

Other varieties of fossil resin closely allied to amber, but regarded as distinct from Prussian or Baltic amber (succinite), are the following:—

Beckerite (E. Pieszczek, 1880), a black resin occurring with Prussian amber.

Burmite, Birmite, or Burmese amber (F. Noetling, 1893), a dark reddish-brown, amber-like resin, which has long been mined in Upper Burma and used in China. It is found in large masses, one seen by the writer weighing 33½ lbs., whilst the largest piece of Prussian amber yet found weighs only 9·7 kilos (21¼ lbs.).

Chemawinite (B. J. Harrington, 1891), Cedarite (R. Klebs, 1897), or Canadian amber, found as pale yellow fragments the size of a pea to that of a walnut on the beach of Cedar Lake, near Chemahawin in Saskatchewan.

Delatynite (J. Niedźwiedzki, 1908), from Delatyn in the Galician Carpathians, differs from succinite in containing rather more carbon (79·93 p.c.), less succinic acid (0·74 1·67 p.c.), and no sulphur.

Gedrite (O. Helm, 1878), a bright, pale yellow resin found with Prussian amber, but differing from this in containing less oxygen and no succinic acid; m.p. 140°.

Glessite (O. Helm, 1881), also found with Prussian amber; it contains no succinic acid, but probably some formic acid; m.p. 200°.

Roumanite, Romanite, Rumanite, or Roumanian amber (O. Helm, 1891), a brownish-yellow to brown resin, found in Tertiary sandstone at several places in Roumania; it resembles Prussian amber in containing some succinic acid (0·3–3·2 p.c.), and is characterised by the relatively large amount of sulphur (1·15 p.c.); m.p. 300°.

Simetite, or Sicilian amber (O. Helm and H. Conwentz, 1886), a clear wine-red to garnet-red resin, remarkable for its beautiful green or blue fluorescence, found in the river Simeto and other parts of Sicily. It contains only 0·4 p.c. of succinic acid.

Stantienite (E. Pieszczek, 1880), a brown resin occurring with Prussian amber.

For several papers on amber and amber-like resins, by O. Helm and by P. Dahms, *see* Schr. natf. Ges. Danzig, vols. iv–xii (1878–1908). *See* also Max Bauer, Edelsteinkunde, 2nd edit. 1909, and English transl. (Precious Stones), by L. J. Spencer, 1904. L. J. S.

AMBER, OIL OF. When amber is heated it softens, fuses, and gives off succinic acid, water, oil, and a combustible gas. If the residue (colophony of amber) be more strongly heated, a colourless oil passes over. These oils, according to Pelletier and Walter (Ann. Chem. Phys. [3] 9, 89), have the composition of oil of turpentine. By distilling with water, a pale-yellow oil, having a strong odour and acrid taste, can be obtained. It blackens and thickens on exposure to air and heat, boils at 86°, and has a sp.gr. of 0·758 at 24°. One part of the rectified oil mixed with 24 parts of alcohol (0·830) and 96 of ammonia, forms *eau de luce*, a celebrated old perfume. By mixing 'eau de luce' with nitric acid, artificial musk is made. Its solution in alcohol was formerly considered as a specific for whooping-cough (*v.* also OILS, ESSENTIAL, and RESINS).

AMBER VARNISH *v.* VARNISH.

AMBERGRIS. (*Ambergris*, Fr.: *Ambra*, *Ambar*, Ger.) (J. Soc. Chem. Ind. 1890, 429.) Is found in the sea, near the coasts of tropical countries, and as a morbid product in the intestines of the cachalot or sperm whale (*Physeter macrocephalus*).

Ambergris is generally found in fragments, but pieces have been obtained weighing upwards of 270 lbs. Its sp.gr. ranges from 0·780 to 0·926 (0·780 to 0·896 Brande, 0·908 to 0·920 Pereira). If of good quality, it adheres like wax to the edge of a knife with which it is scraped, retains the impression of the nails, and emits a fat odoriferous liquid on being penetrated with a hot needle. It is generally brittle, but on rubbing it with the nail it becomes smooth like hard soap. Its colour varies from black to white. Its smell is peculiar, and not easily counterfeited. It melts at 62·2°, at 100° it is volatilised as a white vapour; on a red-hot coal it burns and is entirely dissipated. Water has no action on it; acids, except nitric acid, act feebly upon it; ether and the volatile oils dissolve it; so do the fixed oils, and also ammonia when assisted by heat; alcohol dissolves a portion of it.

The principal constituent of ambergris is *ambrein* (*q.v.*); its inorganic constituents are carbonate and phosphate of calcium, with traces of ferric oxide and alkaline chlorides.

Used by perfumers. The Chinese test its purity by scraping it upon boiling tea, in which it should wholly melt.

AMBERITE *v.* EXPLOSIVES.

AMBLYGONITE. Fluo-phosphate of aluminium and lithium $AlPO_4,LiF$, crystallising in the anorthic system. It is usually found as whitish cleavage masses much resembling felspar in appearance, from which it is distinguished by its higher sp.gr. 3·01–3·09 and chemical characters. It occurs in granitic rocks at Montebras in France, Cácares in Spain (with tin ore), Pala in California, &c. At each of the places named it has been mined for the preparation of lithium salts, the phosphate being a by-product. It contains about 10 p.c. of lithia. A variety in which the lithium is largely replaced by sodium has been found as greyish-white cleavage-masses in pegmatite near Canyon City in Fremont Co., Colorado, and named natramblygonite or fremontite. In another variety, known as montebrasite from Montebras in France, hydroxyl largely replaces the fluorine. The general formula for the mineral is then

$$(Li,Na)Al(F,OH)PO_4$$

L. J. S.

AMBREÏN. (*Ambreine*, Fr.; *Ambarstoff*, Ger.) Isolated by Pelletier and Caventou, by digesting ambergris in hot alcohol, sp.gr. 0·827. Ambreïn $C_{23}H_{40}O$, purified by repeated crystallisations from alcohol, is a white solid, separating in slender needles, m.p. 82°, which exhibit the phenomenon of superfusion for a long time even if sown with crystals. When warm and dry, it becomes highly electrified on slight rubbing. It has no optical activity, and is a neutral substance, insoluble in water, but soluble in most organic solvents, from which it does not crystallise out at all readily. When acted on by bromine in carbon tetrachloride solution, it gives an *octobromo-* derivative $C_{23}H_{32}OBr_8$, a white vitreous solid. Chlorine, under similar conditions, decomposes it. On warming ambreïn with phosphorus pentachloride, a white, amorphous mass of *pentachloro-ambrein* $C_{23}H_{35}OCl_5$ is obtained (Riban, Compt. rend. 1912, 154, 1729).

AMBRITE. A brown translucent resin, similar to retinite, found in association with New Zealand coal (*v.* RESINS).

AMEISINE. Trade name for aluminium formate.

AMENYL. Trade name for the *hydrochloride* of *methyl hydrastimide*. Forms yellowish needles, m.p. 227°. Soluble in hot water or alcohol.

AMERICAN COW or **MILK TREE WAX** *v.* WAX.

AMERICAN ELEMI *v.* OLEO-RESINS.

AMETHYST. A purple transparent variety of crystallised quartz (SiO_2), used as a gem-stone. So named, from ἀμέθυστος, 'not drunken,' owing to the ancient belief that the stone when worn as a charm prevented intoxication (*v.* QUARTZ). L. J S.

AMETHYST. Tetramethyl safranine and tetraamyl safranine are found in commerce under this name (*v.* AZINES).

AMETHYST, ORIENTAL, *v.* CORUNDUM.

AMIANTHUS (*Amiante,* Fr.) *Mountain flax* (*v.* ASBESTOS)

AMIDASE *v.* ENZYMES.

AMIDATION. The operation of introducing the amino group NH_2, as in the production of aniline from nitrobenzene by means of iron and hydrochloric acid.

AMIDE POWDER. An explosive similar to ordinary gunpowder, in which, in place of the sulphur, an ammonium salt is employed in combination with saltpetre, in such proportions that on ignition potassamide, volatile at high temperatures, is formed. This increases the useful effect of the explosive, which burns without residue (Gaens, Eng. Pat. 14412, 1885; J. Soc. Chem. Ind. 5, 678).

AMIDINES. Compounds containing amidogen and imidogen attached to the same carbon atom, *e.g.* *acetamidine* $CH_3{\cdot}C(NH)NH_2$; *benzamidine* $C_6H_5C(NH)NH_2$. They are formed by the action of amines on thio- amides or nitriles, or on the products formed by acting on the amides with phosphorus pentachloride, or by treating the cyanamides with the Grignard reagent (Adams and Beebe, J. Amer. Chem. Soc. 1916, 38, 2768).

AMIDOAZOBENZENE or **ANILINE YELLOW** *v.* AZO- COLOURING MATTERS.

AMIDOGENE. An explosive made by dissolving 73 parts of potassium nitrate and 1 part magnesium sulphate in one-third their weight of boiling water; 8 parts of ground wood charcoal, 8 parts of bran, and 10 parts of sulphur are added, and the whole is digested for two hours at 140°; it is then dried at 50° and made into cartridges (Gemperle, J. Soc. Chem. Ind. 3, 191; 1, 201; Biedermann's Chem. Tech. Jahrb. 7, 146).

AMIDOGUANIDINE *v.* HYDRAZINES.

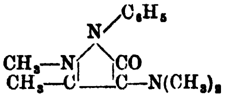
AMIDOL. Trade name for 2:4-diaminophenol hydrochloride, used as a photographic developer.

AMIDONAPHTHOLS *v.* AZO- COLOURING MATTERS.

AMIDONAPHTHOPHENAZINE *v.* AZINES.

AMIDOPHENOPHENANTHRAZINE *v.* AZINES.

AMIDOPYRINE (*Pyramidon*). Trade names for 4-dimethylamino antipyrine.



Prepared by treating an acid solution of antipyrine with sodium nitrite, reducing the nitroso-antipyrine to amino-antipyrine, condensing with benzaldehyde, and decomposing the benzylidene derivative with hydrochloric acid. The product on methylation yields amidopyrine.

AMINES. Amines or 'ammonia bases' may be regarded as substances derived from ammonia by the substitution of hydrocarbon radicals for hydrogen. They may also be looked upon as derived from hydrocarbons by the replacement of one or more hydrogen atoms by NH_2 or its alkyl substitution products NHR or NRR′. The definition of the term may be taken to include alkyl derivatives of hydrazine and hydrazoic acid, and compounds such as nitrosamines diazo-compounds; also others which contain nitrogen linked to nitrogen or elements other than carbon, as well as to alkyl- residues. It also includes compounds in which the nitrogen forms part of a ring, as in pyridine, pyrrol, and their derivatives, among which the alkaloids may be mentioned. The majority of these more complex substances are treated of in detail in special articles (*see* arts. AZO-COLOURING MATTERS; AZINES; BONE OIL; QUINOLINE, &c.), and come within the scope of this only in so far as they possess the general characteristics of the ammonia bases.

Amines are classed as primary, secondary, or tertiary, according as one, two, or three of the hydrogen atoms of ammonia have been replaced by alkyl or aryl groups. Thus the general formula of the primary amines is NH_2R, of the secondary amines NHRR′, and of the tertiary amines NRR′R″, where R, R′, and R″ may be identical or represent different radicals. The reactions of the amines differ to some extent according as the substituting radicals are (1) all aliphatic; (2) mixed aliphatic and aromatic, with the nitrogen attached to the aliphatic residue, as in benzylamine; (3) mixed aliphatic and aromatic, with the nitrogen attached to a carbon atom of the benzene ring, as in methyl aniline; and (4) pure aromatic amines such as aniline itself, di- and tri-phenylamine, and their homologues. Substances of groups (1) and (2) will be referred to here as aliphatic and aromatic amines respectively, and those of groups (3) and (4) as aromatic amino- compounds. Aromatic amino- compounds serve as the starting materials in many of the different branches of the dyeing industry, and are prepared artificially in large quantities (*see* arts. ANILINE; AZO- COLOURING MATTERS; TRIPHENYLMETHANE COLOURING MATTERS; DIPHENYLAMINE, &c.).

With the important exception of the vegetable alkaloids, the amines are not widely distributed in nature, though some of the lower members of the fatty series (methylamines) occur in plants and in the blood of some animals. They are, however, found as decomposition products of animal and vegetable organisms, and of mineral substances. Thus the methylamines are found in herring brine and in decomposing fish. Others, chiefly diamines, are found in certain pathological conditions of the urine, and as decomposition products of the animal tissues (ptomaines). The decomposition of proteins give rise to large numbers of amino-acids. Aniline was first isolated as a product of the distillation of indigo, and it and its homologues as well as other bases are present in the distillates from bone oil (Dippel's oil), and of coal tar. A mixture of fatty amines is obtained in the dry distillation of the residues in the beet-sugar industry, and this, under the name of 'trimethylamine,' of which it contains about 5 p.c., is used in France for the preparation for industrial purposes of methyl chloride; on account of the greater solubility of its hydrochloride, it has also been used instead of ammonia in the preparation of potassium carbonate, in a manner analogous to the Solvay method for the preparation of sodium carbonate, but the process does not seem to have been commercially successful.

General methods of preparation.

1. *By action of ammonia or its alkyl derivatives on substitution products (generally haloid or hydroxyl derivatives) of hydrocarbons.*

The method first described by Hofmann (Phil. Trans. 1850, 1, 93; 1851, 2, 357), of heating alkyl halides (preferably bromides or iodides) with ammonia, is available for the preparation of primary, secondary, and tertiary amines of the fatty series, and if aniline is substituted for ammonia, for the preparation of secondary, tertiary, and aromatic amino- compounds. Quaternary ammonium compounds are also formed in the reactions, which may be represented as follows:—

$$\mathrm{NH_3 + RBr = NH_2R{\cdot}HBr}$$
$$\mathrm{NH_2R + R'Br = NHRR'{\cdot}HBr}$$
$$\mathrm{NHRR' + R''Br = NRR'R''{\cdot}HBr}$$
$$\mathrm{NRR'R'' + R'''Br = NRR'R''R'''Br}$$

The reaction will take place, though only very slowly, in aqueous solution, more quickly in alcoholic solution, and best on heating in alcoholic solution in sealed tubes at 100°. The products obtained may contain haloid salts of one or all of the possible amines, and of the quaternary bases, and the proportions vary with the conditions of experiment (Werner, Chem. Soc. Trans. 1918, 113, 899; 1919, 115, 1010). On distilling the product with excess of alkali a mixture of the three amines is obtained; the three amines may be separated from the mixture by making use of their different modes of reaction with oxalic ester, the chlorides of aromatic sulphonic acids, Grignard's reagent, acetic anhydride, or acetyl chloride, which are dealt with below. The three ethyl amines have been separated by fractional distillation (Garner and Tyrer, Chem. Soc. Trans. 1916, 109, 174. *Cf.* also Price, J. Soc. Chem. Ind. 1918, 37, 82.

In the preparation on the large scale of secondary and tertiary aromatic amino- compounds, *e.g.* dimethylaniline, the primary amine is heated under pressure directly with the alcohol and hydrochloric or sulphuric acid at 180°–200°. Here the alkyl group is exchanged directly for hydrogen without the intermediate separation of the alkyl halide. The presence of other negative groups in the benzene molecule increases the ease with which the NH_2 group can displace halogen groups. Thus the chlorine atoms of chlorbenzene can be replaced by NH_2 groups by the action of ammonia if the benzene ring also contains NO_2 groups. A catalytic method of preparing mono- and di-methylaniline, in which the vapours of methyl alcohol and aniline are passed over aluminium oxide at 400°–430°, is described by Mailhe and de Godon (Compt. rend. 1918, 166, 467).

Amines may also be obtained by heating zinc ammonium chloride with alcohols at 250°–260° (Merz and Gasiorowski, Ber. 1884, 17, 623).

Alcohols or phenols will react with ammonia or its alkyl derivatives on heating in the presence of zinc chloride, calcium chloride, or other catalytic agent (Merz and Weith, Ber. 1880, 13, 1298; Merz and Mueller, Ber. 1886, 19, 2901).

Mixtures of the vapours of alcohol and ammonia or primary amine led through tubes containing finely divided thoria or tungsten oxide at 360° give amines (Sabatier and Mailhe, Compt. rend. 1908, 148, 898).

Sodamide or its alkyl substitution products may be used instead of ammonia in the case of aliphatic amines.

$$\mathrm{NH_2Na + CH_3Cl = NH_2{\cdot}CH_3 + NaCl}$$

(Lebeau, Compt. rend. 1905, 140, 1042; Chablay, Compt. rend. 1905, 140, 1262). *Cf.* O. Matter, D. R. PP. 301450, 301832. Sodamide will also react with anhydrous sulphuric esters of the aliphatic series, and with aromatic sulphonic acids to give primary amines (Jackson and Wing, Ber. 1886, 19, 902; Titherley, Chem. Soc. Trans. 1901, 79, 399).

By heating ammonium chloride with a concentrated solution of formaldehyde under pressure, methylamine, dimethylamine, and trimethylamine are successively produced (Eschweiler, D. R. P. 80520, 1893).

2. *By reduction of nitrogen-containing substances.*

Primary amines may be obtained by the reduction of nitro- compounds, nitroso- compounds, oximes, hydrazones, azo- and hydrazo- compounds, amides and amidines, and nitriles. Since the nitro- compounds of aromatic hydrocarbons are easily prepared by direct nitration, the reduction of nitro- compounds is by far the most generally used method for the preparation of aromatic primary amines. Zinin in 1842 prepared aniline from nitrobenzene, by the action of alcoholic ammonium sulphide, and this method is still in use for the reduction of the dinitrobenzenes to the nitroanilines. On the commercial scale, as for instance in the preparation of aniline, iron and water with some hydrochloric acid is usually employed as the reducing agent. Another method for the reduction of nitro- compounds, nitriles, oximes, and hydrazones, consists in heating in a stream of hydrogen in the presence of finely divided nickel or copper (Sabatier and Senderens, Compt. rend. 1902, 125, 225). A great deal of work on this method, resulting in a large number of patents, has been carried out. With a copper catalyst obtained by reducing the carbonate, formate, oxalate, or nitrate by hydrogen or carbon monoxide below red heat, reduction of a nitro- compound is effected by hydrogen at a temperature of 200° C. or less. Higher temperatures lead to impure products and to poisoning of the catalyst (Badische Anilin und Soda Fabrik, D. R. PP. 263396, 1914; 282568, 1915). Other contact agents are described by the same patentees in Eng. Pat. 5692, 1915. According to D. R. P. 282492, 1915 (Meister, Lucius, and Bruning) a quantitative yield of aniline is obtained by passing nitrobenzene, steam, and hydrogen at 120° C., over finely divided nickel. In Eng. Pat. 6409, 1915 (Badische Anilin und Soda Fabrik), the reduction of nitrobenzene by carbon monoxide in presence of steam and a contact agent, is described.

Nitro- compounds may be reduced to primary amines electrolytically, in aqueous or alcoholic acid solution, at zinc, lead, tin, copper, or mercury cathodes, with a current density of 0·18 amp /sq. cm. Tin and lead are particularly effective if they are present on the cathode in a spongy state (C. F. Boehringer and Sohne, D. R. P. 116942, 1900).

The reduction of nitroso- compounds, oximes, and hydrazones, though often useful in the laboratory for preparing special amino-compounds, is seldom of use on the large scale. The reducing agents used are, for nitroso- compounds, such as nitrosophenol, sulphuretted hydrogen in presence of ammonia; for oximes and hydrazones, sodium amalgam and acetic acid.

The reduction of azo- compounds, which takes place according to the equation

$$R{-}N{=}N{-}R'+2H_2=R{-}NH_2+NH_2{\cdot}R'$$

is mainly used in the production of aromatic primary diamines (*cf.* *p*-phenylenediamine, but can be used for the production of aminophenols or their derivatives. Thus (D. R. P. 48543), by diazotising one molecule of *p*-aminophenetol and coupling with phenol the azo- compound $C_2H_5OC_6H_4{-}N_2{-}C_6H_4OH$ is produced, and this on ethylation and reduction gives two molecules of *p*-aminophenetol. The usual reducing agents for azo- compounds are stannous chloride, zinc-dust and water or acetic acid, and sodium hyposulphite ($Na_2S_2O_4$).

Amides, amidines, and nitriles are best reduced by sodium and alcohol.

$$R{\cdot}CO{\cdot}NH_2 \rightarrow R{\cdot}CH_2NH_2$$
$$R{\cdot}CH(NH){\cdot}NH_2 \rightarrow R{\cdot}CH_2NH_2+NH_3$$
$$R{\cdot}CN \rightarrow R{\cdot}CH_2{\cdot}NH_2$$

The formation of methylamine by the reduction of alkali cyanides and ferrocyanides with hydrogen in the presence of colloidal palladium has been patented (Riedel, 1913, D. R. P. 264528). For the catalytic reduction of hydrocyanic acid see Barratt and Titley, Chem. Soc. Trans. 1919, 115, 902.

Secondary amines may be produced by reduction of the *N*-esters of the oximes (Goldschmidt, Ber. 1892, 25, 2594; Dunstan and Goulding, Chem. Soc. Trans. 1897, 71, 573; 1901, 79, 628) or of the *iso*nitriles, or of the condensation products formed by the action of primary amines on aldehydes.

$$(CH_3)_2{\cdot}C\underset{O}{\text{——}}NCH_3 \rightarrow (CH_3)_2CH{\cdot}NHCH_3$$

$$R{-}N:C \rightarrow R{\cdot}NH{\cdot}CH_3$$
$$R{\cdot}N:CH{\cdot}R' \rightarrow RNH{\cdot}CH_2R'$$

A special case of the third reaction—the methylation of primary amines by means of formaldehyde, without isolation of the intermediate condensation product—is of great technical importance. According to a patent of F. Bayer & Co. (D. R. P. 287802, 1916), any primary amine may be methylated by being heated to a high temperature with formaldehyde in presence of some reducing agent other than formaldehyde or formic acid. A process for the preparation of methylaniline by the action of formaldehyde on aniline has been described by G. T. Morgan (Eng. Pat. 18081, 1915). The mechanism of the reactions involved in methylation by formaldehyde has been investigated by E. A. Werner (Chem. Soc. Trans. 1917, 111, 844).

3. *From amides by the action of bromine and potash.* (Hofmann, Ber. 1882, 15, 762.)

This reaction is mainly applicable to the preparation of primary fatty amines, and gives good yields only with the lower members of the series. The first product of the reaction is a bromamide, and this on further treatment with potash gives potassium bromide and an *iso*cyanate, which is saponified, giving an amine and a carbonate, the alkyl group being transferred from the carbon to the nitrogen atom, as in the 'Beckman rearrangement' (Mohr, J. pr. Chem. 1906, [2] 73, 177, 228).

$$CH_3{\cdot}CONH_2+KOH+Br_2$$
$$=CH_3{\cdot}CONHBr+KBr+H_2O$$
$$CH_3{\cdot}CONHBr+KOH=CH_3{\cdot}NH_2+CO_2+KBr$$

Azides on boiling with alcohol or water, and subsequent treatment with conc. HCl give amines.

$$R{\cdot}CO{\cdot}N_3+C_2H_5{\cdot}OH=RNH{\cdot}COOC_2H_2+N_2$$
$$R{\cdot}NH{\cdot}COOC_2H_5+H_2O$$
$$=RNH_2+CO_2+C_2H_5OH$$

(Curtius, Ber. 1894, 27, 779; 1896, 29, 1166; Forster, Chem. Soc. Trans. 1909, 95, 433).

4. *From compounds containing imido (or amido) groups in which one atom of hydrogen is replaceable by alkali metals.*

(*a*) From *iso*cyanates, *iso*thiocyanates, and *iso*cyanides.

Alkyl *iso*cyanates (prepared from metallic *iso*cyanates and alkylhaloids) are hydrolysed by alkalis (Wurtz, Annalen, 1849, 71, 330).

The interest of this method is mainly historical, since it led to the discovery of the amines by Wurtz in 1848. Primary amines are the chief product, but secondary and tertiary amines are also formed in small quantities.

$$C_2H_5NCO+H_2O=C_2H_5{\cdot}NH_2+CO_2$$

Alkyl *iso*thiocyanates and *iso*cyanides are hydrolysed by treatment with concentrated hydrochloric acid.

$$C_2H_5NCS+H_2O=C_2H_5{\cdot}NH_2+COS$$
$$C_2H_5NC+H_2O=C_2H_5{\cdot}NH_2+HCOOH$$

(*b*) Phthalimide, on treatment with alcoholic potash, gives potassium phthalimide, and this gives an alkyl derivative on treatment with alkyl iodide, which on hydrolysis with fuming HCl yields a primary amine.

$$C_6H_4(CO)_2NK+RI=C_6H_4(CO)_2NR+KI$$

$$C_6H_4(CO)_2NR+2H_2O=C_6H_4(COOH)_2+NH_2R$$

(Gabriel, Ber. 1887, 20, 2224; 1891, 24, 3104). Gabriel and Ohle (Ber. 1917, 50, 804, 819) find that alkylene oxides will react with potassium phthalimide with the ultimate formation of aminohydroxy compounds.

(*c*) A similar method, available for the preparation of secondary amines from primary, is due to Hinsberg (Annalen, 1891, 179, 265). The sodium derivative of a substituted benzenesulphonamide (derived from the action of benzene sulphonylchloride on a primary amine) is treated with an alkyl iodide, and the product hydrolysed with hydrochloric acid at 120°–180°.

$$C_6H_5SO_2{\cdot}NR{\cdot}Na \rightarrow C_6H_5SO_2{\cdot}NRR' \rightarrow NHRR'$$

Johnson and Ambler use toluene-ω-sulphonamides in the same way (J. Amer. Chem. Soc. 1914, 36, 372). E. Fischer finds that a better yield of the amine is obtained by treating the disubstituted sulphonamide with hydriodic acid and phosphonium iodide (Ber. 1915, 48, 93).

(*d*) The derivatives of the amides of the carboxylic acids, though less suitable, on account of their less acidic properties, can be used in the same way as the derivatives of the sulphonamides (Titherley, Chem. Soc. Trans. 1901, 79, 399).

(5) *From compounds which certain substances form with alkyl haloids.*

(*a*) Hexamethylene tetramine, formed by the action of ammonia on formaldehyde, gives addition compounds of the type $C_6H_{12}N_4{\cdot}RI$ with alkyl iodides. These on treatment with HCl and alcohol are decomposed, giving primary amines (Delépine, Compt. rend. 1897, 124, 292; Ann. Chim. Phys. 1898, [7] 15, 508).

(*b*) Magnesium alkyl iodides form addition compounds with phenyl *isocyanate*; these, on treatment with water are converted into anilides, which yield amines on saponification (Blaise, Compt. rend. 1901, 132, 38, 478, 978).

6. *By distillation of amino- acids with baryta.*

$$CH_3CH\left\langle\begin{matrix}COOH\\NH_2\end{matrix}\right. = CH_3{\cdot}CH_2{\cdot}NH_2 + CO_2$$

7. *Aliphatic primary and secondary amines may be obtained by the action of potash on the p-nitroso- derivatives of secondary and tertiary aromatic amino- compounds.*

$$NO{\cdot}C_6H_4{\cdot}N(CH_3)_2 + KOH$$
$$= NO{\cdot}C_6H_4{\cdot}OK + N(CH_3)_2H$$

$$NO{\cdot}C_6H_4{\cdot}NHCH_3 + KOH$$
$$= NO{\cdot}C_6H_4{\cdot}OK+NH_2{\cdot}CH_3$$

8. *Tertiary amines can be obtained by heating primary and secondary bases with excess of potassium alkyl sulphate.*

$$RR'NH+CH_3OSO_3K=RR'NCH_3+HOSO_3K$$

General Properties.

The amines of the aliphatic series are volatile inflammable substances, the lower members being gases or liquids with low boiling-points, very soluble in water and strongly alkaline to litmus; the density of the liquid members of the series is about 0·75 that of water, and increases slightly with increase in the molecular weight. Their basicity, measured by the conductivity method, is considerably greater than that of ammonia, and they will saponify esters and precipitate oxides from the salts of many of the heavy metals. They have an ammoniacal and fishy odour. The smell, inflammability, boiling-point, and solubility in water become less with increase in the molecular weight, and the highest known members are odourless solids at ordinary temperatures. They react with moist air with formation of

carbonates. Aromatic amines (benzylamine and its homologues) closely resemble the aliphatic amines, but are not quite so strongly basic in character, owing to the presence of the negative phenyl group. The aromatic amino-compounds (aniline and its homologues) are less basic than ammonia, and the basicity diminishes with increase of the number of phenyl-groups attached to the nitrogen atom. Thus the salts of diphenylamine are hydrolysed by water to a greater extent than those of aniline, whilst triphenylamine is a neutral body and forms no salts with acids. Comparatively few amines are known which contain only aromatic groups; of these aniline and diphenylamine are prepared on the large scale in the dyeing industry, as well as many secondary and tertiary amino compounds containing both fatty and aromatic groups.

The aromatic amines are much more easily substituted by halogens, the nitro group and the sulphonic group than the hydrocarbons from which they are derived, and the substituted derivatives obtained are of great importance in the dye industry. In substituting with halogens or nitric acid it is often necessary to protect the amino group by acetylation, the acetyl group being subsequently removed. The purely aliphatic amines find little use outside synthetical chemistry. Some are used in the preparation of drugs; they have also been used (as well as derivatives of aromatic amines) as catalysts in the vulcanisation of rubber (Twiss, J. Soc. Chem. Ind. 1917, 780).

The above lists of the chief homologues of methylamine and aniline are taken from Meyer and Jacobsen's Lehrbuch der Organischen Chemie.

All classes of amines form addition products with acids, containing one molecule of base to one molecule of monobasic acid. Compounds containing three molecules of HCl to one of amine have also been obtained (Korczynski, Ber. 1908, 41, 4379). The picrates are specially characteristic, and are used for the identification of the amines, as are also the double salts with platinum and gold chlorides, which have the general formulæ $B_2H_2PtCl_6$ and $BHAuCl_4$ respectively. Many aliphatic amines form hydrates with one molecule of water of crystallisation. Double salts with mercuric chloride and stannous and stannic chlorides (Druce, Chem. Soc. Trans. 1918, 113, 715), and with silver salts, crystallise well, and organic analogues of ammonium pyrophosphate and arsenate are known, but are not very stable (Brisac, Bull. Soc. chim. 1903, [3] 29, 591). With alkyl halides they form quaternary ammonium compounds of the type $NRR'R''R'''I$, where $RR'R''R'''$ may be the same or different radicals. In cases where these radicals are all different, the substances are capable of existing in two enantiomorphous optically active forms, and a number of these have been isolated. Enantiomorphic compounds of the type $RR'R''N{=}O$ have also been isolated (Meisenheimer, Ber. 1908, 41, 3966; Annalen, 1911, 385, 117). The quaternary ammonium compounds, unlike their inorganic analogues, are not decomposed on boiling with potash; on heating alone they give tertiary amines and alkyl halides. The corresponding bases are obtained from their halides by treatment with moist silver oxide; they are strongly alkaline to litmus, and the solutions generally decompose easily on evaporation, but some of the aliphatic members have been obtained crystalline by evaporation *in vacuô*. The rate of formation of quaternary ammonium compounds from tertiary amines and alkyl haloids is found to vary greatly with the constitution of the reacting substance and the nature of the solvent (Menschutkin, Zeitsch. physikal. Chem. 1890, 6, 41; Wedekind, Ber. 1899, 32, 511; Annalen, 1901, 318, 90; Preston and Jones, Chem. Soc. Trans. 1912, 101, 1930; Thomas, Chem. Soc. Trans. 1913, 103, 594).

The formation of quaternary ammonium compounds by addition of excess of methyl iodide to an amine gives a quantitative method for the determination of the number of replaceable hydrogen atoms in the substance. Analysis of the original compound and of its quaternary methyl derivative gives the number of methyl groups which have entered into the molecule.

Compounds containing five hydrocarbon radicals attached directly to nitrogen were for a long time thought to be incapable of existence. Such compounds have now been isolated by Schlenk and Holtz (Ber. 1916, 49, 603; 1917, 50, 274).

With several reagents, the different classes of amines show different reactions, and separation and purification of the amines formed in many of the methods above referred to may be carried out by making use of such differences. Primary and secondary amines sometimes give similar reactions, whilst tertiary amines are more stable.

Reactions.

1. *With nitrous acid.*

Primary amines, on boiling with potassium or sodium nitrite in acid solution, give alcohols or phenols with evolution of nitrogen.

$$RNH_2+HONO = ROH+N_2+H_2O$$

In many cases where a primary alcohol would be expected a mixture of primary and secondary alcohols is obtained (Henry, Compt. rend. 1907, 145, 899, 1247).

Secondary amines give nitrosamines, which on boiling with conc. HCl are again transformed into the original amines.

$$RR'NH+HONO = RR'N{\cdot}NO+H_2O$$
$$RR'N{\cdot}NO+2HCl = RR'NH{\cdot}HCl+NOCl$$

Tertiary amines do not react.

Primary aromatic amino- compounds react differently if their solutions are kept cooled. They give diazo- compounds according to the following equation:—

$$RNH_2,HCl+HONO = RN:NCl+2H_2O.$$

This reaction is of the greatest importance, for the diazo- compounds are very unstable, and on treatment with various substances either form substitution products of benzene hydrocarbons with evolution of nitrogen, or retain the nitrogen and form azo- compounds, which are the parent substances of the azo- dyes. Thus, if the diazo- compound be boiled with water, alcohol, cuprous chloride, bromide, or cyanide, phenol, benzene, chlor- brom- or cyan- derivatives respectively are produced. If the diazo- compound is treated with a substance containing a phenol or aromatic amino- group, a coloured substance is formed which is capable of fixing itself as a dye on a fabric. Compounds derived from unsubstituted amines have only a limited application for dyeing purposes, as they are generally insoluble in water; the sulphonic acids derived from them are, however, generally soluble, and are used extensively (*see* art. AZO-COLOURING MATTERS). The reactions are expressed by the following equations:—

$$C_6H_5N_2Cl+C_6H_5OH=C_6H_5N:NC_6H_4OH+HCl$$
$$C_6H_5N_2Cl+C_6H_5N(CH_3)_2$$
$$=C_6H_5N:NC_6H_4N(CH_3)_2+HCl$$

Tertiary aromatic compounds, such as dimethylaniline, react with nitrous acid to form *p*-nitroso compounds, where the nitroso nitrogen is attached to the carbon of the benzene ring in the para- position to the substituted amino- group. These are highly coloured substances, and serve as intermediate compounds in the production of certain colouring matters (methylene blue, &c.), which are used in the colour industry. On treatment with caustic potash they give secondary amines and salts of nitroso phenol.

Since nitrites of primary, secondary, and tertiary amines have been isolated (Wallach, Chem. Zentr. 1907, ii. 54; Neogi, Chem. Soc. Trans. 1912, 101, 1610; and 1914, 105, 1270), it is probable that in all the above-mentioned reactions the nitrite of the amine is formed as an intermediate product.

2. *With chlorides of aromatic sulphonic acids.*

Primary and secondary amines in strong alkaline solution are converted into amides by shaking with chlorides of aromatic sulphonic acids; tertiary amines do not react. Of these amides, $Ph{\cdot}SO_2NHR$ and $PhSO_2NRR'$ respectively, the first only are soluble in dilute alkalis with formation of salts. The primary and secondary amines can be regenerated from the amides by boiling with conc. HCl or H_2SO_4 at 120°–150° (Hinsberg, Ber. 23, 2963; Annalen, 1891, 265, 178). E. Fischer (Ber. 1915, 48, 93) recommends hydrolysis by hydriodic acid and phosphonium iodide. These reactions provide the only generally applicable method for separating mixtures of primary, secondary, and tertiary amines.

3. *With acetyl chloride or acetic anhydride.*

Primary and secondary amines give, as a rule, acetyl derivatives which are insoluble in cold water; tertiary amines either do not react, or form soluble acetates and hydrochlorides. The primary and secondary amines may be regenerated by hydrolysis of the acetyl derivatives. Since the velocity of the formation of the acetyl derivative of the primary is much greater than that of the secondary amine, a method based on this difference in property has been used to separate the two (Menschutkin, Chem. Zentr. 1900, 1, 1071; Potozki and Gwosdow, *ibid.* 1903, ii. 339).

The action of benzoy chloride is similar to that of acetyl chloride.

4. *With oxalic ester.*

Several of the aliphatic primary and secondary amines react with ethyl oxalate, the former giving solid diamides and the latter liquid oxamic esters. Tertiary amines do not react. Primary and secondary amines are regenerated by boiling with potash (Hofmann, Ber. 1870, 3, 109, 776; Duvillier and Buisine, Ann. Chim. Phys. [5] 23, 299). Hofmann used these reactions for the separation of the three ethylamines, and it has been used since in other cases.

5. *With magnesium methyl iodides.*

Primary amines react, giving two molecules of methane for every molecule of amine:

$$RNH_2+2MeMgI = RN(MgI)_2+2CH_4$$

Secondary amines react in a similar manner, but give one molecule of methane for every molecule of amine:

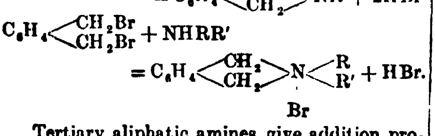
$$RR'NH+CH_3MgI = RR'NMgI+CH_4$$

Tertiary amines either do not react or they form addition compounds with the reagent (Sudborough and Hibbert, Chem. Soc. Trans. 1909, 95, 477; Hibbert and Wise, Chem. Soc. Trans. 1912, 101, 344).

6. *With o-xylylene bromide.*

Primary amines react, giving two molecules of HBr and liquid derivatives of *o*-xylyleneimine (dihydro*iso*indol)

Secondary amines react, giving crystalline quaternary ammonium bromides and one molecule of HBr:



$$C_6H_4<\begin{array}{l}CH_2Br\\CH_2Br\end{array}+NH_2R = C_6H_4<\begin{array}{l}CH_2\\CH_2\end{array}>NR+2HBr$$

$$C_6H_4<\begin{array}{l}CH_2Br\\CH_2Br\end{array}+NHRR' = C_6H_4<\begin{array}{l}CH_2\\CH_2\end{array}>\underset{Br}{N}<\begin{array}{l}R\\R'\end{array}+HBr.$$

Tertiary aliphatic amines give addition products of one molecule of xylylenebromide with two of amine. Tertiary aromatic amines and amino- compounds do not react (Scholtz, Ber. 1898, 31, 1707).

7. *With aromatic aldehydes.*

Primary and secondary amines form compounds with loss of water:

$$C_6H_5CHO+NH_2R = C_6H_5CHNR+H_2O.$$
$$C_6H_5CHO+2NRR'H = C_6H_5CH(NRR')_2+H_2O.$$

Tertiary amines do not react (Schiff, Annalen, 159, 159).

8. *With chloroform and potash.*

Primary amines give isocyanides on warming,

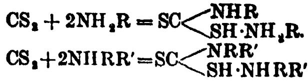
$$RNH_2+CHCl_3+3KOH = RNC+3KCl+3H_2O$$

(Hofmann, Ber. 3, 767).

Secondary and tertiary amines give no characteristic reaction.

9. *With carbon disulphide.*

Aliphatic primary and secondary amines react as follows:—



$$CS_2+2NH_2R = SC<\begin{array}{l}NHR\\SH\cdot NH_2R.\end{array}$$

$$CS_2+2NHRR' = SC<\begin{array}{l}NRR'\\SH\cdot NHRR'.\end{array}$$

On boiling the product of the action of CS_2 on primary amines with metallic salts ($HgCl_2$ or $FeCl_3$), mustard oils are produced, and primary amines partly regenerated.

$$SC<\begin{array}{l}NHR\\SH\cdot NH_2R\end{array} = SCNR+H_2S+NH_2R.$$

(Hofmann, Ber. 8, 105, 461; 14, 2754; 15, 1290).

Aromatic amines give substituted thioureas.

$$2RNH_2+CS_2=H_2S+(RNH)_2CS.$$

10. *With the alkali metals.*

Primary and secondary amines dissolve with evolution of hydrogen and formation of substances of the type RNHK or RNK_2. Tertiary amines do not react.

11. *With oxidising agents.*

Oxidation with potassium permanganate decomposes aliphatic amines with formation of aldehydes and acids.

With Caro's acid (H_2SO_5), primary amines of the type RCH_2NH_2 are oxidised to hydroxylamines and hydroxamic acids, all of which give a characteristic colouration with ferric chloride. Ketoximes are formed from amines of the type $RR'CH\cdot NH_2$, whilst those of the type $RR'R''C\cdot NH_2$ give nitroso- and nitro- derivatives (Bamberger, Ber. 1902, 35, 4293; 1903, 36, 710).

With hydrogen peroxide aliphatic, secondary, and tertiary amines give hydroxylamines and N-oxides of type RR'NOH and RR'R''NO (Dunstan and Goulding, Chem. Soc. Trans. 75, 1104).

Oxidation of aniline and its para compounds gives quinone.

12. *With hypochlorous acid.*

Tertiary amines react with hypochlorous acid to give a dialkylchloramine (Meisenheimer, Ber. 1913, 51, 166):

$$(CH_3)_3N+2HClO = (CH_3)_2N\cdot Cl+CH_2O+H_2O+HCl$$

DIAMINES.

These may be regarded as derived from hydrocarbons by replacement of two hydrogen atoms by two amino- groups, or from two molecules of ammonia by replacement of two hydrogen atoms one from each molecule by a hydrocarbon residue. Certain of them occur as decomposition products of the animal organism, the chief of these being *putrescine* (tetramethylene diamine), and *cadaverine* (pentamethylene diamine). Diamino- acids are an important product of the decomposition of proteins.

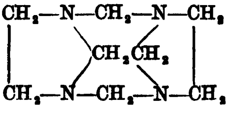
Preparation.—The methods are entirely analogous to those used in the preparation of monamines. Aliphatic diamines are obtained by the action of aqueous ammonia on dihalogen derivatives of hydrocarbons; this method is not generally applicable to the preparation of aromatic mono- or diamino- compounds, but a modification of it, which consists in treatment of *p*-chlormonamines with aqueous ammonia in presence of copper salts, is used in the commercial manufacture of *p*-phenylene diamine and its homologues (Ger. Pat. 204848, 1908). Aromatic diamino- compounds are prepared on the commercial scale chiefly by the reduction of dinitro- compounds; but practically all the methods for the production of monamines are also available for that of diamines.

Properties.—The aliphatic diamines are strongly basic substances, their basicity increasing with the number of methylene groups (Bredig, Zeitsch. physical. Chem. 1894, 13, 308). Their boiling-points are much higher than those of the corresponding monamines. Their hydroxides, which are diacid bases, are extremely stable, and are only decomposed on boiling with caustic alkalis or distillation over metallic sodium. The list of the chief aliphatic diamines and their physical constants (*see* p. 133) is taken from Meyer and Jacobsen's Lehrbuch der Organischen Chemie. The unsubstituted aromatic diamino compounds differ from the corresponding monamines by being easily soluble in water. Their solutions in water are easily oxidised, but the dry bases are stable in air.

Reactions.—Diamines give the ordinary reactions characteristic of the amino- group, but primary aromatic *o*-amino- compounds and to some extent aliphatic diamines, possess in addition, the property of forming condensation products containing nitrogen rings. *m*- and *p*-diamines do not exhibit this property.

1. *With aldehydes.*

With aliphatic diamines, cyclic compounds are formed as well as the ordinary alkylidene bases. Thus the action of formaldehyde on cold solutions of ethylene diamine results in the formation of a compound $C_8H_{18}N_4$, to which the formula



has been assigned (Bischoff, Ber. 1898, 31, 3254).

Aromatic *o*-diamino- compounds give aldehydines or anhydro bases:

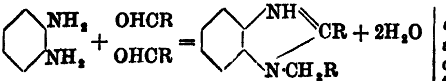
ακ-diaminodecane . . .	$NH_2(CH_2)_{10}NH_2$	61·5°	140° (12 mm.)	—
βη-dimethyl-βη-diaminooctane	$(CH_3)_2C(NH_2)(CH_2)_4(NH_2)C(CH_3)_2$	31°	226°–229°	0·8344 $\left(\frac{28°}{0°}\right)$



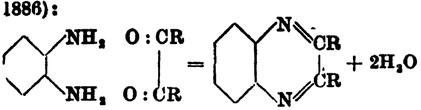
(Ladenburg and Engelbrecht, Ber. 1878, 11, 1653; Hinsberg, *ibid.* 1886, 19, 2025).

The aldehydines are strongly basic bodies, and not decomposed on boiling with dilute acids and alkalis. They are very stable towards oxidising and reducing agents. Their derivatives are used as dyes.

p- and *m*-diamines give alkylidene bases.

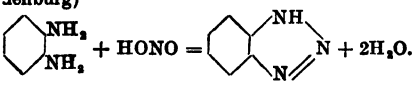
2. *With 1.2-dicarbonyl compounds* (*aldehydes or ketones*).

o-Diamino compounds react to give quinoxaline (azine) derivatives (Hinsberg, Annalen, 342, 1886):



3. *With nitrous acid.*

o-Diamino- compounds form azimines (Ladenburg)



Diamino- compounds both *m*- and *p*- will react in the ordinary way in presence of much hydrochloric acid, giving bis-diazo- compounds; in neutral solutions *m*-diamino- compounds give triamino azo benzene and its homologues. The reaction in the case of *m*-phenylene diamine is:

$$2C_6H_4(NH_2)_2 + HONO$$
$$= NH_2{\cdot}C_6H_4{\cdot}N:N{\cdot}C_6H_3(NH_2)_2.$$

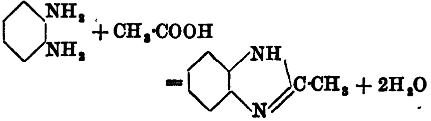
The substances formed are brown and very deeply coloured. The reaction is used as a test for the presence of nitrites in water analysis (Griess, Ber. 1878, 11, 624).

Aliphatic diamines give glycols and oxides

4. *With organic acids, acid chlorides or anhydrides.*

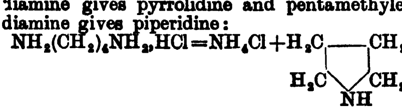
Aliphatic diamines and *m*- and *p*-diamino- compounds form normal derivatives; in the cases of aliphatic substances, these derivatives are partially decomposed on heating, giving cyclic compounds of the iminoazole type:

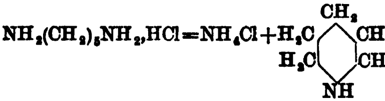
o-Diamino- compounds give similar compounds, without the intermediate formation of the acyl derivative:



5. *With mineral acids.*

All diamines form stable salts. Those of the aliphatic series are decomposed on heating with separation of ammonium salt and formation of cyclic compounds. Thus, tetramethylene diamine gives pyrrolidine and pentamethylene diamine gives piperidine:





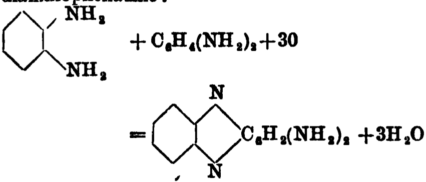
The higher homologues, however, do not form ring compounds containing a corresponding number of atoms in the ring. Thus, octomethylene diamine hydrochloride, on heating, does not give octomethylene imine, which would contain a ring of nine atoms, but 2-butylpyrrolidine. Similarly, decamethylene diamine gives 2-hexylpyrrolidine (Blaise and Houillon, Compt. rend. 1906, 142, 1541; 1906, 143, 361).

The aromatic diamines are the starting-points for the preparation of a large number of dyes, and hence are of commercial importance. The following are the chief members of the series:—

o-Phenylenediamine $C_6H_4(NH_2)_2$. First obtained by Griess by the distillation of *o-m*- and *m-p*- diaminobenzoic acid:

$$\underset{(1,\,2,\,3,\text{ or }1,\,3,\,4)}{C_6H_3(COOH)(NH_2)_2} = \underset{(1,\,2)}{C_6H_4(NH_2)_2} + CO_2$$

(J. pr. Chem. [2] 3, 143). By the reduction of *o*-nitraniline $C_2H_4(NO_2)$ (NH_2) (1, 2) (Zincke and Sintenis, Ber. 6, 123), or of *o*-dinitrobenzene $C_6H_4(NO_2)_2$ (1, 2) (Rinne and Zincke, Ber. 7, 1374), with tin and hydrochloric acid.—Crystallises from water in laminæ, melting at 102°. Boils at 252°. Readily soluble in water, alcohol, and ether. Diacid base, the sulphate $2[C_6H_4(NH_2)_2,H_2SO_4]\ 3H_2O$ forms nacreous laminæ. It gives all the reactions for *o*-diamino-compounds referred to above. On oxidation with ferric chloride it gives a red compound, diaminophenazine:



m-Phenylenediamine $C_6H_4(NH_2)_2$. By reducing *m*-dinitrobenzene or *m*-nitraniline with iron filings and acetic acid (Hofmann, Proc. Roy. Soc. 11, 518; 12, 639), or with tin and hydrochloric acid (Gerdemann, Zeitsch. f. Chem. 1865, 61). By reducing either (1, 2, 4)- or (1, 2, 6)-dinitrobenzoic acid with tin and hydrochloric acid, the carboxyl group being eliminated in the process (Zincke and Sintenis, Ber. 5, 791; Griess, Ber. 7, 1223). On a manufacturing scale it is prepared by reducing dinitrobenzene with iron turnings and hydrochloric acid.—Separates from its solutions as an oil which does not readily solidify unless brought in contact with a crystal of the base. Melts at 63°, and boils at 287°. Readily soluble in water. It gives the typical reactions of *m*-diamino- compounds (*see* above).

By the action of a diazobenzene salt on *m*-phenylenediamine, *chrysoïdine* (unsymmetrical diamidoazobenzene) is produced:

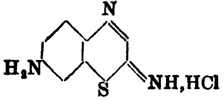
$$C_6H_5N_2Cl + C_6H_4(NH_2)_2$$
$$= HCl + C_6H_5N:N{\cdot}C_6H_3(NH_2)_2.$$

In the manufacture of phenylene-brown and chrysoïdine the solution of crude *m*-phenylenediamine hydrochloride obtained by the reduction of *m*-dinitrobenzene is employed, without first isolating the base. A violet colouring matter is obtained by heating *m*-phenylenediamine with aniline hydrochloride to 190°–200°, and a blue colouring matter by heating it with *m*-phenylenediamine hydrochloride (Krause, Ber. 9, 835).

p-Phenylenediamine $C_6H_4(NH_2)_2$. Obtained by reducing *p*-dinitrobenzene (Rinne and Zincke, Ber. 7, 871), or *p*-nitraniline (Hofmann, Proc. Roy. Soc. 12, 639), or aminoazobenzene (Martius and Griess, J. pr. Chem. 97, 263), with tin and hydrochloric acid, aniline being formed simultaneously in the case of aminoazobenzene. Along with diaminodiphenylamine by reducing aniline-black with tin and hydrochloric acid or with hydriodic acid and amorphous phosphorus (Nietzki, Ber. 11, 1097). By distilling (1, 2, 5)-diaminobenzoic acid (Griess, Ber. 5, 200). By action of *p*-chloraniline on aqueous ammonia in presence of copper salts. Crystals, melting at 147°. Boils at 267°. Sublimes in leaflets. Readily soluble in water, alcohol, and ether. Yields quinone on oxidation. When oxidised in the presence of primary amines or phenols it gives indamines and indophenols, these on heating produce safranines. By heating it with sulphur to 150°–180°, it is converted into diaminothiodiphenylamine (*leucothionine, Lauth's white*)

$$NH\begin{cases}C_6H_3(NH_2)\\C_6H_3(NH_2)\end{cases}S$$

which, when oxidised with ferric chloride, yields thionine (*Lauth's violet*)



The latter colouring matter may also be obtained by the simultaneous oxidation of *p*-phenylenediamine and sulphuretted hydrogen by ferric chloride in aqueous solution (Lauth, Compt. rend. 82, 1441; Bull. Soc. Chim. 25, 422; Bernthsen, Annalen, 230, 108). If dimethyl-*p*-phenylenediamine $C_6H_4(NMe_2)(NH_2)$ is substituted for *p*-phenylenediamine in the foregoing reaction, tetramethylthionine (*methylene blue*) is formed (*v.* Methylene blue).

Tolylene-diamines (*Diaminotoluenes*)

$C_6H_3(CH_3)(NH_2)_2$.

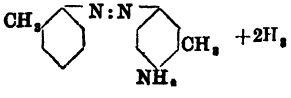
All the six possible compounds are known. Their physical constants are as follows:—

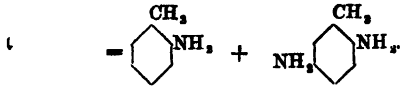
	M.pt.	B.pt.
1-Methyl-2 : 3-diaminobenzene	61°	255°
„ 2 : 4 „ „	99°	283°–285°
„ 2 : 5 „ „	64°	273°
„ 2 : 6 „ „	103°	—
„ 3 : 4 „ „	88°	265°
„ 3 : 5 „ „	—	284°

Only two of these, however, are of technical importance.

Tolylenediamine $C_6H_3(CH_3)(NH_2)_2$ (1, 2, 4). Obtained by the reduction of the corresponding dinitrotoluene. Sparingly soluble in cold, readily soluble in boiling water, in alcohol, and in ether. Forms crystalline salts. As the two amino groups in this compound are in the meta- position to one another, it is an analogue of *m*-phenylenediamine, which it resembles in many of its reactions: thus 2 : 4-tolylenediamine may either wholly or in part replace the *m*-phenylenediamine used in the manufacture of phenylene-brown, producing colouring matters the shade of which is redder than that of ordinary phenylene-brown.

Tolylenediamine $C_6H_3(CH_3)(NH_2)_2$ (1, 2, 5) is obtained by the reduction of the corresponding *m*-nitro-*o*-toluidine $C_6H_3(CH_3)(NH_2)(NO_2)$ (1,2,5) with tin and hydrochloric acid (Beilstein and Kuhlberg, Annalen, 158, 350; Ladenburg, Ber. 11, 1651). Formed along with *o*-toluidine when the aminoazotoluene prepared from *o*-toluidine is treated with the same reducing agent:





The two bases may be separated by fractional distillation (Nietzki, Ber. 10, 832). This reaction is utilised in preparing the mixture of *o*-toluidine and γ-tolylene-diamine which, after the addition of a second molecule of a monamine (either aniline or *o*- or *p*-toluidine), yields on oxidation safranine. On a large scale the aminoazotoluene is reduced with iron turnings and hydrochloric acid. Crystallises in colourless rosettes of tabular crystals. Readily soluble in water, alcohol, and ether, sparingly soluble in benzene. Yields on oxidation toluquinone $C_6H_3(CH_3)O_2$.

Other diamines of this series are—

Xylylene diamines:

1.3-dimethyl, 2.4-diaminobenzene, m.p. 64°.
1.3- „ 4.6 „ „ „ 104°.
1.3- „ 2.5 „ „ „ 77°.

Diaminotrimethylbenzenes: diamino-pseudocumenes:

1.2.4-trimethyl, 5.6-diaminobenzene, m.p. 90°.
1.2.4- „ 3 6 „ „ m.p. 78°.

Diamino mesitylene:

1.3.5-trimethyl, 2.4-diaminobenzene, m.p. 90°.

Similar diamines have been prepared from naphthalene and other hydrocarbons.

TRIAMINES, TETRAMINES, AND PENTAMINES.

Very few of these substances are known. Their properties are similar to those of other substances containing the amino group.

1.2.3-*triaminopropane*; b.p. 190° (Curtius, J. pr. Chem. 1900, 62, 232).

2.3.5-*triaminohexane* (Morelli and Marchetti, Atti del Accad. Lin. 1908, [5] 17, 1, 250).

The three modifications of triaminobenzene are all known.

1.2.3-*triaminobenzene*; m.p. 103°; b.p. 336°.

1.2.4-*triaminobenzene* is formed by reduction of *o*-*p*-dinitraniline or of chrysoidine. On oxidation it gives triaminophenazin.

1.3.5-*triaminobenzene* is only known in the form of its salts.

1.2.3.4. and 1.2.4.5-*tetraminobenzenes* prepared by the reduction of oximes and nitro compounds, have been isolated as their sparingly soluble sulphates (Nietzki and Schmidt, Ber. 1889, 22, 1648; Nietzki, Ber. 1887, 20, 2114).

Pentaminobenzene has been obtained as the hydrochloride with 3 molecules of HCl, by reduction of triaminodinitrobenzene (from tribrombenzene and ammonia). Pentaminotoluene has been similarly obtained.

Reduction of triaminotrinitrobenzene gives pentaminobenzene (Palmer and Jackson, Ber. 1888, 21, 1706; Palmer and Grindley, *ibid.* 1893, 26, 2304). T. S. M.

AMINO-ACIDS. The amino-acids may be conveniently described under the two headings (*a*) *Aliphatic Amino-acids*, and (*b*) *Aromatic Amino-acids.*

Aliphatic Amino-acids. The amino-fatty acids are of great physiological importance, many of them occurring in plant and animal organisms. They are products of proteid degradation, and may be obtained from proteins by heating with hydrochloric acid or baryta water. The general methods in use for preparing these acids are:

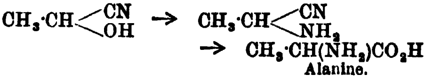
(i.) By treating the monohalogenated fatty acids with ammonia:

$CH_2Cl{\cdot}COOH \rightarrow CH_2(NH_2)COOH$

Chloracetic acid. Glycine.

For examples, *cf.* Fischer and Smits (Ber. 1906, 39, 351).

(ii.) By heating the cyanhydrin of an aldehyde or ketone with ammonia and then hydrolysing the product, whereby an *α*-amino-acid is produced:



$$CH_3{\cdot}CH\genfrac{<}{}{0pt}{}{CN}{OH} \rightarrow CH_3{\cdot}CH\genfrac{<}{}{0pt}{}{CN}{NH_2} \rightarrow CH_3{\cdot}CH(NH_2)CO_2H$$

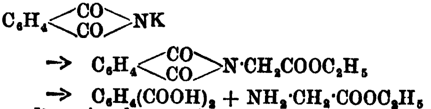
Alanine.

(iii.) By the reduction of the cyanofatty acids with nascent hydrogen (Zn or HCl or by heating with HI):

$$CN{\cdot}CO{\cdot}OH + 2H_2 = CH_2(NH_2)CO_2H$$

Cyanoformic acid.

(iv.) By Gabriel's phthalimide reaction (*v.* preparation of amines 4 (*b*)), using a halogen substituted ester instead of an alkyl haloid:

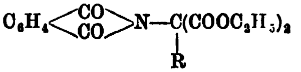


$$C_6H_4\genfrac{<}{>}{0pt}{}{CO}{CO}NK \rightarrow C_6H_4\genfrac{<}{>}{0pt}{}{CO}{CO}N{\cdot}CH_2COOC_2H_5 \rightarrow C_6H_4(COOH)_2 + NH_2{\cdot}CH_2{\cdot}COOC_2H_5$$

By using brommalonic ester the compound

$$C_6H_4\genfrac{<}{>}{0pt}{}{CO}{CO}N{\cdot}CH{\cdot}(COOC_2H_5)_3$$

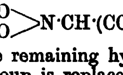
is obtained. The remaining hydrogen atom of the methylene group is replaceable by sodium, and by reacting with alkyl haloids on the sodium compound, compounds of the general formula



$$C_6H_4\genfrac{<}{>}{0pt}{}{CO}{CO}N{-}\underset{\displaystyle R}{\underset{|}{C}}(COOC_2H_5)_2$$

are obtained. From these, by suitable treatment, it is easy to get acids of the general formula $NH_2{\cdot}CHR{\cdot}COOH$ (Sörenson, Zentralblatt. 1903, ii. 33).

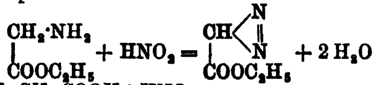
The amino-acids are crystalline bodies with high melting-points, usually soluble in water, but sparingly soluble in alcohol and ether. The *α*- compounds are sweet, the *β*-compounds less so, and the *γ*-compounds not at all. Moulds grow well in solutions of *γ*-amino-acids, less well in *β*-acids, and hardly at all in *α*-acids. They are amphoteric, *i.e.* feeble bases and feeble acids, and there is reason to think that in solution they exist as internal salts, *e.g.* glycocoll:



$$\begin{array}{l}CH_2{-}NH_3\\ \qquad\quad |\\ CO{-}O.\end{array}$$

They have, in addition to the properties characteristic of amines and of acids, the following special properties:—

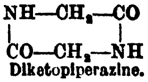
(1) Their esters, with nitrous acid, give diazo- compounds, although the acids themselves undergo with nitrous acid the normal reaction of aliphatic amines



$$\begin{array}{l}CH_2{\cdot}NH_2\\ |\\ COOC_2H_5\end{array} + HNO_2 = \begin{array}{l}CH\genfrac{<}{}{0pt}{}{N}{N}\!\!\Vert\\ |\\ COOC_2H_5\end{array} + 2\,H_2O$$

$$NH_2{\cdot}CH_2{\cdot}COOH+HNO_2 = HO{\cdot}CH_2{\cdot}COOH+H_2O$$

(2) Anhydrides, which are in fact derivatives of piperazine, are formed by *α* amino-acids, *e.g.* glycocoll gives glycide



$$\begin{array}{l}NH{-}CH_2{-}CO\\ |\qquad\qquad\ \ |\\ CO{-}CH_2{-}NH\end{array}$$

Diketopiperazine.

Heating with glycerol promotes the formation of these anhydrides (L. C. Maillard, Ann. Chim. 1915 [ix.] 3, 48; 4, 225).

Important amino-acids are glycine, alanine, phenylalanine, tyrosine, leucine, valine, serine, cystine, tryptophane, histidine, arginine, lysine, aspartic acid, and glutaminic acid, which are described under their respective headings (*v.* also PROTEINS).

(*b*) **Aromatic Amino-acids.** A true aromatic amino-acid such as anthranilic acid, contains both the amino- and the carboxyl- groups united to carbon atoms in the benzene ring. Isomeric with these are acids which contain the amino-group or the carboxyl- group or both, introduced into fatty side chains, the last two classes being really substituted fatty acids.

The general methods in use for preparing aromatic amino-acids are:

(i.) By reducing the corresponding nitro-acids:

$C_6H_4(NO_2)COOH(1{:}2) \rightarrow C_6H_4(NH_2)COOH(1{:}2)$

o-nitrobenzoic acid. Anthranilic acid.

(ii.) By treating the halogen substituted esters of carboxylic acids with potassium phthalimide and hydrolysing the product with hydrochloric acid at 200°.

The aromatic amino-acids are used in the preparation of azo-dyestuffs (*q.v.*).

o-Aminobenzoic acid. Anthranilic acid

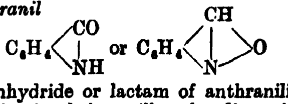
$$C_6H_4(NH_2)CO_2H \quad (1:2)$$

It was first obtained by heating indigo with caustic potash (Fritzsche, Annalen, 39, 83). It may be prepared by the reduction of *o*-nitrobenzoic acid with tin and hydrochloric acid (Beilstein and Kühlberg, Annalen, 163, 138), or with zinc and sodium bisulphite (Goldberger, Chem. Zentr. 1900, ii. 1014; *v.* also Preuss and Binz, Zeitsch. angew. Chem. 1900, [16] 385 and Bad. Anil. u. Soda Fab. Eng. Pat. 18319; J. Soc. Chem. Ind. 1900, 774); by heating *o*-chlorbenzoic acid and ammonia at 125° under pressure (Farbw. Meister, Lucius und Brüning, D. R. P. 145604; Chem. Soc. Abst. 1904, i. 50); by treating phthalimide with sodium hypochlorite and hydrochloric acid or bromine and caustic potash (Hoogewerff and van Dorp, Ber. 1891, Ref. 966; Bad. Anil. und Soda Fab. D. R. P. 55988; Frdl. ii. 546; Amsterdamsche Chininefabrik, Eng. Pat. 18246; J. Soc. Chem. Ind. 1891, 831); by boiling phthalhydroxylamic acid, formed by treating phthalic anhydride with hydroxylamine, with caustic soda or sodium carbonate (Cie. Par. de Coul. d'Aniline, Fr. Pat. 318050; J. Soc. Chem. Ind. 1902, 1392; Farbw. Meister, Lucius und Brüning, Eng. Pat. 1982, D. R. P. 136788; Basler Chemische Farbw.; D. R. PP. 130301, 130302); by reducing sulphanthranilic acid electrolytically or with sodium amalgam (Kalle and Co. D. R. P. 129165; Chem. Zentr. 1902, i. 1138; D. R. P. 146716; Chem. Soc. Abst. 1904, i. 159); by treating *o*-nitrotoluene with concentrated alcoholic or aqueous alkali (Bad. Anil. und. Soda Fab. D. R. P. 114839; Chem. Zentr. 1900, ii. 1892); by heating isatoic acid with concentrated hydrochloric acid (Kolbe, J. pr. Chem. [2] 30, 124); and by oxidising aceto-*o*-toluidide with permanganate in presence of magnesium sulphate and hydrolysing the product (Bad. Anil. und Soda Fab. D. R. P. 94629).

Anthranilic acid is of great commercial importance, as it is one of the intermediate products in the manufacture of synthetical indigo. It crystallises in colourless plates, m.p. 144·6°, and is readily soluble in alcohol or water. It condenses with formaldehyde, forming compounds which are of use in the preparation of indigo (Heller and Fiesselmann, Annalen, 324, 118; Bad. Anil. und Soda Fab. D. R. PP. 117924, 158090, 158346; J. Soc. Chem. Ind. 1905, 615). Reduction with sodium amalgam in hydrochloric acid solution yields *o*-aminobenzylalcohol (Langguth, Ber. 1905, 2062). Concentrated hydriodic acid decomposes it at 200° into ammonia, carbon dioxide, aniline and benzoic acid (Kwisda, Monatsh. 12, 427); whilst nitrous acid converts it in aqueous solution into salicylic acid. Anthranilic acid is employed in the preparation of azo- dyestuffs (*q.v.*) (*v.* also Bayer and Co. D. R. P.P 58271, 60494, 60500, 86314; Frdl. iii. 614 *et seq.*; iv. 795).

The methyl ester of anthranilic acid occurs in Neroli oil (oil of orange flowers) (Walbaüm, J. pr. Chem. 1899, 59, [6–7] 350). It is prepared by heating anthranilic acid with methyl alcohol and hydrochloric acid (Erdmann, Ber. 1899, 1213; D. R. P. 110386) or from acetylanthranilic acid, methyl alcohol and mineral acids (Erdmann, D. R. P. 113942; Chem. Zentr. 1900, ii. 831). It is a crystalline solid, m.p. 24·5°, b.p. 135·5° (15 mm.). The ethyl ester melts at 13° and boils at 136°–137° (13·5 mm.); at 266°–268° (corr.) (Frankel and Spiro, Ber. 1895, 1684) Aminobenzoic acid alkamine esters (*v. p*-aminobenzoic acid).

Anthranil



is the anhydride or lactam of anthranilic acid, its constitution being still under discussion. It is prepared by treating the dimercury derivative of *o*-nitrotoluene (obtained by suspending *o*-nitrotoluene in water and heating it with freshly precipitated mercuric oxide and caustic soda) with concentrated hydrochloric acid and decomposing the product with water (Kalle and Co. Fr. Pat. 370522; D. R. P. 194364; J. Soc. Chem. Ind. 1907, 278; 1908, 713); by heating *o*-nitrotoluene with caustic soda to 170° (Kalle and Co. D. R. P. 194811; Chem. Soc. Abstr. 1908, i. 786); by the reduction of *o*-nitrobenzaldehyde with aluminium amalgam (Brühl, Ber. 1903, 3634); and by the oxidation of *o*-aminobenzaldehyde with a neutral solution of Caro's persulphuric acid (Bamberger and Demuth, Ber. 1903, 829; 2042).

Anthranil is an oil, readily volatile in steam, possesses a peculiar odour, and boils at 210°–213°. It dissolves in alkalis to form salts of anthranilic acid and on treatment with acetic anhydride yields acetylanthranilic acid.

***m*-Aminobenzoic acid.** *Benzamic acid* $C_6H_4(NH_2)CO_2H$ (1 : 3), is prepared by reducing *m*-nitrobenzoic acid with ammonium sulphide and subsequently precipitating the acid with tartaric acid (Holleman, Rec. Trav. Chim. 1902, [ii.] 21, 56; *v.* also Gerland, Annalen, 91, 188). It is a colourless crystalline solid, m.p. 174°; sparingly soluble in cold, readily so in hot water. Reduction with sodium amalgam in hydrochloric acid yields *m*-aminobenzyl alcohol (Langguth, Ber. 1905, 2062). Concentrated hydriodic acid transforms it into ammonia and benzoic acid (Kwisda, Monatsh. 12, 428). *m*-Aminobenzoic acid is used in the preparation of azo-dyestuffs (*q.v.*) (Bayer and Co., D. R. PP. 58271, 59081, 60494, 60500, 63104, 64529, 69445, 74198, 74516, 78493, 86314; Frdl. iii. 614 *et seq.*, 777 *et seq.*; iv. 793, 795; Ges. f. Chem. Ind., D. R. P. 76127; Frdl. iii. 746). Aminobenzoic acid alkamine esters (*v. p*-aminobenzoic acid).

p-Aminobenzoic acid $C_6H_4(NH_2)CO_2H$ (1 : 4), is prepared by the reduction of *p*-nitrobenzoic acid with ammonium sulphide (Fischer, Annalen, 127, 142) or with tin and hydrochloric acid (Beilstein and Wilbrand, Annalen, 128, 164). It is a colourless crystalline solid, m.p. 186°–187°, readily soluble in water, alcohol, or ether. Strong hydrochloric acid at 180° converts it into aniline and carbon dioxide (Weith, Ber. 1879, 105) and hydriodic acid at 200° into ammonia, carbon dioxide, and benzoic acid (Kwisda, Monatsh. 12, 428). *p*-Aminobenzoic acid is used in the preparation of azo- dyestuffs (*q.v.*) (Bayer and Co. D. R. PP. 58271, 60494, 60500, 86314; Frdl. iii. 614 *et seq.*; iv. 795; Ges. f. Chem. Ind., D. R. P. 76127; Frdl. iii. 746).

Many complicated alkyl- and alkamine esters of the aminobenzoic acids have been prepared and they are claimed to be valuable anæsthetics (Farbw. Meister, Lucius, and Bruning, D. R. PP. 170587, 172301, 172447, 172568, 179627, 180291, 180292, 194748, Eng. Pat. 17162, Fr. Pat. 361734, U. S. Pat. 812554; J. Soc. Chem. Ind. 1906, 607; 1907, 434; Chem. Soc. Abstr. 1906, i. 845 *et seq.*; 1907, i. 923; 1908, i. 638; Merck, D. R. P. 189335; J. Soc. Chem. Ind., 1908, 471; Bayer and Co. D. R. PP. 211801, 218389, Eng. Pat. 4321; J. Soc. Chem. Ind. 1909, 854; Chem. Zentr. 1910, i. 782; Fritzsche, Eng. Pat. 2020, Fr. Pat. 398259, D. R. P. 213459; J. Soc. Chem. Ind. 1909, 814).

4-*Amino-o-toluic acid* $C_6H_3{\cdot}CH_3(NH_2)CO_2H$ (1 : 4 : 2); m.p. 196°. Obtained by the reduction of 4-nitrotoluic acid with tin and hydrochloric acid (Jacobsen and Wierss, Ber. 1883, 1959).

5-*Amino-o-toluic acid* $C_6H_3{\cdot}CH_3(NH_2)CO_2H$ (1 : 5 : 2); m.p. 153°, is obtained by the reduction of 5-nitrotoluic acid with tin and hydrochloric acid (Jacobsen, Ber. 1884, 164).

6-*Amino-o-toluic acid* $C_6H_3{\cdot}CH_3(NH_2)CO_2H$ (1 : 6 : 2). Method of preparation as above; m.p. 191° (J. and W. *l.c.*).

2-*Amino-m-toluic acid* $C_6H_3{\cdot}CH_3(NH_2)CO_2H$ (1 : 2 : 3). Method of preparation as above; m.p. 132° (Jacobsen, Ber. 1881, 2354), 172° (Jürgens, Ber. 1907 4409).

4-*Amino-m-toluic acid* (*Methylanthranilic acid*) $C_6H_3{\cdot}CH_3(NH_2){\cdot}CO_2H$ (1 : 4 : 3). Obtained by reduction of 4-nitro-*m*-toluic acid with tin and hydrochloric acid (Jacobsen, Ber. 1881, 2354) or by treating *p*-methylisatoic acid with concentrated hydrochloric acid (Panaotovic, J. pr. Chem. [2] 33, 62); m.p. 172° (Ehrlich, Ber. 1901, 3366), 175° (Findeklee, Ber. 1905, 3533).

6-*Amino-m-toluic acid* $C_6H_3{\cdot}CH_3(NH_2)CO_2H$

(1 : 6 : 3); m.p. 167°. Obtained by reduction of 6-nitro-*m*-toluic acid (Beilstein and Kreusler, Annalen, 144, 147).

2-Amino-p-toluic acid $C_6H_3{\cdot}CH_3{\cdot}(NH_2){\cdot}CO_2H$ (1:2:4); m.p. 164°–165°. Method of preparation as above (Ahrens, Zeitsch. f. Chemie, 1869, 104).

3-Amino-p-toluic acid (*Homo-anthranilic acid*) $C_6H_3{\cdot}CH_3(NH_2)CO_2H$ (1 : 3 : 4); m.p. 177°. Method of preparation as above (Niementowski and Rozanski, Ber. 1888, 1997; Noyes, Amer. Chem. J. 10, 479).

1′-Amino-o-toluic acid (*Benzylamine-o-carboxylic acid*) $NH_2{\cdot}CH_2{\cdot}C_6H_4{\cdot}CO_2H$ (1 : 2). Obtained by digesting 1 part of *o*-cyanobenzylphthalimide with 4 parts of concentrated sulphuric acid (Gabriel, Ber. 1887, 2231). Crystalline non-volatile solid.

1′-Amino-m-toluic acid (*Benzylamine-m-carboxylic acid* $NH_2{\cdot}CH_2{\cdot}C_6H_4{\cdot}CO_2H$ (1 : 3); m.p. 215°–218°. By heating at 200° a mixture of 2 grams *m*-cyanobenzylphthalimide and 10 c.c. concentrated hydrochloric acid (Reinglass, Ber. 1891, 2419).

1′-Amino-p-toluic acid (*Benzylamine-p-carboxylic acid*) $NH_2{\cdot}CH_2{\cdot}C_6H_4{\cdot}CO_2H$ (1 : 4). Method of preparation as above (Günther, Ber. 1890, 1060). Crystalline solid.

2-Amino-α-toluic acid (*2-Aminophenylacetic acid*) $NH_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}CO_2H$ (1 : 2) is not known in the free state; all attempts to prepare it result in the formation of its anhydride, oxindole.

Oxindole

$$C_6H_4{<}\begin{matrix}CH_2\\NH\end{matrix}{>}CO$$

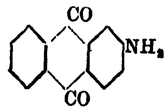
is obtained by treating 2-nitro-α-toluic acid with tin and hydrochloric acid (Bayer, Ber. 1878, 583), or by reducing dioxindole with tin and hydrochloric acid, or with sodium amalgam (Bayer and Knop, Annalen, 140, 29). Crystallises in colourless needles; m.p. 120°.

3-Amino-α-toluic acid (*3-Aminophenylacetic acid*) $NH_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}CO_2H$ (1 : 3). Obtained by reducing 3-nitro-α-toluic acid with tin and hydrochloric acid; m.p. 148°–149° (Gabriel and Borgmann, Ber. 1883, 2065).

4-Amino-α-toluic acid (*4-Aminophenylacetic acid*) $NH_2{\cdot}C_2H_4{\cdot}CH_2{\cdot}CO_2H$ (1 : 4). Method of preparation as above (Radziozewski, Ber. 1869, 209); m.p. 199°–200° (Bedson, Chem. Soc. Trans. 1880, 92).

α-Aminophenylacetic acid $C_6H_5{\cdot}CH(NH_2)CO_2H$. Obtained by heating α-phenylbromacetic acid with aqueous ammonia at 100°–110° (Stückenius, Ber. 1878, 2002); m.p. 256° (Tiemann, Ber. 1880, 383). Sublimes without melting at 265° (Elbers, Annalen, 227, 344). T. S. M.

2-AMINOANTHRAQUINONE



red needles; m.p. 302°. Is employed in the manufacture of indanthrene and indanthrene dyes (*v.* INDANTHRENE). It is made technically by heating under pressure at 170°, a mixture of sodium anthraquinone-2-sulphonate with an aqueous solution of barium chloride and dilute ammonia. The filtered product is washed with water, dilute hydrochloric acid, and weak sodium hydroxide solutions, and is crystallised from chlorobenzene (Farbw. vorm Meister, Lucius und Brüning, D. R. P. 267212).

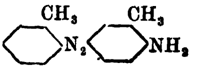
Or the sodium anthraquinone-2-sulphonate, in the form of a paste, is mixed with manganese dioxide and ammonia solution, and heated at 200°. The product is treated with sulphurous acid or acid sodium sulphite to remove the manganese, and dried.

A mixture of sodium dichromate and ammonium chloride may be substituted for the manganese dioxide (Bad. Anilin und Soda Fab. D. R. P. 256515). For details, *see* Cain's Intermediate Products for Dyes.

Alternative methods are to condense *m*-aminobenzoylbenzoic acid by means of sulphuric acid (Basle Chem. Works, D. R. P. 148110), or the carbamide derivative of the same acid (Akt. für Anilinfab. Eng. Pat. 8914, 1914); by hydrolysing 2-*p*-toluenesulphonylaminoanthraquinone (Ullmann, D. R. P. 224982); by the action of ammonia and oxidising agents on *meso*halogen anthracene-2-sulphonic acids (Bad. Anilin und Soda Fab. D. R. P. 288996); or by heating 2-chloroanthraquinone with ammonia (Farbenfab. vorm. F. Bayer and Co. D. R. P. 295624).

AMINOAZOBENZENE (*Aniline yellow*) *v.* AZO- COLOURING MATTER.

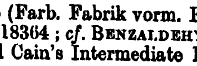
***o*-AMINOAZOTOLUENE**



may be made by heating to 25°–30° *o*-toluidine with an aqueous solution of sodium nitrite and hydrochloric acid in a lead-lined iron pan fitted with a jacket for water-cooling and a stirring arrangement. The excess of toluidine is removed by neutralising with hydrochloric acid when the *o*-aminoazotoluene hydrochloride separates out. It is employed in the manufacture of cloth reds and safranine, and is sold as Yellow Fat colour and as Fast Azo- Garnet base (*cf.* Cain's Intermediate Products for Dyes).

The base is sparingly soluble in water, readily soluble in alcohol and ether; m.p. 100°.

m-**AMINOBENZALDEHYDE** is prepared by heating a mixture of *m*-nitrobenzaldehyde with a solution of sodium hydrogen sulphite and ferrous oxide, made by boiling a solution of ferrous sulphate with chalk. After filtration the solution is acidified and boiled to expel sulphur dioxide (Farbw. vorm. Meister, Lucius und Bruning, D. R. P. 62950, 66241). Or the nitrobenzaldehyde may be heated with an aqueous solution of sodium hyposulphite, the solution cooled, mixed with hydrochloric acid, again boiled to expel sulphur dioxide. On cooling, the anhydro- derivative of *o*-aminobenzaldehyde



separates out (Farb. Fabrik vorm. F. Bayer und Co. D. R. P. 218364; *cf.* BENZALDEHYDE, *Derivatives* of; and Cain's Intermediate Products for Dyes).

α-**AMINOCAPROIC ACID** *v.* LEUCINE.

p-**AMINOCARVACROL.** A photographic developer, resembling metol and *p*-aminophenol in developing properties; its solution keeps better than that of the latter. Obtained by reducing an ammoniacal solution of *p*-nitroso carvacrol by hydrogen sulphide when *p*-amino carvacrol separates in colourless leaves (Brit. J. Phot. 1910, 56, 534).

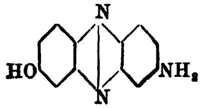
***p*-AMINODIPHENYLAMINE**

m.p. 75°; b.p. 354° (in hydrogen), is prepared by heating together in an oil-bath at 180°–185° a mixture of sodium 2-chloro-5-nitrobenzenesulphonate (from *p*-chloronitrobenzene), glycerol, chalk, and aniline. After dilution with water, sodium carbonate is added, and the excess of aniline removed by steam distillation. After filtration sodium *p*-nitrodiphenylamine-*o*-sulphonate crystallises out. This is warmed with hydrochloric acid, and nitrodiphenylaminesulphonic acid is formed as a brownish-red oil, which by further heating is converted into the crystalline *p*-nitrodiphenylamine. This is separated, treated with ammonia, washed, and dried. To reduce it, it is dissolved in alcohol, ammonium chloride added, heated to boiling, and mixed with zinc-dust, and a small quantity of a solution of sodium hydrogen sulphite, the whole filtered into 50 p.c. sulphuric acid, when insoluble aminodiphenylamine sulphate separates out. By treating this salt with water and ammonia the free base is obtained. (For details, *see* Cain's Intermediate Products for Dyes.)

AMINOETHYL ALCOHOL *v.* CHOLINE.

4-β-AMINOETHYLGLYOXALINE *v.* ERGOT.

3-AMINO-7-HYDROXYPHENAZINE

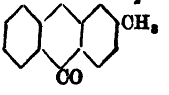


is obtained, according to Nietzki and Simon (Ber. 1895, 28, 2974), by heating an aqueous solution of 2 : 4-diamino-4′-hydroxydiphenylamine hydrochloride with ammonia and manganese oxide until the blue colour disappears, filtering, and acidifying with hydrochloric acid, when the phenazine hydrochloride separates. The free base is obtained by treating the hydrochloride with sodium carbonate.

Ullmann and Gnaedinger (Ber. 1912, 45, 3442) blow air through a solution of *m*-phenylenediamine sulphate and *p*-aminophenol hydrochloride, containing sodium hydroxide. The compound $NH : C_6H_3(NH_2) : N{\cdot}C_6H_4{\cdot}OH,2H_2O$ is obtained, which, on solution in ammonia, warmed, and again treated with air until the blue colour changes to red, yields, after filtration and addition of hydrochloric acid, the phenazine hydrochloride.

3-Amino-7-hydroxyphenazine melts at 360°, and dissolves in alcohol or ether with a green fluorescence.

1-AMINO-2-METHYLANTHRAQUINONE



Obtained by adding sodium nitrate to a cooled solution of methylanthraquinone in sulphuric acid and reducing the 1-nitro-2-methylanthraquinone so formed by sodium sulphide or stannous hydroxide; m.p. 202°. Insoluble in water; readily soluble in alcohol, ether, benzene, or acetic acid (Römer and Link, Ber. 1883, 16, 695; Scholl and Holdermann, Ber. 1907, 40, 1696).

AMINONAPHTHOL SULPHONIC ACIDS *v.* NAPHTHALENE.

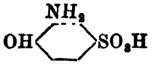
AMINONAPHTHOPHENAZINE *v.* AZINES.

***p*-AMINOPHENOL**  may be made by reducing *p*-nitrophenol with tin and hydrochloric acid in presence of sulphuric acid when *p*-aminophenol sulphate separates. The base is liberated by sodium carbonate, acid sodium sulphite being added to prevent oxidation. The reduction may also be made by sodium hyposulphite in alkaline solution, or by iron, ferrous chloride, and hydrochloric acid, or by the catalytic action of nickel.

p-Aminophenol may also be prepared by reducing *p*-azophenol $OH{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_4{\cdot}OH$, with stannous chloride or zinc-dust and sodium hydroxide; or by the action of sodium hyposulphite or sodium sulphide on a hot alkaline solution of *p*-hydroxyazobenzene. The *p*-aminophenol sulphate may be obtained from a solution of nitrobenzene in sulphuric acid by the action of zinc-dust, or by electrolytic reduction using carbon cathodes (Darmstadter, D. R. P. 150800); or a copper cathode in a lead cylinder as an anode (Soc. Chem. Ind. Basle, Eng. Pat. 18081, 1915).

p-Aminophenol forms white crystalline plates melting at 184°. It rapidly oxidises in air. Comes into commerce as *Ursol P* for dyeing fur, and as a photographic developer under the name of *Rodinal.*

2-AMINOPHENOL-4-SULPHONIC ACID



Obtained by nitrating phenol-*p*-sulphonic acid with nitric acid and reducing with iron; or by sulphonating *o*-aminophenol; or by fusing aniline-2 : 5-disulphonic acid with sodium hydroxide.

AMINOPHENOPHENANTHRAZINE *v.* AZINES.

AMINOPHENYLACETIC ACID *v.* AMINO-ACIDS (AROMATIC).

α- and β-AMINOPROPIONIC ACIDS *v.* ALANINE.

AMINOSALICYLIC ACID *v.* SALICYLIC ACID.

α-AMINO-*iso*-VALERIC ACID *v.* VALINE.

AMLA (Beng.), **AMLIKA** (Hind.), **AMLIKU** (Ass.), **OWLA** (Mechi), **NELLI** and **TOPPINELLI** (Tam.). A euphorbiaceous Indian tree, *Phyllanthus emblica* (Linn.), the fruits of which (*Emblic myrobalans*) are used in a fresh condition as a laxative, and, when dried, as an astringent (Dymock, Pharm. J. [3] 10, 382). The fruits are also pickled and eaten, and used for tanning and dyeing.

AMMONAL *v.* EXPLOSIVES.

AMMONIA. *Volatile alkali, alkaline air, spirit of hartshorn.* Solutions of ammonia have been known from very early times, but the substance itself was first clearly recognised by

Priestley, who obtained it by heating the aqueous solution and collecting the gas, which he termed *alkaline air*, over mercury. Scheele proved that it contained nitrogen; and Berthollet, and more accurately Austin, demonstrated its real nature, and determined the proportions of its constituents.

Ammonia (or its salts) is found in small quantities in the air, and in most natural water; in the juice of plants, in most animal fluids, in many soils, and in a few minerals, ochres, clays, marls, &c. Ammonia can be obtained synthetically in small quantity by the passage of electrical discharges through a mixture of nitrogen and hydrogen (Donkin, Pogg. Ann. 21, 281); or heating the mixture to a high temperature (Haber, Zeitsch. Elektrochem. 1914, 20, 597; Maxted, Chem. Soc. Trans. 1918, 113, 168, 386; 1919, 115, 113; J. Soc. Chem. Ind. 1918, 37, 232); or as nitrite by the action of a strong induction spark on a mixture of nitrogen and water vapour (Thénard, Compt. rend. 76, 983); or as chloride by sparking a mixture of hydrogen, nitrogen, and hydrogen chloride (Deville, Compt. rend. 60, 317); or by the action of heated spongy platinum, pumice, &c., on a mixture of hydrogen and nitric acid.

For laboratory purposes the gas is usually prepared by heating a mixture of ammonium chloride or sulphate with slaked lime, or by gently warming the concentrated solution, and drying the gas over quicklime. (For the preparation of the chemically pure gas, *see* Stas, Zeitsch. anal. Chem. 6, 423.)

Ammonia is a colourless gas, having a very pungent characteristic smell, and is poisonous when breathed in quantity, destroying the mucous membrane. It has a sp.gr. of 0·5967 (air = 1), 1 litre of the gas at 0° and 760 mm. weighing 0·7708 gram, and readily liquefies on compression, the critical temperature being 132·9°±0·1, and the critical pressure 112·3±0·1 atm. (Cardoso and Gillay, J. chim. phys. 1912, 10, 514). Its critical density is 0·2362 (Berthoud). Liquid ammonia is colourless and very mobile, and has a sp.gr. at 0°/4° of 0·6385 (Dieterici), 0·6388 (Drewes), the coefficient of expansion being very high and increasing rapidly with the temperature. It boils under atmospheric pressure at −33·2-34·6° (Burrell and Robertson), and freezes to a white crystalline solid at −77° (Keyes and Brownlee), −77° (Brill), the vapour pressure being as follows (Regnault, J. 1863, 70):—

at	−30°	1·14 atm.	at	0°	4·19 atm.
„	−20°	1·83 „	„	10°	6·02 „
„	−10°	2·82 „	„	20°	8·41 „

The dependence of the vapour pressure on temperature down to the freezing-point may be expressed by the equation: $\log p = -1969{\cdot}65/T + 16{\cdot}19785 - 0{\cdot}0423858T + 5{\cdot}4131 + 10^{-5}T^2 - 3{\cdot}2715 \times 10^{-8}T^3$.

Its latent heat of evaporation decreases from 333·0 Cal. at −42° to 252·6 Cal. at 49°. The variation of the latent heat with the temperature may be expressed by the formula

$$L = 32{\cdot}968\sqrt{133-\theta} - 0{\cdot}5985(133-\theta)$$

in which θ represents the actual temperature and 133 the critical temperature. The specific heat of saturated ammonia vapour expressed in joules per gram per degree varies from −4·42 at −45° to −3·36 at 45°. To reduce these numbers to 20° Calories, they must be divided by 4·163 (Osborne and van Dusen, J. Amer. Chem. Soc. 1918, 40, 14). The specific heat of liquid ammonia increases from 1·058 at −45° to 1·173 at 45°. Its dependence on temperature may be expressed by the equation:

$$c = 0{\cdot}7498 - 0{\cdot}000136\theta + 4{\cdot}0263\sqrt{133-\theta}$$

in which c is expressed in terms of the 20° Calorie and θ is the temperature (Osborne and van Duser, *l.c.*). Liquid ammonia is produced commercially in large quantity for employment in freezing machines. In many of its physical properties the liquid resembles water, and it acts as a solvent for a large number of substances.

Ammonia gas burns with difficulty in the air when cold, but inflames more readily on heating, and still more readily in oxygen, giving a greenish-yellow flame of high temperature. In presence of suitable catalysts, such as copper, iron, nickel, and especially platinum, ammonia is oxidised by oxygen at lower temperatures with production of oxides of nitrogen, the manufacture of nitric acid from ammonia by Ostwald's process (Eng. Pat. 698, 1902) being carried out in this manner. A number of the elements, when heated in ammonia gas, yield corresponding nitrides: boron, magnesium, and titanium being especially active in this respect, whilst the alkali metals give rise to amides. With carbon at temperatures above 750° ammonia is partly dissociated, and partly converted into hydrocyanic acid, the presence of the latter in crude coal gas being largely due to this reaction.

Many salts combine with ammonia to form stable compounds at the ordinary temperature, the ammonia playing the same part as water of crystallisation. It is evolved on heating, liquid ammonia having been first obtained by Faraday, in 1823, by warming the compound with silver chloride $2AgCl,3NH_3$, in a sealed tube.

The action of heat upon ammonia has been investigated by Ramsay and Young (Chem. Soc. Trans. 45, 92), Perman (Proc. Roy. Soc. 74, 110; 76A, 167), Haber and v. Oordt (Zeitsch. anorg. Chem. 44, 341), and Nernst and Jost (Zeitsch. Elek. 13, 521). Under atmospheric pressure, decomposition commences at temperatures below 500°, its extent increasing rapidly with the temperature, but the speed with which equilibrium is attained between undecomposed ammonia and nitrogen and hydrogen varies greatly according to the nature of the surfaces with which the gases are in contact. Glass is very inactive, but porcelain and many metals and their oxides have a very strong accelerating effect In presence of the latter decomposition becomes nearly complete at 630° under atmospheric pressure, but the last traces do not disappear even at 1000°. Conversely, in presence of iron as catalyst, Haber and v. Oordt find that at 1000° traces of ammonia are formed from nitrogen and hydrogen at atmospheric pressure, and Nernst and Jost have found that small quantities are formed at the same temperature under the greater pressure at 50–70 atm. At temperatures of 500°-550° under 200 atm. pressure, in presence of metallic osmium or uranium, nitrogen and hydrogen combine to a considerable extent (*see* below).

It has been shown by Regener (Sitzungsber, K. Akad. Wiss. Berlin, 1904, 1228), and by D. Berthelot and Gaudechon (Compt. rend. 1913, 156, 1243), Coehn and Pringent (Zeitsch. Elektrochem. 1914, 20, 275) that ammonia is completely decomposed by ultra-violet light.

Under certain conditions a mixture of air and ammonia gas may be exploded by an electric spark (Schlumberger and Piotrowski, J. Gasbel. 1914, 57, 941). Fires which have occurred in the neighbourhood of refrigerating machines have been attributed to ignition of mixtures of air with ammonia, or, according to Behr, to the ignition of hydrogen formed in the machine by decomposition of ammonia at the high temperature and pressures produced by starting with a closed discharge stop-valve (Cattaneo, Zeitsch. ges. Kalte-Industrie).

Ammonia gas is very soluble in water, alcohol, ether, and many saline solutions, the aqueous solution (caustic ammonia or *liquor ammoniæ*) being of great commercial importance. One gram of water at 0° and 760 mm. absorbs 1148 c.c. or 0·875 gram of ammonia, at 10° 0·679 gram, at 20° 0·526 gram, at 30° 0·403 gram, and at 100° 0·074 gram (Roscoe and Dittmar, Chem. Soc. Trans. 12, 128; Sims, Chem. Soc. Trans. 14, 1; *see* also Perman, Chem. Soc. Trans. 79. 718; 83, 1168). In the act of solution much heat is evolved, and according to Thomsen, $NH_3+aq. = 8430$ cals.

The density of aqueous solutions of ammonia of varying strength is shown in the accompanying table, according to the determinations of Lunge and Wiernik.

DENSITY OF AQUEOUS SOLUTIONS OF AMMONIA AT 15° (LUNGE AND WIERNIK).

The solution is very strongly alkaline, and unites with acids to form the ammonium salts, and it is frequently supposed that the solution contains ammonium hydroxide $NH_4·OH$, corresponding to NaOH and KOH. The evidence for this view is not altogether conclusive, and the physical properties of the solution at the ordinary temperature are in some respects opposed to the presence of the compound NH_4OH, and in favour of the supposition that the ammonia is dissolved as such. At very low temperatures, however, Rupert (J. Amer. Chem. Soc. 31, 866; 32, 748) has shown that two definite hydrates exist, the freezing-point curve of mixtures of ammonia and water in varying proportions showing two well-defined minima at −87° and −94° respectively, the composition at these two points corresponding to the formulæ NH_3,H_2O and $2NH_3,H_2O$. The first-named forms small colourless crystals resembling those of sodium and potassium hydroxide; and the latter, larger needle-shaped crystals. Whether these are true hydrates or are to be regarded as ammonium hydroxide NH_3OH and ammonium oxide $(NH_4)_2O$, is at present uncertain.

The aqueous solution of ammonia also dissolves many metallic oxides and hydroxides, such as Ag_2O,$Cu(OH)_2$, as well as many salts which are insoluble in water, such as silver chloride and phosphate, and cuprous chloride, and also acts as a solvent for many fats and resins. The solution of cupric hydroxide in ammonia is of considerable commercial importance, as it is a solvent for cellulose, and is used in large quantities in the manufacture of artificial silk.

I. Technical sources of ammonia.[1] Ammonia is formed in nature chiefly during the decay of nitrogenous organic substances, and consequently exists in considerable quantity both in the soil and the atmosphere. Whilst this is of the greatest importance for agriculture, it is only possible in very exceptional cases to utilise this source for the manufacture of ammonium salts, the greater proportion of the world's production being obtained by the destructive distillation of nitrogenous organic matter, chiefly coal.

A. *Natural occurrence of ammoniacal compounds in quantity of commercial importance.*—Ammonium carbonate has been found in guano deposits on the West Coast of South America, and has been imported into Europe, a sample imported into Germany in 1848 consisting essentially of ammonium bicarbonate mixed with some insoluble matter. Ammonium sulphate is contained in the Tuscan 'soffioni,' and is there obtained in considerable quantity as a by-product in the manufacture of boric acid. Ammonium chloride, together with sulphate, is sometimes found in the neighbourhood of volcanoes.

B. *Synthetic processes for production of ammonia.*—Very many attempts have been made to effect the manufacture of ammonia from atmospheric nitrogen and hydrogen, and a large number of processes with this object have been patented, but until recently, no method which has been proposed has proved successful on a commercial scale, for although, as stated above, nitrogen and hydrogen combine together to a slight extent to form ammonia, when heated together under suitable conditions, the yield at high temperatures was so small that the cost of production would be prohibitive. With many of the methods proposed—such as those of Swindells (Eng. Pat. June 21, 1876), Rickman (Eng. Pat. 3341, 1878), Glover (Eng. Pat. 1890, 1880), Solvay (Bull. Soc. chim. 25, 527), Wagner (Jahresbericht. 1876, 444), Bassett (Eng. Pat. 4338, 1879)—it is very doubtful whether, in fact, any ammonia is produced synthetically, the ammonia obtained being more probably all derived from the nitrogen present in the coal or coke employed in each of these processes. The processes of Johnson (Chem. News, 43, pp. 42, 288), Woltereck (J. Soc. Chem. Ind. 1908, 158, 978; Eng. Pat. 2461, 1902; 16504, 1904; 8358, 1905), Mond (J. Soc. Chem. Ind. 1889, 505), and Roth (D. R. P. 191914), in which a mixture of nitrogen and hydrogen is passed over various heated catalytic agents, do not appear to have resulted in any commercial yield of ammonia. Haber (Zeitsch. Elek. Chem. 16, 244) has found that when a mixture of 1 vol. of nitrogen and 3 vols. of hydrogen is heated with metallic osmium to 550° under a pressure of 200 atm., a very considerable production of ammonia takes place amounting to 8 p.c. of the mixed gas, and although osmium is too scarce and expensive for technical use, it may be replaced by metallic uranium with good results. With a small apparatus constructed to allow of the circulation of the mixed gas under this pressure over uranium heated to about 500°, and cooling between each passage of the gas over the metal, Haber has synthesised ammonia at the rate of about 90 grams per hour, the ammonia separating out on cooling under these conditions as a liquid.

The Haber process has now been developed on a very large scale by the Badische Anilin und Soda Fabrik, and it is stated that in 1918 a quantity of ammonia equivalent to 400,000 tons of ammonium sulphate was manufactured by this method (Eng. Pats. 17642, 17951, 1909; 10441, 13097, 15975, 19249, 19778, 20127, 1910; 61, 5833-6, 21151, 24657, 25252, 28167, 1911; 1161, 3345, 9841, 22352, 25259, 1912; 24823, 1913; 8763, 1915). The work done by them has especially consisted in the design and construction of suitable plant to withstand the combined high temperatures and high pressures necessary for successful working, and the selection of suitable catalysts of less expensive character than the osmium and uranium employed in the small scale experiments. No details of the exact construction of plant or of the actual catalyst now employed have been published, but Benthsen (Zeitsch. angew. Chem. 1913, 10) states that the more expensive forms of the latter first used can be replaced by cheaper metals such as iron, manganese, and molybdenum, which are 'activated' by the addition of other substances. Contact 'poisons' both in the catalyst itself and in the mixture of nitrogen and hydrogen used must be very completely excluded; the following substances especially having proved very deleterious: sulphur, selenium, tellurium, phosphorus, arsenic, boron, some hydrocarbons, and the readily fusible metals or their oxides, such as lead, bismuth, and tin. Much experimental work on the direct synthesis of ammonia from nitrogen and hydrogen has been carried out in Great Britain during the last few years, both on the laboratory and on a semi-industrial scale, the results of which have only been partially published (*see* Maxted, Chemical Age, 1919, 1, 514, 540, 590). Up to the present (1919) no plant has been erected for the production of ammonia by this method in this country.

Attempts to effect the synthesis of ammonia from a mixture of nitrogen and hydrogen by the passage of the silent discharge or sparks have failed to give a sufficient yield for commercial success, and a similar lack of success long attended the efforts to produce ammonia by combining atmospheric nitrogen with elements which readily form nitrides, such as boron, titanium, magnesium, and subsequent conversion of the nitride into ammonia by the action of steam. Recently, however, Serpek and the Soc. Gen. des Nitrures (Eng. Pats. 13579, 1906; 7507, 15995-7, 1909; 13086, 1910; 23544, 25141, 1911; 8347-9, 10036, 22435, 25630, 1912; 10975, 11091, 21366, 23740, 24731, 27030, 27971, 1913; 4287, 22586, 24533, 1914) have developed a process dependent on the formation of aluminium nitride by the action of carbon and nitrogen on alumina at high temperatures, and subsequent conversion of the nitride into ammonia, with recovery of the alumina, by heating with water under pressure. To carry out the process, bauxite, which reacts more readily than pure alumina, is preheated to a temperature of about 1600° and passing through a revolving electric carbon-resisting furnace, the nitrogen being supplied from a current of producer-gas passing through the furnace in the opposite direction to the flow of bauxite. The crude nitride is then heated under pressure with dilute alkali, which effects the conversion into ammonia much more readily than water. A number of plants working this process are being erected in France by the Soc. Gen. des Nitrures.

---

[1] For more complete details, *see* Lunge's Coal-Tar and Ammonia (Gurney and Jackson, 1916).

C. *Production from cyanides.*—It has long been known that nitrogen combines at high temperatures with carbon and alkalis with production of cyanides, and many attempts have been made during the last fifty years to manufacture cyanides in this manner and to convert these subsequently into ammonia by the action of superheated steam. The large demand for cyanides themselves, resulting from their employment in the extractions of gold from the mine tailings, and the fact that at present nitrogen, in the form of cyanide, commands a higher price than in the form of ammonia, has made such processes of no value for ammonia production under existing conditions, and in fact, at the present time, the opposite process of converting ammonia into cyanides is carried on to a large extent. The methods proposed, so far as they relate to cyanide production, will be discussed under that heading, but one method may be here mentioned, namely, the manufacture of calcium cyanamide, $Ca:N{\cdot}C\vdots N$, according to Frank and Caro's process (J. Soc. Chem. Ind. 1908, 1093), by the action of nitrogen on heated calcium carbide, this being simultaneously a cyanogen and an ammonia derivative (*v. Cyanamide*, art. NITROGEN, ATMOSPHERIC, UTILISATION OF). This substance may readily be converted into ammonia by the action of superheated steam, but it is for the most part directly employed on the land as a nitrogenous manure.

D. *Ammonia from urine, sewage, and animal excreta.*—Urine is not merely the oldest, but for centuries was the only source of obtaining ammonia compounds on a commercial scale. It is stated that sal-ammoniac made from it was an article of commerce as early as 1410, and that the Jesuit Sicard in 1720 saw the manufacture of it in the Delta of the Nile. In Egypt sal-ammoniac was made by burning camels' dung and collecting the sublimate. Putrefied urine (in which the urea has passed into ammonium carbonate) has been used for centuries, and to a certain extent is still used by dyers as a source of ammonia for scouring wool and other purposes.

Normal urine contains per litre from 20 to 35 grams urea (carbamide), which after a short time is changed into ammonium carbonate under the influence of a micro-organism. An adult man produces from 22 to 37 grams urea per 24 hours, together with a little uric acid, corresponding to 12·5–21 grams NH_3 per day, or between 9 and 17 lbs. per annum. If all the ammonia obtainable from London urine were recovered this would amount to 100,000 tons of ammonium sulphate per annum.

Owing to the now almost universal adoption of the removal of sewage by means of water, the dilution of the ammonia in the combined sewage is so great that its recovery is hardly practicable, but with concentrated pan sewage, recovery of ammonia is carried on in a few places, especially in Paris. A large number of patents have been taken out for the recovery of ammonia both from sewage and also from the more concentrated sludge deposited in the collecting tanks at the sewage works, among which may be mentioned Duncan (D. R. PP. 27148, 28436), Young (Eng. Pat. 3652, 1882), Bolton and Wanklyn (Eng. Pat. 5173, 1880), Gesellschaft für Wasserabklärung, Berlin (D. R. P. 161166), Butterfield and Watson (Eng. Pat. 19502, 1905), Taylor and Walker (U.S. Pat. 603668).

Ketjen (Zeitsch. angew. Chem. 1891, 294) also reports a successful recovery of ammonia from concentrated sewage by distillation with lime at Amsterdam.

E. *Ammonia from guano, &c.*—Whilst the ammonia obtainable from excreta is mostly lost for immediate recovery, as it quickly passes away into the water, the soil, or the air, there are a few exceptions to this rule presented by the deposits of birds' excrements on some desert islands, and a few similar cases. In this 'guano,' ammonia salts exist already preformed, and ammonia can be formed from other nitrogenous substances contained therein by heating guano with lime (as patented by Young in 1841), but this process is not remunerative, since the direct manurial value of guano is much superior to that of the ammonia salts obtainable therefrom.

F. *Manufacture of ammonia by the destructive distillation of nitrogenous organic matter.*—The total quantity of ammonia commercially produced by more of the methods described above is at present almost negligible, nearly the whole of the world's supply of ammonia and its salts being obtained either as a by-product in the course of other manufactures in which nitrogenous organic matter is subjected to the process of destructive distillation, or manufactured synthetically from nitrogen and hydrogen. Much the greatest proportion is obtained in the manufacture of illuminating gas, power gas, or coke from coal, and in the distillation of shale for the production of shale oil. A considerable amount is also recovered from the gases evolved from blast-furnaces where coal is used as fuel, and smaller quantities from the distillations of bones, horn, and other animal refuse, and also from the residue obtained from beet-root molasses.

The total production of ammonia in the United Kingdom, calculated as sulphate, for the year 1913, previous to the outbreak of war, and for 1917 and 1918, is shown in the following table, the figures for 1889 being also given to indicate the increase in production during the past 30 years. The statistics are taken from the Annual Reports of the Chief Alkali Inspector:—

	1889	1913	1917	1918
Gas works	87,000	182,180	188,478	173,541
Iron works	5,500	19,956	13,621	12,717
Shale works	22,000	63,061	60,560	58,311
Coke ovens	—	133,816	166,354	164.448
Producer gas and other carbonising works	3,000	33,605	29,604	23,534
	117,500	432,618	458,617	432,551

The world's production for 1907, 1910, and 1913 (in metric tons of 2204 lbs.) is estimated as follows:—

	1907	1910	1913
Great Britain .	331,220	369,000	438,932
Germany . .	287,000	383,000	549,000
United States .	81,400	116,000	176,900
France . .	52,700	57,000	75,400
Belgium and Holland . .	55,000	41,000	48,600
Other countries .	88,000	145,800	123,200
	895,320	1,111,800	1,412,032

Coal always contains nitrogen in greater proportion than is present in fresh vegetable matter, this being probably due to the remains of animals inhabiting the coal-forming forests and swamps. The total percentage of nitrogen found in the coal usually varies between the limits of 0·9 and 2·0 p.c.; thus Tidy (Lunge's Coal Tar and Ammonia) found in Welsh coal 0·91 p.c., in Lancashire coal 1·25 p.c., and in Newcastle coal 1·32 p.c., whilst Foster (Inst. Civ. Eng. 77, iii. 23) found in Welsh anthracite 0·91 p.c., in English coals 1·66–1·75 p.c., and in Scotch cannel 1·28 p.c. Schilling (J. Gasbel, 1887, 661), using the Kjeldahl method of estimation, obtained from Westphalian coal 1·50 p.c., from Saar coal 1·06 p.c., from Silesian coal 1·35 p.c., from Bohemian coal 1·36 p.c., from Saxon coal 1·20 p.c., from Boldon (Durham) coal 1·45 p.c., from Pilsener cannel 1·49 p.c., and from Bohemian lignite 0·52 p.c. McLeod (J. Soc. Chem. Ind. 1907, 137) analysed 80 samples of Scotch coals and cannels, and found percentages of nitrogen varying from 0·91 to 1·87, and averaging 1·43.

The world's production of coal in 1909 amounted to about 950,000,000 tons, containing on the average probably some 1·3 p.c. of nitrogen, which, if the whole were recovered as ammonia, would represent an output of about 48,000,000 tons of ammonium sulphate per annum. In fact, however, the production, as shown by the above figures, only amounts to about $\frac{1}{50}$ of this quantity. Fully 90 p.c. of the coal is consumed in such a manner that the recovery of the nitrogen is impracticable, and where the processes in use are mostly such that ammonia is recovered, only a relatively small proportion of the nitrogen is actually obtained in the form of ammonia, for reasons discussed later in considering the different manufactures in which it is produced.

(*a*) *Production o ammonia in the manufacture of coal gas, and of coke in by-product coke ovens.*—In this country the carbonisation of coal in retorts for the manufacture of illuminating gas for general distribution at present yields the largest contribution of ammonia, but the output from this source is being rapidly approached by that obtained in the analogous process of carbonising the coal in ovens for the manufacture of hard metallurgical coke. Formerly the great bulk of such coke was manufactured in beehive ovens, in which case no by-products were recovered, but these are now being rapidly replaced by by-product recovery ovens. In Germany and in the United States by far the largest proportion is obtained from coke ovens.

In both industries, however, only a portion of the nitrogen of the coal is recovered in the form of ammonia, the remainder being distributed in the coke, as nitrogenous compounds in the tar, as cyanide in the gas and ammoniacal liquor, and as free nitrogen in the gas. The relative proportion of the nitrogen obtained in the different forms varies considerably, being dependent both on the nature of the coal and on the conditions of carbonisation; the rate at which the latter proceeds, and especially the temperature employed have a marked influence. At low temperatures, such, for example, as are employed in the manufacture of 'coalite' (about 450°), a very large proportion of the nitrogen remains in the coke, but with higher temperatures, although more nitrogen is given off from the coke primarily in the form of ammonia, this is partly converted into hydrocyanic acid by the action of incandescent carbon and partly dissociated into its elements, the latter being especially the case when the volatile products as well as the residual coke are strongly heated.

The maximum yield of ammonia, when coal is carbonised in horizontal retorts or in ovens, appears to be obtained with a carbonising temperature of 900°–950°, and the normal production calculated as sulphate is usually from 20–25 lbs. per ton of coal carbonised in such plant. With vertical retorts, with even higher carbonising temperatures, a higher yield is obtained, as in spite of such higher temperatures, the volatile products can escape from the action of heat without being raised to so high a temperature as is the case in horizontal retorts or ovens. Where the charge in the vertical retorts is steamed during carbonisation to increase the water-gas production in the retort, still higher production of ammonia is obtained, and the yield may then amount to 40–50 lbs. of sulphate per ton of coal.

Many attempts have been made to increase the proportion of nitrogen converted into ammonia, but none applicable to these two industries has had any success. Cooper's lime process (Eng. Pat. 5713, 1882), in which lime is added to the coal before carbonisation, was tried in many works, and abandoned, as, although a greater yield of ammonia was obtained, the gain in this respect was more than counterbalanced by the loss due to depreciation in the quality of the resulting coke.

The following tables, which give figures obtained over a long period of working in gas-works and coke ovens respectively, probably represent a fair average of the distribution of the nitrogen in the two industries under modern conditions, although doubtless in different works considerable variations from these figures occur. The gas-works figures are given by McLeod (J. Soc. Chem. Ind. 1907, 137) as the result of working at the Provan Gas Works, Glasgow, and the coke-oven figures by Short (J. Soc. Chem. Ind. 1907, 581) for the working of Otto-Hilgenstock Coke Ovens, using Newcastle coal.

	Gas works	Coke ovens	
Nitrogen in coke .	58·3 .	43·31	p.c. of total
„ in tar .	3·9 .	2·98	„
„ as ammonia	17·1 .	15·16	„
„ as cyanide .	1·2 .	1·43	„
„ as free nitrogen in the gas	19·5 .	37·12	„

McLeod does not appear, however, to include in his cyanide figures the hydrocyanic acid removed from the gas during condensation, allowance for which would probably raise the cyanide figure to about 1·5 p.c.

In both gas and coke-oven works the ammonia is recovered by cooling the gas, when tar and aqueous vapour condense, the condensed water removing a large portion of the ammonia and other gaseous impurities from the gas, and the remainder being recovered by washing the cooled gas with water. Recently, also, especially in coke-oven works, processes have been adopted in which the ammonia is directly recovered from the hot gas by washing with sulphuric acid after removal of the tar. Methods for manufacturing ammonium sulphate direct from the crude gas, in which the sulphuretted hydrogen present is simultaneously oxidised to form the necessary sulphuric acid, have been described by Feld (Eng. Pat. 3061, 1909) and Burkheiser (Eng. Pat. 20920, 1908; 21763, 1908; 17359, 1910), but the processes are still (1910) in the experimental stage.

The various apparatus employed and methods of working are described in the articles on Gas (Coal) and Coke.

(*b*) *Production of ammonia in the manufacture of producer gas from coal.*—In the manufacture of producer gas from carbonaceous fuel (*see* Gas, Producer) by the introduction of limited amounts of air and steam into the incandescent fuel, the whole of the carbon of the latter is gasified together with the nitrogen it contains. Where the quantity of steam added is limited, so as to ensure that the gas produced shall only contain small percentages of carbon dioxide, the temperature of the producer is such that almost the whole of the ammonia formed from the nitrogen is dissociated into its elements as fast as it is produced. If, on the other hand, a large excess of steam is employed, the temperature of the producer is so much lowered that the greater part of the ammonia escapes decomposition, and may then be recovered from the gas evolved. The latter contains much larger percentages of hydrogen and carbon dioxide than that obtained by the use of smaller quantities of steam, but is still capable of economic employment, especially in gas engines. The process is therefore now largely adopted for producers using bituminous fuel, especially in the Mond Gas plant, in which up to about 75 p.c. of the nitrogen in the coal is recovered as ammonia. This is usually obtained direct as sulphate by washing the crude gas with dilute sulphuric acid, and subsequent evaporation and crystallisation of the solution obtained; the sulphate thus produced has, however, generally a yellow or brownish colour, due to the presence of small amounts of tarry matter.

The use of such large proportions of steam is impracticable in gas works or coke ovens where gas of high calorific power or coke of good quality or both is required, but with the lower grade of calorific power now manufactured, a moderate proportion of steam may be admitted without undue reduction of the calorific power, and results, as mentioned above, especially with vertical retorts, in the production of greater yields of ammonia.

(*c*) *Production of ammonia from shale.*—In the distillation of Scotch bituminous shales for the production of shale oil (*see* Paraffin), ammonia is also evolved, and is recovered in a similar manner to that employed in gas works. In this case also the introduction of steam (and also of limited quantities of air) during the distillation has the effect of largely increasing the percentage of nitrogen recovered as ammonia. The objections to the method which hold in the case of the gas industry do not apply in the shale-oil manufacture, as the chief product, the shale oil, is not materially affected by the use of steam, and the coke formed is in any case of little value. The gas produced, even when steam is used, is sufficiently good for the purpose for which it is used, namely, for heating the retorts. The addition of steam for increasing the yield of ammonia was, in fact, first worked out to practical success in this industry, chiefly by Young and Beilby (Eng. Pat. 1587, 1881; 2164, 1881; 4284, 1881; 1377, 1882; 5084, 1882; see also Beilby, J. Soc. Chem. Ind. 1884, 216), its application in the case of carbonisation of coal in producers for the same purpose being of rather later date.

(*d*) *Ammonia from blast furnaces.*—Where coal is used as fuel in blast furnaces for cast-iron production, the waste gases contain considerable quantities of ammonia and tarry matters, which are now largely recovered from the gas, the latter, after purification, being employed in gas engines. In most English districts, the coal available is not sufficiently hard for use in the furnaces, and hard coke is used, the employment of coal being confined chiefly to the West of Scotland and to North Staffordshire, where coal of sufficient hardness can be obtained. The recovery of the tar and ammonia is effected by cooling and washing in a similar manner to that employed in gas works, the apparatus being suitably modified to allow for the fact that the tar and ammonia are much more diluted with other gases, and that large quantities of dust are mechanically carried along with the gas from the blast furnace. Processes for the washing of the gas with dilute sulphuric acid do not appear so far to have been permanently successful, and the same is true of the process of Addie (Eng. Pat. 4758, 1882; 3246, 1883), in which the gas was mixed with sulphur dioxide and passed through a scrubber fed with water, the resulting solution of ammonium sulphite being oxidised to sulphate by injection of air.

The yield of ammonium sulphate obtained from blast furnaces is very similar to that obtained in gas works and from coke ovens, namely from 20 to 25 lbs. per ton of coal.

(*e*) *Ammonia from peat.*—Vast deposits of peat exist in many places, especially in Ireland and Prussia, and as this contains a good deal of nitrogen, amounting in some cases to 4 p.c. of the dry peat, many attempts have been made to recover this nitrogen as ammonia. The great difficulty in the way has been the very large quantity of water contained in the peat, which is costly to remove, and hitherto very little ammonia has been put on to the market from this source. Of the earlier attempts that of Grouven (D. R. PP. 2709, 13718, 18051) is of interest, inasmuch as this represents one of the first attempts to increase the yield of ammonia by injection of steam during distillation, but although prolonged experiments were made with the process, it was ultimately abandoned. Lencauchez suggested the use of peat in gas producers with subsequent ammonia recovery, and patents relating to the matter were taken out by Ruderer, Loe, and Gumbart (D. R. P. 53844), Kuntze (Eng. Pat. 9052, 1891), and Pieper (Eng. Pat. 28190, 1896); Woltereck (Eng. Pat. 16504, 1904; 28963, 1906; 28964, 1906).

Frank and Caro, in conjunction with the Mond Gas Co. (Zeitsch. angew. Chem. 1906, 1569), find that peat containing 50 p.c. of water may be employed in place of coal in the Mond Gas plants, with production of gas suitable for gas engines, and a yield of about 90 lbs. of ammonium sulphate per ton of dry peat.

(*f*) *Ammonia from bones, horn, leather, hair, skins, and other animal refuse.*—In the distillation of bones for the manufacture of bone charcoal (animal charcoal, or 'char'), used especially in sugar refining, large quantities of ammonia are formed, together with tar rich in pyridines, known as 'Dippel's oil.' The carbonisation is frequently carried out, especially in France and Germany, by heating the bones in open pots placed in a furnace, in which case the tar and ammonia are so largely diluted with hot furnace gases that their recovery is rendered very difficult. In this country generally, and to an increasing extent elsewhere, the carbonisation is effected in closed retorts, and the tar and ammonia recovered in accordance with the usual gas works practice, the yield of ammonia being equivalent to about 50–60 lbs. of sulphate per ton of dry bones.

Other animal refuse, such as wool, hair, skin, waste leather, &c., is sometimes carbonised in a similar way, the residue being employed as manure, and the ammonia recovered from the gases. Sometimes, however, these materials are simply heated in cylinders in a current of steam, which renders them friable and capable of ready disintegration, when they are directly employed as manure. A further proposal is to utilise the nitrogen by heating the dried refuse with concentrated sulphuric acid, whereby the nitrogen is converted quantitatively into ammonium sulphate, as in the well-known Kjeldahl method of estimating nitrogen.

(*g*) *Ammonia as a by-product in the beet-root sugar industry.*—During the evaporation of beet-root juice, small amounts of ammonia are evolved, which Vibrans (D. R. P. 15513) has proposed to collect. Much larger amounts can, however, be obtained by the distillation of the 'vinasse,' *i.e.* the residue left after fermenting the sugar remaining in the molasses, and distilling off the alcohol produced. This contains nitrogenous bases, especially betaïne, and on dry distillation yields ammonia and trimethylamine. Vincent (Chem. News, 39, 107) carried out the distillation with the primary object of obtaining trimethylamine and from the latter methyl chloride, but the ammonia was simultaneously recovered as sulphate. The residue from the distillation is rich in potassium salts, and is employed as a manure or worked up into pure salts. Other patents dealing with the recovery of ammonia by distillation of vinasse are those of Ernst (D. R. P. 13871), Lederer and Gintl (D. R. P. 17874), and Meyer (Eng. Pat. 17347, 1887). Bueb (Eng. Pat. 7175, 1895; 26259, 1898; see also Ost, Zeitsch angew. Chem. 19, 609) utilises the vinasse for the production of both ammonia and cyanides, the latter being the product especially aimed at. In his process the vinasse is carbonised in retorts in the ordinary manner, and the gases, which contain ammonia and trimethylamine, but little hydrocyanic acid, are then passed through a highly heated brickwork chamber, the ammonia being only slightly affected, whilst the trimethylamine is converted chiefly into hydrocyanic acid. The resulting gases, containing about 7 p.c. of ammonia and 7 p.c. of hydrocyanic acid, are passed through sulphuric acid to recover the ammonia as sulphate, and the gas freed from ammonia employed for the manufacture of cyanide.

II. **Properties and Composition of Ammoniacal Liquor.** The ammoniacal liquor obtained by the washing and cooling of the gases produced by destructive distillation, is, after separation from tar by settling, a liquid having a colour from pale yellow to dark brown, and smelling strongly of ammonia, sulphuretted hydrogen, and also of phenols. Its specific gravity usually varies from 1·01 to 1·03. In the coal-gas manufacture, the liquor is usually obtained in three stages, viz. (1) the hydraulic main liquor, formed during the cooling of the gas to temperatures of 50°–60°, which is usually weak (0·5–1·0 p.c. of NH_3), owing to the lessened solubility of ammonia at that temperature; (2) the condenser liquor, produced in the subsequent cooling of the gas to atmospheric temperature, which is more concentrated (2–3·5 p.c. of NH_3); and (3) the scrubber and washer liquor, formed by washing the cooled gas to effect complete removal of the ammonia, the strength of which varies considerably, and depends largely on the construction of the washing plant, and the supervision of the working. The first two products together form the 'virgin liquor,' *i.e.* solution produced from the water formed by the condensation of the steam always present in the crude gas; but the liquor from all sources is usually collected together with the tar in a common storage well or wells. Frequently the weak hydraulic main liquor is used, after cooling, in the preliminary washers or scrubbers, thereby effecting a further partial removal of the ammonia, and becoming simultaneously concentrated, but for the complete removal of the ammonia the gas must be washed with fresh water in the final scrubber. In coke-oven works the conditions prevailing in these respects are very similar generally to those in gas works.

The quantitative composition of the ammoniacal liquor varies considerably, not only in that obtained at different stages of the process, but also in the average liquor obtained, being dependent on the nature of the coals carbonised, the conditions of carbonisation, and the construction and working of the condensing and scrubbing plant. The qualitative composition varies but little; the primary products formed in the liquor are ammonium chloride, sulphides, carbonates, and cyanide, produced by the action of the ammonia solution on the acid constituents of the crude gas, viz. hydrochloric acid, sulphuretted hydrogen, carbon dioxide, and hydrocyanic acid. The strongly acid hydrochloric acid is absorbed in the earlier stages of the cooling, chloride being only present to any extent in the hydraulic main and condenser liquor, but the total quantity of ammonia present is insufficient to remove the whole of the remaining acid gases, which are separated later by special purification processes. Other ammonium salts are, however, produced in the liquor by secondary reactions; thus the sulphide is oxidised by the oxygen always present in the crude gas, and later by the oxygen of the air to which it is exposed during storage, yielding polysulphides, thiosulphate, sulphate, and possibly sulphite. The cyanide reacts with the polysulphide, forming thiocyanate, and possibly also with thiosulphate, forming thiocyanate and sulphite, so that polysulphide is rarely found in the liquor. Small quantities of ferrocyanide are also sometimes formed by the action of ammonium cyanide on the ironwork of the apparatus. In addition, the liquor always contains small quantities of pyridine, and considerable amounts of substances derived from the tar, especially phenols.

From the point of view of the subsequent working up of the ammoniacal liquor, it is important to distinguish between the amount of 'volatile' and 'fixed' ammonia present. The former represents the ammonia present as sulphide, carbonate, and cyanide, and in combination with the phenols, the term being given because the ammonia in this form is completely dissociated and volatilised by simply boiling the solution; whereas that present as chloride, sulphate, thiosulphate, and thiocyanate is not evolved to any material extent under these conditions, and is therefore termed 'fixed' ammonia. For its recovery it is necessary to add to the liquor a sufficient amount of a stronger alkali to combine with the whole of the above-named acids present. The 'fixed' ammonia in the average liquor usually amounts to from 20 to 25 p.c. of the whole, but the proportion is much higher in the hydraulic main and condenser liquor.

The quantity of phenols present in gas-works liquor usually varies from 0·1 to 0·35 gram per 100 c.c. (Skirrow, J. Soc. Chem. Ind. 1908, 58).

The above table gives the results of a number of analyses of ammoniacal liquor from gas-works, coke-ovens, shale-works, and iron-works, made by Linder, on behalf of the Chief Alkali Inspector, and published in the annual reports of the latter. In addition an analysis is also given of the liquor obtained in low-temperature carbonisation as practised in the coalite manufacture, and two analyses of German gas-works liquor, by Mayer and Hempel (J. Gasbel, 1908, 428). (For methods of analysis, *see* Linder (Alkali Inspector's Report, 1909, 15), and Mayer and Hempel (*l.c.*).) In these analyses the whole of the carbon dioxide and sulphuretted hydrogen present is calculated as the normal carbonate and sulphide respectively, and in Linder's analyses the difference between the total sulphur and that present as sulphide, sulphate, and thiocyanate is calculated as ammonium thiosulphate.

The existence of free ammonia (or its

hydroxide) is a point on which considerable difference of opinion exists. The above analytical results appear to show that in the case of average stored liquor, the quantity of acids present, including phenol, is usually sufficient to combine with the whole of the ammonia but at the same time it is very probable that some of the salts, especially the sulphides and carbonates, undergo hydrolytic dissociation into acid and free ammonia or its hydroxide in the solution. With the hydraulic main liquor, formed at temperatures mostly above 60°, the acids found are insufficient to combine with the whole of the ammonia, some of which must therefore be present in the free state. The existence of free ammonium cyanide in the liquor has also frequently been denied, but more perfect methods of analysis have shown that this is undoubtedly often present in small quantity even in stored gas-works liquor, and that in coke-oven liquor, which is usually only stored for a short time before working up, the amount may be considerable. The presence of cyanide is objectionable, as it increases the amount of hydrocyanic acid in the waste gases from the manufacture of ammonium sulphate (*see* below).

III. Valuation of Ammoniacal Liquor. In this country, for technical purposes, the strength of the ammoniacal liquor is mostly expressed in terms of 'ounce-strength,' this figure representing the number of ounces avoirdupois of pure sulphuric acid required to neutralise the ammonia contained in 1 gallon of the liquor, and for statistical purposes or sale, the volumes of liquor are usually converted into the equivalent volume of liquor of 10-oz. strength. In order to convert these figures into the more generally familiar ones of grams per 100 c.c., the 'oz.-strength' figures must be multiplied by 0·217, and conversely, to convert figures representing grams per 100 c.c. into oz.-strength, the former must be multiplied by 4·61.

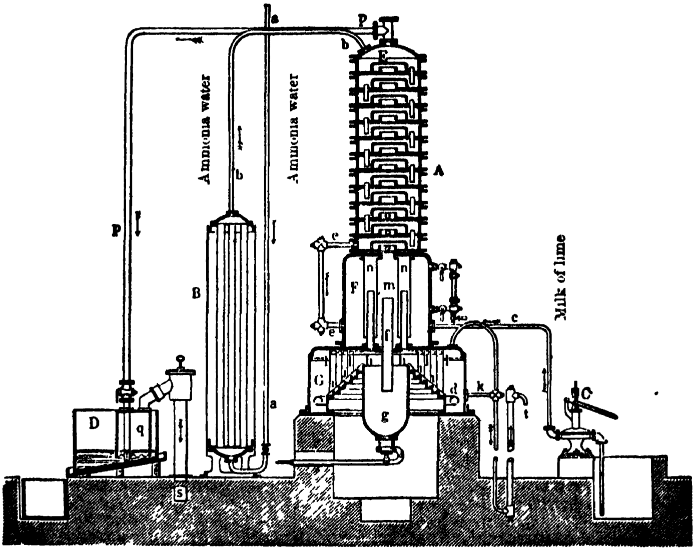

Fig. 1.

For approximate purposes the ammonia content of the liquor is frequently estimated from the density, it being found that each 1° Twaddell corresponds roughly to 2-oz. strength. This approximation is sufficient for such purposes as the control of the daily working of the washers and scrubbers on the works, but quite unsuitable for purposes where fair accuracy is desired, as a liquor showing 5°Tw., for example, may vary in actual content from 8- to 12-oz. strength, as against the supposed 10-oz. For any but the roughest purposes, ammonia is estimated by the usual method of distilling a known volume, after addition of alkali to decompose the fixed salts, collecting the distillate in excess of standard acid, and titrating the unused acid with standard alkali. The liquid must not be distilled to dryness, as otherwise the thiocyanates may be decomposed with formation of ammonia, giving too high results.

IV. Working up of Ammoniacal Liquor. In the earlier days of the utilisation of gas liquor, this was simply neutralised with sulphuric or hydrochloric acid, and the resulting solution evaporated, but the products obtained were very impure, containing tarry matter and thiocyanate, and the escaping gases, especially the sulphuretted hydrogen, created great nuisance. At present the ammonia is almost invariably recovered from the liquor in the first instance by distillation. Formerly, also, in many cases, only the volatile ammonia was recovered, as this could be obtained without addition of alkali, the fixed ammonia being run off with the waste liquor; but this procedure is now becoming exceptional, the fixed ammonia, except in the case of some small plants, being also mostly recovered by addition of the necessary alkali. On account of its cheapness, lime is almost always employed for this purpose, but in some small plants, caustic soda is used, for although the cost of the latter is much greater, this is held by some makers to be compensated for in such plants by the fact that the stills run much longer without cleaning.

The plant employed in the distillation has been of various types; at first an intermittent process of distilling the liquor in externally fired boilers was adopted, the distillation being continued until the whole of the volatile ammonia was expelled with the steam. Addition of lime to drive off the fixed ammonia was rarely practised with such plants, owing to the formation of thick deposits of lime salts on the heated boiler plates. These plants have now been almost entirely superseded by continuous column stills, constructed on the general principle of the Coffey still, the intermittent system being now employed only in very small works or in special cases, such as the distillation of liquors containing very large quantities of fixed ammonia, in which case the addition of the necessary amount of lime renders the liquid so thick that these must be stirred by mechanical agitators to effect complete recovery of the ammonia. The annual report of the Chief Alkali Inspector for 1909 shows that in the various districts into which the United Kingdom is divided for administration purposes under the Alkali Act, the proportion of liquor distilled by intermittent stills varies from about 7 p.c. to *nil*, and probably averages over the whole country from 1 to 2 p.c.

For the purpose of heating the stills, three methods have been employed: (1) external firing; (2) by means of internal coils through which steam is passed; and (3) by blowing live steam through the stills. The first plan gives a high fuel consumption, as well as trouble from lime deposits on the heated portions of the still; and of the other two methods the use of live steam is the most economical in fuel consumption, and is therefore now almost invariably adopted.

The ammonia evolved on distillation is converted at once either into ammonium sulphate, concentrated gas liquor, pure aqueous ammonia, or liquefied ammonia. The remaining salts of commercial importance, namely, ammonium chloride, carbonate, and nitrate, are now rarely manufactured directly from the ammonia as evolved from the stills, but are obtained either from ammonium sulphate or aqueous ammonia previously prepared from the gas liquor. Much the largest proportion of the liquor is converted into sulphate, the demand for this salt being greatest, owing to its employment as a nitrogenous manure. The method of manufacture of this salt will therefore be described first, followed by that of the other commercially important ammonia derivatives.

Ammonium sulphate.—A description of the different forms of intermittent still formerly adopted for obtaining the ammonia in the liquor, but now seldom used, may be found in Lunge's Coal Tar and Ammonia 4th ed. Of the continuous stills, those of Grüneberg and Blum (D. R. P. 33320) and of Feldmann (Eng. Pat. 3643, 1882) will be described, more recent forms differing from these only in detail and not in general principles. In the manufacture of sulphate, the volatile ammonia is first driven off, lime being then added to the liquor to liberate the fixed ammonia, the combined gases evolved being passed through sulphuric acid.

The apparatus of Grüneberg and Blum is shown in Fig. 1, as arranged for the manufacture of sulphate. A is the still, B the gas-liquor heater or economiser, C the lime pump, and D the saturator charged with acid for absorption of the ammonia. The gas liquor enters the economiser B by means of pipe *a*, and is heated by the hot waste gases from the saturator, and passes thence by the pipe *b* to the top of the column E of the still. This column is divided into a number of compartments by horizontal division plates, the liquor flowing downwards from compartment to compartment by the overflow pipes, the admitted steam travelling upwards in the reverse direction through the central pipes *o*, covered by hoods having serrated edges, which compel the steam to bubble through the liquor in each compartment, thus driving off the 'volatile' ammonia and also the volatile acids present, viz. carbon dioxide, sulphuretted hydrogen, and hydrocyanic acid.

The lime vessel F, into which milk of lime is pumped by means of pump C and pipe *c*, serves to expel the fixed ammonia, and the boiler G, with its stepped cone, serves to boil the liquor in thin sheets, by means of the steam coil *d*, and thus to set free the last portions of ammonia. In B the first heating of the liquor takes place by means of the hot vapours from the saturator D, which ascend through the bell *q*, the pipe *s*, and the inner pipes of B, while the liquor, arriving at *a*, rises up in B. It then enters through *b* into the dephlegmating column E, and finds its way downward from chamber to chamber, till it gets into the lime vessel F. From here it overflows by pipe *f* into the sludge-catcher *g*, overflows here again all round at *hh*, and runs over the cone *i* downwards from step to step; from the pipe *k* it is discharged continuously and quite spent to the overflow *l*. The steam travels in the opposite way—namely, along the steps of cone *i*, upwards in pipe *m*, and through *n* into the lime vessel F. From here the mixed steam and ammonia vapours ascend into the column E, and traverse this from chamber to chamber, and ultimately leave it by the pipe *p*. This pipe enters the saturator D, charged with sulphuric acid. The sulphuretted hydrogen, carbon dioxide, &c., collecting in the bell *q*, are led through the flue *s* into the economiser B, where they give up their heat to the gas liquor, and lose their steam in the shape of condensed water. Ultimately they are conveyed away by a pipe not shown in the diagram for treatment to prevent nuisance, the methods adopted for the purpose being described below.

In the apparatus of Feldmann (D. R. P. 21708), Fig. 2, the gas liquor, after having passed through the ordinary rectifying column A, flows into a vessel B, into which milk of lime is pumped by G in regular intervals, whilst the whole is kept agitated by steam injected into the mixture. The liquor, after having deposited most of the lime, flows into a second column C, where the ammonia set free by the lime is distilled off: the spent liquor runs away continuously through *g*, and the gases and vapours pass over by pipe *h* into the first column BA, which serves both for retaining the water and for driving off the volatile ammonium salts contained in the crude gas liquor. The economiser J, and the saturator B, with the gas-bell F, require no special explanation.

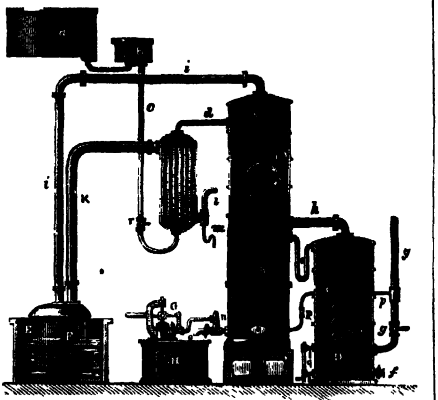

FIG. 2.

In more recent types of still, only a single column is usually employed, the lime being introduced into one of the compartments of the lower portion of the still, which may be made of larger size for this purpose, the hood being also more deeply sealed to effect more vigorous agitation. The mixture of liquor and lime then passes through the lower compartments of the still, constructed in a similar manner to those above. A still of this type, manufactured by the Berlin Anhaltische Maschinen Actien-Gesellschaft is shown in Fig. 3.

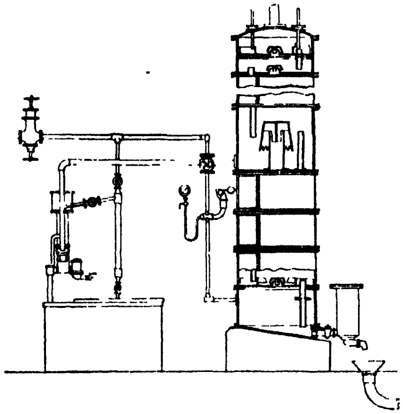

FIG. 3.

Other modifications relate chiefly to improvements in mechanical details, and in making the parts more accessible for cleaning, especially in the portions of the still where lime is present. Thus Wilton (Eng. Pat. 24832, 1901) replaces the central pipe for the steam and circular hood, by a narrow opening extending over nearly the full diameter of the still, and covers this with an inverted trough having serrated edges, which can readily be removed for cleaning from a small manhole at the side. Scott (Eng. Pat. 3987, 1900; 11082, 1901) has patented a process in which the whole of the plant is kept under vacuum, whereby considerable economy of fuel is claimed. The plant and method of working are described by Ballantyne (J. Gas Light. 82, 869).

Absorption of the ammonia in sulphuric acid.—The gases from the still, consisting chiefly of ammonia steam, carbon dioxide, sulphuretted hydrogen, and small quantities of hydrocyanic acid, are conveyed to the saturator (D in Fig. 1, E in Fig. 2) charged with sulphuric acid. This is constructed either of solid lead throughout, or of wood or iron lined with lead, the gases being conducted in by means of a perforated leaden pipe which distributes them over a large area in the saturator and keeps the liquid thoroughly agitated. In some cases, dilute sulphuric acid is used, this being removed and replaced by fresh acid when nearly neutralised. The solution, after settling, is concentrated and crystallised, the mother liquor being returned to the saturator. The dilute solution of ammonium sulphate obtained by direct washing of the crude gas with acid, as in the Mond Gas process, is evaporated and crystallised in a similar way. In most cases, however, when distilling gas liquor, a much stronger acid (of about 140° Tw.) is used which soon becomes saturated, after which the ammonium sulphate crystallises out as formed, and is removed by various means, fresh acid being run in to replace that removed as sulphate. Two types of saturator are employed, (*a*) partly open, (*b*) closed. A common construction of the former type is shown in Fig. 4, the gases entering by the pipe *b* perforated as shown, and bubbling through the acid, the waste gases being led off by the pipe *c*; the sulphate accumulates on the floor of the saturator. The front of the saturator is open, and separated from the closed portion by the sealing curtain *a*, which does not reach to the bottom, and enables the attendant to remove the sulphate periodically by fishing with a perforated ladle, the crystals being placed on a lead-lined drainer fixed so that the mother liquid flows back to the saturator.

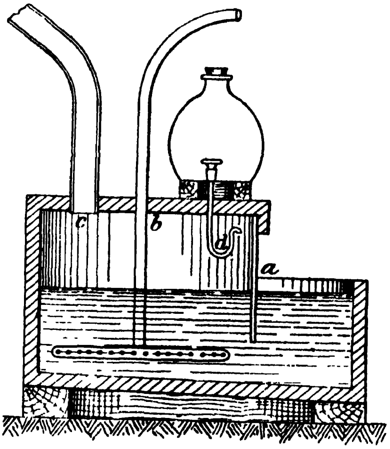

FIG. 4.

When sufficiently dry, the product is placed into stock, or it may be at once dried by a centrifugal machine.

In place of 'fishing,' the sulphate may be periodically or continuously removed from the saturator by means of a steam-ejector, which forces it together with much liquor on to the drainer, thence into a centrifugal machine, the mother liquor in either case returning to the saturator.

With a closed saturator other means of removing the sulphate are adopted, a representative of this type being the Colson saturator, the bottom of which consists of an inverted cone, to the apex of which is fixed a right-angled bend, closed by a simple valve, consisting of a copper disc pressed against the flange of the outlet pipe by a screw clamp. During working this is opened to a sufficient extent to allow the sulphate to fall out almost as soon as it is formed.

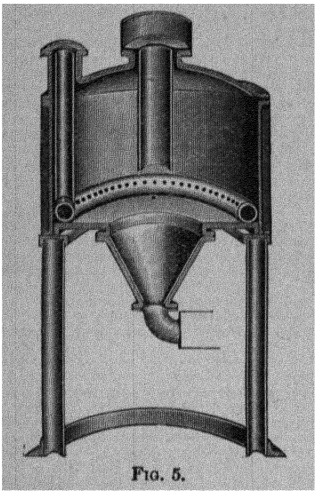

Fig. 5.

The ammonium sulphate thus obtained usually contains from 24 to 25 p.c. of ammonia, equivalent to about 93–99 p.c. of pure ammonium sulphate. It usually contains from 0·1 to 0·5 p.c. of free sulphuric acid, the remainder consisting of moisture and small quantities of insoluble matter. The salt produced with modern plant has mostly a white or greyish-white colour, discolouration by tarry matter being now of rare occurrence with continuous stills, if the liquor is properly separated from tar by settling previous to distillation. When pyrites sulphuric acid is employed, the resulting sulphate may be coloured yellow or brown, by arsenic sulphide, which depreciates its value, and makers therefore prefer to use acid obtained from brimstone or spent oxide. In many cases, however, pyrites acid is used, and the arsenic sulphide which rises as a scum to the surface of the liquid in the saturator removed as it forms, or preferably the acid is previously treated with a portion of the waste gases from the saturator, the sulphuretted hydrogen in which precipitates the arsenic as sulphide, the latter being removed before the acid enters the saturator.

In some cases the sulphate assumes a blue colour on standing in the air, owing to the formation of traces of Prussian blue. From the researches of Forbes Carpenter and Linder (Chief Alkali Inspector's Report, 1905, 51), it appears that this is mostly due to local alkalinity occurring in some portion of the liquid in the saturator, in which case hydrocyanic acid is absorbed at that point, and, with the traces of iron always present, forms ammonium ferrocyanide; the latter, on exposure to the air, oxidises, forming Prussian blue. Priming of the still, resulting in the introduction of ferrocyanides and thiocyanates into the saturator, has a similar effect, but the production of the blue salt often occurs in absence of priming. Its formation is best avoided by maintaining the liquid hot and of sufficient acidity, and arranging that the passage of the gas shall effect a thorough mixing of the liquid in the saturator, so as to prevent the occurrence of local alkalinity.

Waste products in the manufacture of Ammonium Sulphate.—Three waste products are formed in the process: (*a*) the effluent liquor; (*b*) the aqueous condensate from the cooling of the waste gases; (*c*) the waste gases. The effluent liquor is run into settling tanks, where it deposits suspended lime salts, and becomes cooled. The clarified liquor is sometimes run into the sewers, but as it contains large quantities of lime salts (especially thiocyanate and phenols), this is frequently not permitted, and its disposal is often a matter of great difficulty. In gas works it is sometimes got rid of by employing it to quench the hot coke from the retorts, and in some cases it is even evaporated to dryness. Fowler (Alkali Inspector's Report, 1907, 51) allows the liquor, after considerable dilution, to pass through coke filters inoculated with sewage bacteria, which, if gradually accustomed to the liquor, oxidise the thiocyanates and phenols, yielding a fairly pure effluent, and this may be employed for dilution of the fresh liquor going on to the filter. Radcliffe (Eng. Pat. 10075, 1905) removes the thiocyanates by precipitating as cuprous thiocyanate with copper sulphate in presence of sulphurous acid, the latter being obtained by burning a portion of the waste gases. Grossmann (Eng. Pat. 20387, 1905; 7932, 1907; J. Soc. Chem. Ind. 1906, 411) has also described a process for avoiding the production of waste liquor and recovery of the ferrocyanide and thiocyanates present in it.

The avoidance of the production of waste liquor altogether is an especial object in the process of the Otto-Hilgenstock Coke Oven Co. (Eng. Pat. 12809, 1908) now being adopted in some coke-oven works. In this the gas from the ovens is treated for the removal of tar at temperatures above that at which water condenses, and then passed directly through sulphuric acid; the aqueous condensate obtained in the subsequent cooling of the gas is free from ammonia, and only contains small amounts of impurity, and it is claimed that no difficulty is experienced in disposing of it. Wilton (Eng. Pat. 16355, 1909) has patented a somewhat similar process with the same object.

The aqueous condensate obtained by cooling the waste gases is a very noxious-smelling liquid, and is hence termed 'devil-liquor.' It contains sulphuretted hydrogen, pyridines, and similar substances, and hydrocyanic acid, and is also difficult to dispose of. The hot condensate from the liquor-heater or economiser is less objectionable than that obtained in the further cooling of the waste gases, which contains much more sulphuretted hydrogen; but if the latter is returned to the pipe conveying the hot condensate and the waste gases from the economiser, most of the sulphuretted hydrogen is driven off again into the waste gases, and the combined liquor, after cooling, may be mixed with the effluent from the stills without increasing the difficulty of dealing with the latter (Broadberry, J. Gas Light. 69, 345).

The waste gases, after cooling, consist chiefly of carbon dioxide, sulphuretted hydrogen, and smaller quantities of hydrocyanic acid, as well as strongly smelling empyreumatic vapours derived from the tar. With coke-oven liquors, which often contain considerable quantities of cyanide, the amount of hydrocyanic acid may be considerable, necessitating additional care in dealing with it owing to the poisonous nature of the gas. In many cases the gases are burned under the boiler or other furnaces, and discharged with the products of combustion from the chimney; or the gases may be burned separately and the resulting sulphur dioxide absorbed by passing the products through a limestone tower down which water is passing, yielding a solution of calcium bisulphite, or through scrap-iron towers, when a solution of ferrous sulphate is formed (Wilton, Eng. Pat. 15468, 1901). With small and medium-sized plants, the sulphuretted hydrogen and hydrocyanic acid are mostly removed by oxide of iron, in a similar manner to that employed for purifying coal gas. In place of purifying boxes, conical heaps of oxide of iron on a concrete floor are now much used, the gas being introduced from the bottom at the centre of the heap; the spent oxide obtained is saleable for its sulphur content. The sulphuretted hydrogen may also be precipitated with metallic salts, and where sulphuric acid is also made, the gases are burned and passed into the chambers, thus recovering the sulphur as sulphuric acid. A considerable proportion of the waste gas is converted into sulphur by the Claus process (Eng. Pat. 3606, 1882; 5070, 1883; 5958, 1883), also used on the large scale in the Chance sulphur-recovery process. By this method, sufficient air is mixed with the gas to react with the sulphuretted hydrogen in accordance with the equation $2H_2S+O_2=2H_2O+2S$, and the mixture passed through a kiln containing heated ferric oxide, the sulphur formed being deposited in cooling chambers, and the residual gases passed through a small limestone tower and oxide-of-iron purifier to remove any sulphur dioxide or sulphuretted hydrogen remaining. The sulphur obtained is not very pure, owing to tarry matters, &c., present in the gases treated.

Manufacture of Caustic Ammonia (Liquor Ammoniae) and of Liquefied Ammonia.—The pure aqueous solution of ammonia was formerly manufactured by distilling ammonium sulphate with lime in intermittent stills provided with mechanical arrangements for stirring the somewhat thick cream, but it is now usually made by the direct distillation of gas liquor, with suitable purification of the gas evolved from the stills, which is then dissolved in water. In addition to the pure aqueous solution, a crude solution containing sulphide, and sometimes carbonate, is also largely manufactured, this being cheaper and equally applicable to many purposes, especially in the manufacture of soda by the ammonia-soda process, and for the preparation of other ammonium salts. This crude product is termed 'concentrated gas liquor,' two kinds being manufactured, the one containing from 16 to 18 p.c. of ammonia, with both sulphide and carbonate present, and the other from 18 to 26 p.c. of ammonia, with some sulphide but little or no carbonate.

In the manufacture of the first-named liquor, the gases from the stills, worked as in the manufacture of the sulphate, pass through a reflux condenser, to remove some of the steam present, and then through a direct condenser, the gases from which are washed with water. Working in this manner, it is not practicable to obtain a greater strength of ammonia than 16–18 p.c., as with higher concentrations stoppages occur in the condenser from crystallisation of ammonium carbonate.

25 *p.c. Concentrated Liquor.*—In the manufacture of this liquor containing little or no carbonic acid and only small amounts of sulphuretted hydrogen, the crude gas-liquor is first subjected to a preliminary heating to temperatures somewhat below 100° (Hill's process), at which temperature a large proportion of the carbon dioxide and sulphuretted hydrogen are evolved, accompanied by only small quantities of ammonia, the latter being recovered by washing the evolved gases with water or weak ammoniacal liquor, or by other suitable means; the preheated liquor is then distilled as in the case of the sulphate process with the addition of sufficient lime to decompose completely all fixed ammonium salts present, and the steam and gases from the still passed through a reflux condenser, to remove the bulk of the steam, and thence to a condenser; the condensate from the reflux condenser, which contains a considerable amount of ammonia, is returned to the still. The concentrated liquor from the final condenser contains usually about 25 p.c. of ammonia, and has a yellowish colour. It is usually almost free from carbonic acid, and should not contain more than 0·5 p.c. of sulphuretted hydrogen. In addition small amounts of cyanide, ferrocyanide, and thiocyanate are mostly present, derived from the hydrocyanic acid evolved from the crude liquor, and also small amounts of phenols and of pyridine bases.

Pure Caustic Ammonia.—In the manufacture of this product, the procedure in the first part of the process is the same as in the case of the production of the 25 p.c. concentrated liquor To further purify the gases evolved from the still, and to remove as completely as possible all impurities from them after passing the reflux condenser, the gases traverse a set of two or three washers containing cream of lime to remove carbon dioxide, sulphuretted hydrogen, hydrocyanic acid, and phenol vapours, the partly used lime flowing back to the stills to effect the decomposition of the fixed ammonium salts, and recovery of ammonia from the cream. To ensure the removal of the last traces of sulphuretted hydrogen, ferrous sulphate solution is sometimes added to the last lime washer, the ferrous hydroxide formed by the action of the lime retaining the gas as ferrous sulphide, or, according to Pfeiffer (J. Gasbel. 1900, 89), a small final washer containing caustic soda solution is added. Solutions of sodium permanganate or ammonium persulphate may also be used (Foucar). The gases then pass through a series of scrubbers charged with wood charcoal, which remove the strongly smelling empyreumatic substances derived from the tar, and in some cases additional purification in this respect is effected by passing the gas through a fatty or high-boiling mineral oil. The resulting purified gas is then led into distilled water, and thus converted into solution of any desired strength up to about 36 p.c. The charcoal scrubbers must be renewed as soon as their activity becomes lessened, the spent material being revivified by heating in closed retorts.

Technical caustic ammonia is usually clear and colourless, and contains only small quantities of pyridine and empyreumatic substances. When these are present in larger quantity, owing to defective action of the charcoal filters, the liquid assumes a yellowish colour on keeping. Its strength is ascertained from its specific gravity.

Liquefied Ammonia.—The liquefied gas, stored in steel cylinders, is now largely produced and employed for refrigeration purposes. It is manufactured from the gas obtained and purified as described for the manufacture of the pure aqueous solution, but instead of passing t into water, it is well dried, and then compressed by suitable pumping machinery. The commercial liquid usually contains small amounts of water, pyridine, and lubricating oil, and traces of other substances, but is now sold, in many cases, as of guaranteed 99·9 p.c. purity.

Ammonium Chloride (Muriate of Ammonia or Sal-ammoniac).—This salt has been manufactured in a similar manner to that employed or the sulphate, by passing the gases from the stills into hydrochloric acid, but as ead is attacked under these conditions, the saturator must be constructed of stoneware or imilar material, which has many disadvantages. t is now usually made by neutralising hydrohloric acid with concentrated gas liquor, and vaporating and crystallising the resulting olution, or by evaporating a solution of ammonium sulphate and sodium chloride in equivalent proportions; the sodium sulphate formed eparates out during concentration as the monohydrate, which is removed by 'fishing,' eaving finally a concentrated solution of ammonium chloride, which is purified by crystallisaion.

It is also manufactured by neutralising 'galvanisers' pickle" (which consists chiefly of errous chloride) with ammonia, and by the action of ammonium carbonate (or of ammonia and carbon dioxide) on calcium chloride solution, he latter being obtained in large quantity as a by-product in the ammonia-soda manufacture, nd in that of potassium chlorate; the solutions, f ammonium chloride obtained in either case are evaporated and crystallised after removal of he precipitated substances.

Ammonium chloride may be obtained in cubical crystals by adding small amounts of ammonium acetate to the crystallising solution. The modification of crystalline form is probably due to acetamide produced by the decomposition of the ammonium acetate.

Ammonium chloride is frequently purified by sublimation, the sublimed product being known as *sal-ammoniac.* In this country the operation is carried out in large iron pots externally heated and covered with a similar concave iron plate on which the sublimate (sal-ammoniac) forms. This is detached at the end of the operation, the surface adhering to the iron, which is always discoloured, being removed previous to sale. In France the discolouration with iron is avoided by using earthenware pots, but the product is more expensive, owing to the fact that the pots are destroyed at each operation.

The commercial crystallised salt is white or only slightly discoloured, whilst the sublimed material has a fibrous structure, and frequently contains small amounts of iron. It is employed in pharmacy, soldering, galvanising, dyeing, and calico-printing, and in small quantities for many other purposes.

Ammonium Carbonate (Sal-Volatile).—The commercial product sold under this name consists of a mixture of ammonium bicarbonate $NH_4 \cdot HCO_3$ with ammonium carbamate $NH_2 \cdot CO \cdot ONH_4$, and contains about 31 p.c. of ammonia and 56 p.c. of carbon dioxide. It is usually prepared by subliming a mixture of about 1 part of ammonium sulphate with 1·5 to 2 parts of chalk in retorts, the evolved gases being passed into leaden chambers, where the carbonate is deposited as crusts on the walls, the exit gases being washed with water or sulphuric acid to recover the uncondensed ammonia. Lunge recommends the passing of an additional quantity of carbon dioxide through the chambers to effect a more complete recovery of the ammonia. As soon as the crust has attained a sufficient thickness it is detached, and is usually purified by resublimation. In Kunheim's process, the carbonate is prepared by passing ammonia obtained by the distillation of gas liquor direct into chambers, where it mixes with carbon dioxide and deposits the carbonate as a crust. (*See also* Bueb, Eng. Pat. 9177, 1910.)

The commercial product forms crystalline crusts, smelling strongly of ammonia, which is partially evolved on exposure to the air, the mass efflorescing and leaving a powder consisting of ammonium bicarbonate. It is employed in wool-scouring, dyeing, and as a constituent of baking powders.

Ammonium Nitrate.—This salt is produced to a very large extent for use in the explosive industry and in the preparation of nitrous oxide. It may be obtained by neutralising caustic ammonia with nitric acid, and evaporating and crystallising the solution if necessary, or by passing ammonia-gas from the stills, after purification, into commercial nitric acid, the heat evolved by the combination causing the evaporation of the water present and production of fused ammonium nitrate. Calcium nitrate may also be converted into ammonium nitrate by passing ammonia and carbon dioxide through its aqueous solution, calcium carbonate being precipitated. It is, however, now chiefly prepared from ammonium sulphate and sodium nitrate by the process of Freeth and Cocksedge (Eng. Pat. 120678). This process depends on the fact that when a solution saturated with respect to ammonium nitrate, sodium nitrate and sodium sulphate at any given temperature, but not in contact with the solid salts, is diluted with sufficient water to enable the sodium salts to be retained in solution at a lower temperature to which it is to be cooled on dilution, then, on cooling to that temperature ammonium nitrate crystallises out in practically pure condition. After separation of the nitrate, the clear solution is concentrated to drive off the amount of water added on previous dilution, and a further quantity of a mixture of equivalent amounts of sodium nitrate and ammonium sulphate added. The whole is maintained at a temperature not lower than that at which the original was saturated previous to dilution with water. Sodium sulphate then separates in practically pure condition, and after its removal the dilution with water and cooling is repeated, and the cycle of operations repeated. In this manner the whole of the ammonium sulphate and sodium nitrate are completely converted into practically pure ammonium nitrate and sodium sulphate.

Calcium nitrate may also be converted into the ammonium salt by passing ammonia and carbon dioxide gases through its aqueous solutions, calcium carbonate being precipitated.

Ammonium phosphate. Monammonium phosphate $(NH_4)H_2PO_4$, and diammonium phosphate $(NH_4)_2HPO_4$ have become commercial products by the process of Lagrange, which starts from commercial calcium superphosphate. This is lixiviated by water and steam, and a solution of 42°Tw. is obtained, together with a residue of calcium sulphate. Some of the latter remains in the solution, and is removed by carefully adding barium carbonate. The filtrate is neutralised by ammonia in slight excess, whereby all the lime is precipitated as basic phosphate, which is washed and used over again for the manufacture of superphosphate. The filtered solution, marking 32°Tw., contains monammonium phosphate, and can be worked for this or for diammonium phosphate. The latter is obtained by gradually mixing the above solution with *liquor ammoniæ* of sp.gr. 0·92, in the proportion of 1¼ equivalents of NH_3 to 1 of $(NH_4)H_2(PO_4)$. The diammonium phosphate at once separates out as a crystalline mass, which, after cooling, is submitted to hydraulic pressure. The operation is carried out in a closed vessel, to prevent the escape of ammonia. The mother liquor is employed for the manufacture of ammonia. The diammonium phosphate is principally used in Lagrange's sugar-refining process.

Ammonium thiocyanate is manufactured in considerable quantity in the crude state, but the product is for the most part simply employed as an intermediate product in the manufacture of cyanides. It occurs, as has been mentioned, in considerable amount in gas-liquor, and also in spent oxide, from which it may be extracted by water, but in both cases it is mixed with so many other impurities that its recovery is not remunerative; it may, however, be easily isolated as cuprous thiocyanate by precipitation with copper sulphate and sulphurous acid. It is prepared synthetically from carbon disulphide by absorbing the latter in ammonia in presence of bases such as lime (Albright and Hood, Eng. Pat. 14154, 1894), the ammonium thiocarbonate first produced undergoing conversion into thiocyanate. A concentrated solution of ammonium thiocyanate is now prepared in a number of gas works, according to the British Cyanide Co.'s and Williams' process (Eng. Pat. 13653, 1901), by passing the crude gas containing ammonia and hydrocyanic acid through a purifier containing sulphur in the form of spent oxide and moistened with water and fed with powdered sulphur, the ammonium polysulphide first formed combining with the hydrocyanic acid to form thiocyanate, solutions of 30–50 p.c. strength being readily obtained, which only contain small amounts of other non-volatile ammonium salts.

The pure salt is used in dyeing and calico-printing, and may be obtained from the crude product by first converting it into the barium salt with baryta-water; or the barium salt may be produced by the action of barium sulphide on cuprous thiocyanate. After purification by recrystallisation, the barium salt is exactly precipitated with ammonium sulphate, and the solution evaporated and crystallised. The white deliquescent salt has frequently a reddish colour, due to the formation of the red ferric thiocyanate, from traces of iron present.

Ammonium persulphate. This salt is now produced on the commercial scale by the electrolysis of ammonium sulphate, and is employed for photographic purposes and as an oxidising agent. The commercial product usually contains small quantities of lead derived from the electrodes used in its manufacture.

H. G. C.

AMMONIACUM, AFRICAN, GUM, PERSIAN, *v.* Gum Resins.

AMMONITE *v.* Explosives.

AMMONIUM MELEQUETA *v.* Cocculus Indicus.

AMPANGABEITE. A rare-earth mineral from Madagascar, described by A. Lacroix in 1912. It is a tantalo-columbate (containing but little titanium) of uranium (UO_3 19·4 p.c.), iron, yttrium, thorium, &c. The crystals are orthorhombic and form sub-parallel groupings of large prisms of a brown colour and bright greasy lustre. Sp.gr. 3·97–4·29, depending on the degree of hydration, the material being optically isotropic. The mineral occurs associated with beryl, columbite, strüverite, and monazite in pegmatite veins at Ampangabe, Ambatofotsikely, and Tongafeno. A considerable number of loose crystals have been collected from the weathered debris of the pegmatite.

L. J. S.

AMPELOPSIDIN, AMPELOPSIN, *v.* Anthocyanins.

AMPHOTROPHIN. Trade name for hexamethylenetetramine camphorate.

AMRAD-GUM. This gum forms white, yellow, and brown lumps of a sweetish taste and resinous smell. An aqueous solution (1 : 2) is viscid and strongly adhesive. It also gives with oil excellent emulsions, which keep very well. The dry substance contains 5·61 p.c. of ash, consisting of carbonic acid, lime, iron, magnesia, traces of phosphoric acid and silica. Has been recommended as a substitute for gum arabic. It was brought into the market some years ago, and comes from the Abyssinian highlands; is probably obtained from *Acacia etbacia* (Schweinfurth). (H. Unger and Kempf. Pharm. Zeit. 33, 218; J. Soc. Chem. Ind. vii. 446.)

AMYGDALASE, AMYGDALIN *v.* GLUCOSIDES.

AMYGDONITRILE GLUCOSIDE *v.* GLUCOSIDES.

AMYGDOPHENIN *v.* SYNTHETIC DRUGS.

AMYL signifies the hypothetical monovalent radical $C_5H_{11}—$, derived from the three isomeric pentanes, C_5H_{12}, by removal of one hydrogen atom. Normal pentane may have one hydrogen atom substituted by a monovalent atom or group in three ways, secondary pentane or dimethylethylmethane may have one hydrogen atom substituted in four ways, and tertiary pentane or tetramethylmethane may have one hydrogen atom substituted in one way. There are thus eight series of derivatives of the radical 'amyl.' It is usual to designate as *amyl compounds* those of the type $CH_3{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2X$, where X signifies a monovalent atom or group, and those of the type  $\begin{matrix}CH_3\\CH_3\end{matrix}\!\!>CH{\cdot}CH_2{\cdot}CH_2X$ as *isoamyl compounds*. Frequently derivatives of the type  $\begin{matrix}CH_3{\cdot}CH_2\\CH_3\end{matrix}\!\!>C<\!\!\begin{matrix}H\\CH_2X\end{matrix}$, when in the optically active form, are referred to as *active amyl compounds*, as the commonly occurring active amyl alcohol belongs to this class. The other types of amyl derivatives are designated according to the usual methods of nomenclature in organic chemistry.

The amyl compounds of technical importance are all prepared from fusel oil, and are therefore in no case pure chemical individuals, but consist of an *iso*amyl compound containing a variable proportion of the corresponding *d*-amyl derivative.

Amyl Alcohols $C_5H_{11}OH$. The eight theoretically possible structural isomerides are all known. Of these, three should also be capable of existing as optically active stereoisomerides. This has been realised in two cases, but not in the third, namely that of methyl*iso*propylcarbinol.

n-**Amyl Alcohol** $CH_3{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2OH$ (Pentanol). This alcohol was prepared in an impure state by Schorlemmer (Annalen, 1872, 161, 269) from crude pentane. Wischnegradsky (Annalen, 1878, 190, 328) concluded that it was present in commercial amyl alcohol, but this has been shown to be incorrect (Tissier, Bull. Soc. chim. [3] 9, 100).

It is a colourless liquid of fusel oil odour; b.p. 137·7°; $D^{20°}_{20°}=0·8168$. It is best prepared by reducing valeramide with sodium and alcohol (Chem. Zentr. 1904 [2] 1698), or by a similar reduction of ethyl-*n*-valerate or ethyl-*n*-propylacetoacetate (D. R. P. 164294, 1905; *see* also Biochem. Zeitsch. 1914, 62, 470; and Annalen, 159, 70; 233, 253).

Isobutyl Carbinol $(CH_3)_2CH{\cdot}CH_2CH_2OH$ (3-methylbutanol). Ordinary *iso*amyl alcohol, fermentation amyl alcohol, is the chief constituent of most fusel oils. It also occurs as angelic and tiglic esters in oil of camomile (Annalen, 195, 99). It constitutes from 50 to 85 p.c. of technical amyl alcohol. (For further details as to the isolation of *iso*amyl alcohol from fusel oil, &c., *see* below under 'Fusel Oil.')

It is a colourless liquid possessing a characteristic, cough-provoking, odour; b.p. 131·4°/760 mm., 46·8°/14·2 mm. It freezes at −134°, and melts at −117·2°; $D^{0°}_{4°}=0·823$. It is soluble in 50 parts of water at 13·5°. One litre of water dissolves 34·7 c.c. isoamyl alcohol; 1 litre of the alcohol dissolves 22·14 c.c. water.

It may be prepared synthetically by reducing *iso*valeric acid (from *iso*butylalcohol), or better, by the action of trioxymethylene on *iso*butylmagnesium bromide (Locquin, Bull. Soc. chim. 1904, [3] 31, 599). It is a strong poison both to human beings and to bacteria. It is about eight times as poisonous to man as ethyl alcohol.

Derivatives.—Urethane, m.p. 64·5°; phenyl urethane, m.p. 54°; phenyl carbamate, m.p. 55°.

Secondary Butyl Carbinol

$CH_3{\cdot}CH_2CH(CH_3){\cdot}CH_2OH$

(2-methylbutanol). Active amyl alcohol, the second constituent of commercial amyl alcohol, is a colourless liquid of similar odour to the above. The vapour does not provoke coughing, but has greater stupefying effects; b.p. 128°; $D^{20°}_{4°}=0·816$; $[a]^{20°}_{D}=-5·90°$.

The active alcohol, in spite of its lævorotation is more correctly termed *d*-amyl alcohol, on account of its genetic relationships with *d*-*iso*leucine and with *d*-valeric acid. The oxidation of the alcohol yields pure *d*-methylethylacetic acid. For the methods of isolating the pure active alcohol from fusel oil, *see* below, under 'Fusel Oil.' It should be noticed that all technical amyl compounds contain variable amounts of the active amyl derivatives.

Derivatives.—Urethane, m.p. 61°; phenyl carbamate, m.p. 30°; 3-nitrophthalate, m.p. 114°.

The active alcohol is partially or wholly racemised by heating above 200°, more especially when in the form of sodium amylate or in the presence of salts soluble in the liquid (Chem. Soc. Trans. 1897, 71, 256; Proc. Roy. Soc. 17, 308). The racemic alcohol has been synthesised by the reduction of natural or synthetic tiglic aldehyde (Herzig, Monatsh. 3, 122), and by the action of secondary butylmagnesium bromide on trioxymethylene (Freundler and Damond, Bull. Soc. chim. [3] 35, 110). It has b.p. 128°/749 mm. Its acid *m*-nitrophthalate melts at 117°. A mixture of racemic with *l*-amyl alcohol was obtained by Le Bel (Bull. Soc. chim. 1878, [2] 31, 104).

Tertiary Butylcarbinol $(CH_3)_3C{\cdot}CH_2OH$ (2·2-dimethylpropanol). This alcohol is a volatile solid melting at 52°–53°, and has a pleasant turpentine-like odour; b.p. 113°–114°. It has all the characteristic properties of a primary alcohol.

It has been prepared by reduction of trimethylacetyl chloride, also, in poor yields, by chlorination, &c., of tetramethylmethane and by the action of a Grignard reagent on paraformaldehyde or methyl formate (Tissier, Ann. Chim. Phys. [6] 29, 340; Samec, Annalen, 351, 256; Bouveault, Compt. rend. 138, 985, 1108).

The action of nitrous acid upon this alcohol yields not this alcohol, but the isomeric dimethylethylcarbinol (Tissier, Compt. rend. 112, 1065).

Methyl-*n*-propylcarbinol $CH_3{\cdot}CH(OH){\cdot}C_3H_7$ (pentanol-2). This is a colourless liquid of b.p. 119°, and $D_{20°}^{20°}=0{\cdot}8102$. It is prepared by the reduction of methyl-*n*-propyl ketone by means of sodium amalgam, or better, by the method of Sabatier and Senderens (Chem. Zentr. 1903, [2] 708). The best method of preparation is by the action of propylmagnesiumbromide on acetaldehyde.

This alcohol is racemic. Le Bel, using *Penicillium glaucum*, obtained a lævorotatory specimen (Compt. rend. 89, 312). Pickard and Kenyon (Chem. Soc. Trans. 1911, 99, 45), by crystallisation of the strychnine and brucine hydrogen phthalates, obtained the pure *d*-alcohol; b.p. 118·5°–119·5°; $D_{4°}^{12{\cdot}3°}=0{\cdot}8169$; $[\alpha]_D^{20°}=+13{\cdot}70°$.

Methylisopropylcarbinol

$CH_3{\cdot}CH(OH){\cdot}CH(CH_3)_2$

(4-methylbutanol-2), a colourless liquid of b.p. 113°, which has the fusel oil odour. It does not freeze at −33°. It has $D_{19°}^{19°}=0{\cdot}819$. Hydrogen halides react with it very slowly to produce only tertiary compounds, such as $C_2H_5{\cdot}(CH_3)_2{\cdot}C{\cdot}Cl$. It has been prepared by the reduction of the corresponding ketone, and, in good yield, by the peculiar action of zinc dimethyl upon bromoacetyl bromide or chloroacetyl chloride (Annalen, 191, 127; 209, 87). It may also be obtained by the interaction of methylmagnesium bromide and isobutylene oxide, chloroacetone, or chloroacetyl chloride (Compt. rend. 145, 21).

This alcohol is racemic; the optically active components have not been isolated.

Diethylcarbinol $C_2H_5{\cdot}CH(OH){\cdot}C_2H_5X$ (pentanol-3). This is a colourless liquid having the usual amyl alcohol odour; b.p. 114°–115°/749 mm.; $D^{14{\cdot}7°}=0{\cdot}8271$.

It is prepared by the action of ethyl formate on zinc ethyl (Annalen, 175, 351), or on ethylmagnesiumbromide (Chem. Zentr. 1901, [2] 623).

Derivative.—Phenyl urethane, m.p. 48°–49°.

Ethyldimethylcarbinol $C_2H_5{\cdot}C(CH_3)_2OH$ (1-1-dimethylpropanol). This alcohol, commonly known as 'amylene hydrate,' is a colourless liquid possessing an odour resembling that of camphor; b.p. 101·5°–102°; m.p. −12°; $D_{15°}^{15°}=0{\cdot}8144$.

It has been prepared synthetically by the interaction of propionyl chloride and zinc dimethyl (Annalen, 190, 328). It is produced commercially by treating amylene with aqueous sulphuric acid, and subsequently boiling the solution. Trimethylethylene, the chief constituent of commercial amylene, is thus quantitatively converted into tertiary amyl alcohol, which is employed medicinally as a hypnotic.

Fusel Oil is the source of all commercial amyl compounds. It is a yellow or brownish liquid possessing a nauseating taste and a characteristic unpleasant, cough-provoking odour. It boils from 80° upwards, but chiefly between 128° and 132°. It has a density of about 0·83. It burns with a bright flame, and its main constituents are usually *iso*amyl alcohol and active (lævorotatory) *d*-amyl alcohol in varying proportions.

The larger quantity of commercial fusel oil is obtained as a residue in the refining of the crude spirit from the fermentation of potatoes or molasses. The separation is effected by fractionating the fermented liquor, usually in a continuously operating plant (*see* under ALCOHOL). When the ethyl alcohol content of the liquid has fallen to 15 p.c. the fusel oil may be removed from the surface, where it separates as an oily layer. Crude spirit after fractionation may contain 95 p.c. of ethyl alcohol, and usually about 0·4 p.c. of fusel oil. Brandy contains at the most only traces, but the spirits having the most pleasing aroma, those from corn or fruit, *e.g.* cherries, &c., may contain up to 0·6 p.c. or more of fusel oil, partly in the form of esters The presence of the fusel oil may increase the intoxicating qualities of the spirit, but the harmful effects of excessive spirit drinking seem to be mainly caused by ethyl alcohol.

The chief constituent of most fusel oils is the mixture of amyl alcohols which constitutes 65–80 p.c. of the whole, and which is sold as commercial amyl alcohol of b.p. 128°–132°. The proportions in which the two amyl alcohols occur in commercial amyl alcohol vary considerably, as Marckwald pointed out, according to the source of the specimen. Ordinary corn or potato amyl alcohol contains from 13·5 to 22 p.c. of the active isomeride, while the amyl alcohol from molasses fusel oil contains from 48 to 58 p.c. of the lævorotatory alcohol. Besides the amyl alcohols, ordinary fusel oils contain usually from 15 to 25 p.c. of *iso*butyl alcohol (b.p. 108°), and from 4 to 7 p.c. of *n*-propyl alcohol (b.p. 97°). But the fusel oils from wines may contain large quantities (as much as 50 p.c. of the whole) of *n*-butyl alcohol. That produced by the Fernbach Fermentation Process is said to contain 65 p.c. of butyl alcohol.

In addition to these main constituents, there are always present in small quantities some or all of the following: hexyl and heptyl alcohols, furfurol, acetaldehyde, *iso*butyl and valeric aldehydes, ammonia and amines, pyridine, pyrazine derivatives, traces of all the fatty acids up to capric acid in the form of ethyl, amyl or oenanthyl esters, terpene and terpene hydrate.

The formation of fusel oil in fermentation has been explained by Ehrlich (Ber. 1906, 39, 4072; 1907, 40, 1027, 2538; 1912, 45, 1006; Biochem. Zeitsch. 1911, 36, 477; *see* also Biochem. Zeitsch. 1907, 3, 121; 1908, 10, 490). Ehrlich has shown that the addition of leucine and *d*-*iso*leucine, in the form of, *e.g.*, hydrolysed egg albumen, during the fermentation process, results in a largely increased yield of amyl alcohols. This is made the basis of a technical method (D. R. P. 177174). Leucine, from egg albumen, can also be converted by dry distillation into amylamine (D. R. P. 193166), and thence into a mixture of amyl alcohols similar to that occurring in fusel oil.

Detection and Estimation.—Fusel oil is best detected in spirits by rubbing a little of the liquid between the hands, when the ethyl alcohol evaporates and the residue reveals itself by its smell. When a large quantity is available for the estimation, it may be accomplished by subjecting the material to fractional distillation. For ordinary purposes the usual method depends on the extraction of the fusel oil from a 30 p.c. ethyl alcohol solution by means of chloroform, the increase in volume of the latter being observed (*see* Ehrlich, Ber. 1907, 40, 1031; Pringsheim, Biochem. Zeitsch. 1907, 3, 233). For another valuable method, *see* Aberhalden's Handbuch der biochemische Arbeitsmethode, ii. 11; *v.* FUSEL OIL.

Uses.—Fusel oil and commercial amyl alcohol are valuable solvents for resins, fats, and oils; amyl alcohol, being much more useful for these purposes than ethyl alcohol, is therefore indispensable in industry. It is much used in the nitrocellulose smokeless powder and lacquer industries. It has been proposed as a raw material for the production of synthetic rubber (Perkin, J. Soc. Chem. Ind. 1912, 31, 616).

Preparation of Isoamyl and d-Amyl Alcohol from Fusel Oil.—This separation was first partially effected by Pasteur (Annalen, 1855, 96, 255) by the fractional crystallisation of the barium salts of the amyl sulphuric acids. Le Bel went further, using the fact that conversion of the alcohols into the chlorides by hydrogen chloride left a more active residue than the original mixture (Bull. Soc. chim. [2] 21, 542; 25, 545). Marckwald finally isolated the two alcohols in a state of chemical purity (Ber. 1901, 34, 479, 485; 1902, 35, 1595, 1602; 1904, 37, 1038), by fractional crystallisation of the 3-nitrophthalic esters and also by using Pasteur's method. All the pairs of derivatives of the two components of natural amyl alcohol examined by Marckwald formed mixed crystals.

To obtain *iso*amyl alcohol, use a potato amyl alcohol containing 80 p.c. of *iso*amyl alcohol and convert it at once into the 3-nitrophthalic ester, which is quickly purified by recrystallisation.

To obtain *d*-amyl alcohol (lævorotatory), use the molasses amyl alcohol containing at least 50 p.c. of the required compound. Saturate with dry hydrogen chloride at 0°, and heat in an autoclave for five hours at 110°. On distillation of the product a liquid is obtained containing 80 p.c. of the active alcohol. This is then converted into the 3-nitrophthalate and recrystallised from benzene until the melting-point of the compound is 114°. The two alcohols are very easily obtained from the acid nitrophthalic esters by hydrolysis.

Amyl Acetate $C_5H_{11}O{\cdot}CO{\cdot}CH_3$. A colourless neutral mobile liquid having a penetrating odour resembling that of jargonelle pears; b.p. 138·5°–139°; $D^{15°}_{4°} = 0{\cdot}875$. Is easily inflammable, and sparingly soluble in water, but easily so in organic solvents. For its preparation, 1 part of commercially pure amyl alcohol, 1 part of glacial acetic acid, and ½ part of concentrated sulphuric acid, are heated at 100° for five hours, the mixture poured into water and the oil separated. The oil is shaken with a strong aqueous solution of sodium carbonate, dried, and distilled. (*See* also Compt. rend. 1911, 152, 1671; and Eng. Pat. 4669, where fusel oil, hydrochloric acid, and calcium acetate are used.)

The alcoholic solution is largely used under the name of 'Jargonelle Pear Essence,' for flavouring confectionery. Amyl acetate is an excellent solvent for gun-cotton, camphor, tannin, and resins, and is therefore greatly used in the celluloid and varnish industries. It is also used in the manufacture of smokeless powder and photographic films. It is recommended as a standard oil in photometry (J. Soc. Chem. Ind. 1885, 262). *See also* ACETIC ACID.

Amyl Ether $C_5H_{11}{\cdot}O{\cdot}C_5H_{11}$. A colourless liquid possessing a pleasant pear-like smell; b.p. 172·5°–173°; $D15° = 0{\cdot}7807$. It is prepared by heating the alcohol to its boiling-point with 1/10 part of concentrated sulphuric acid (D. R. P. 200150), or with 1/10 part of amyl iodide in an autoclave at 250°. It is used as a solvent in the Grignard reaction, for fat extraction, for perfumes, alkaloids, in the varnish industry, and therapeutically.

Amyl Formate $C_5H_{11}O{\cdot}CO{\cdot}H$. A fragrant liquid of b.p. 123·3°; and $D^{0°}_{4°} = 0{\cdot}8944$, prepared from fusel oil and formic acid or from fusel oil, glycerol, and oxalic acid. It is used in the synthetic fruit essence industry and in the laboratory in the preparation of oxymethylene derivatives.

***d*-Amyl Mercaptan** $C_5H_{11}{\cdot}SH$. A liquid of b.p. 119°–121°, was prepared in a state of purity from fusel oil by Vorocek and Vesely (Ber. 1914, 47, 1515) and used to resolve racemic arabinose into its optically active components.

Amyl Nitrite $C_5H_{11}O{\cdot}NO$. A yellow neutral, or feebly acid liquid, possessing a fruity smell; b.p. 97°–99°; $D15° = 0{\cdot}870–0{\cdot}880$. It burns with a brilliant flame. It should be kept protected from light, but in any case it is best either freshly prepared or repeatedly fractionated before use. The vapour should not be inhaled. It is prepared by passing nitrous fumes into amyl alcohol kept at 70°–90° (Balard, Ann. Chim. Phys. [3] 12, 318; Williams and Smith, Pharm. J. 1886, 499). Bouveault and Wahl passed nitrosyl chloride into a dry mixture of pyridine and amyl alcohol (Compt. rend. 136, 1563). For a rapid method of preparation, involving sodium nitrite, *see* Ber. 1886, 19, 915.

The pure isoamyl nitrite has b.p. 97° and $D\,15° = 0{\cdot}880$ (Dunstan and Williams, Pharm. J. 1889, 487).

It is used in the preparation of diazo and *iso*nitroso compounds or nitroso chlorides, and as the 'amylium nitrosum' of medicine for the treatment of epilepsy, asthma, angina pectoris, &c., since it reduces blood pressure and retards the pulse. It is also used in the manufacture of sweets, perfumes, fruit essences, &c., in spite of its harmful effects.

Tertiary amyl nitrite $(CH_3)_2(C_2H_5){\cdot}C{\cdot}O{\cdot}NO$ (Bertoni's 'Amylonitrous Ether') has been used as a substitute for ordinary amyl nitrite, its action being stronger in degree and more lasting. It is a yellow liquid of weak camphoraceous odour and peppermint taste; b.p. 93° (J. Soc. Chem. Ind. 1889, 1003).

Amyl Salicylate $C_5H_{11}O{\cdot}CO{\cdot}C_6H_4{\cdot}OH$ (Amylenol) is a colourless refractive liquid of b.p. 250° (with decomposition), and 115°/2 mm.; $D\,15° = 1{\cdot}065$. It is produced by passing dry hydrogen chloride into a saturated solution of salicylic acid in amyl alcohol, and after some hours pouring into water and working up as usual.

It is used medicinally as an antirheumatic and in the perfume and fruit essence industry C. S. G.

AMYLACETIC ACID (Active) *v.* HEPTOIC ACIDS.

iso-**AMYLACETIC ACID** *v.* HEPTOIC ACIDS.

α- and *β*-**AMYLANS** $n(C_6H_{10}O_5)$?

After first extracting cereals with strong alcohol, the aqueous extract contains gummy lævorotatory colloidal carbohydrates, which are precipitated by strong alcohol. The product so obtained from barley is a mixture, part being soluble in cold water. The insoluble crumbly residue, amounting to 2 p.c. of the barley, is *α*-amylan. It has $[\alpha]_D - 21{\cdot}6$, and does not reduce Fehling's solution; it is gelatinised in hot water, and yields viscous solutions even at 1–2 p.c. concentration. O'Sullivan (Chem. Soc. Trans. 1882, 41, 24) found it to be present in barley, oats, wheat, and rye, especially in the two first named. The soluble product *β*-amylan has $[\alpha]_D - 65°$; it amounts to 0·3 p.c., and is very similar to *α*-amylan in properties.

O'Sullivan obtained from *β*-amylan, by fractional precipitation with alcohol or on boiling with milk of lime, a similar substance $[\alpha]_D - 129{\cdot}7°$. This he regarded as a decomposition product, but this is probably not the case. O'Sullivan states that the amylans yield glucose alone on hydrolysis. Lintner and Düll (Zeit. angew. Chem. 1891, 538) obtained galactose and xylose from barley gum. Wroblewski (Ber. 1893, 30, 2289) obtained arabinose. Lindet (Berlin Congress, 1903, 3, 498) isolated a dextrorotatory gum from barley, in addition to a lævo-rotatory gum.

Contrary to O'Sullivan's statement that diastase is without action on amylan, Horace Brown (Trans. Guinness Research Laboratory, 1906, 317, where there is a full account of amylan) finds that when barley gum is steeped in malt extract it swells up and undergoes gradual liquefaction and solution, and in a few days its colloidal nature is lost. This is one of the most significant changes which mark the conversion of barley into malt.

To prepare 'amylans' in quantity, Brown boils the finely divided grain with water, treats with malt extract at 50°–55° for an hour to liquefy the starch, boils again, and filters. The filtrate is concentrated in vacuum to sp.gr. 1·060, and three volumes 80 p.c. alcohol (by volume) added gradually. The crude amylans are precipitated in large white flocks free from dextrin and have no cupric reducing power. Corrected for ash and nitrogen they amount on a number of dry barleys to about 9·6 p.c., and have $[\alpha]_D + 62°$ to $+73°$. This amount practically accounts for the whole of the missing constituents of the soluble portion of barley after hydrolysis with malt extract.

On hydrolysis about 60 p.c. of glucose is formed, together with arabinose, xylose, and an unknown substance of low angle and reducing power.

The above dextrorotatory amylan represents everything insoluble in 62 p.c. alcohol. By a variation of the method of preparation a carbohydrate $[\alpha]_D - 100{\cdot}34°$, corresponding to Wroblewski's araban, was obtained.

It is obvious that the 'amylans' require further investigation. According to O'Sullivan, it is probably owing to the presence of amylan that unmalted barley cannot be satisfactorily employed in the preparation of beer. Malted grain does not contain it. Distillers using raw grain (oats and barley) have at times much difficulty in separating the wort (solution of sugars, &c.) from the grains (undissolved portion of the grain employed) in consequence of the presence of amylan in quantity, the barleys and oats of some seasons containing much more of it than at other times. E. F. A.

AMYLARINE. *Iso*amyltrimethylammonium hydroxide.

AMYLASE *v.* DIASTASE; *also* ENZYMES.

AMYLENE C_5H_{10}. Eight isomeric amylenes are theoretically possible, and all have been prepared. These hydrocarbons have been chiefly studied by Flavitzky (Annalen, 179, 340), Wyschnegradsky (Annalen, 190, 336), and by Kondakoff (J. Russ. Phys. Chem. Soc. 24, 381), and can be obtained by the action of alcoholic potash on the various amyl iodides; or by the action of dehydrating agents such as sulphuric acid or zinc chloride on amyl alcohol. They can often be converted into one another by the action of hydriodic acid and the subsequent removal of the latter, thus:

$$\mathrm{Me_2CH\,CH:CH_2+HI}$$
$$\longrightarrow \mathrm{Me_2CH\,CHIMe} \xrightarrow[\text{+alcohol}]{\text{KOH}} \mathrm{Me_2C:CHMe}$$

The amylene ordinarily met with is trimethylethylene, and is chiefly obtained by the dehydrating action of zinc chloride on fermentation amyl alcohol.

Preparation.—To prepare amylene, fermentation amyl alcohol (1 part) is shaken with coarsely powdered zinc chloride (1½ parts), allowed to remain for twenty-four hours, and then distilled. The product consists of a complex mixture of paraffins from C_5H_{12} to $C_{10}H_{22}$ with olefines from C_5H_{10} to $C_{10}H_{20}$ (Wurtz, J. 1863, 507). These can be isolated by fractional distillation (Wurtz), but according to Eltekow (J. Russ. Chem. Soc. 14, 379), amylene is most readily obtained if the product is well cooled, and shaken with dilute sulphuric acid (2 vols. of acid to 1 vol. of water), the acid layer separated, diluted with water, and distilled; the distillate consists of amylene (trimethylethylene) and tertiary amyl alcohol, and the latter, on distillation with sulphuric acid (1 : 1), yields pure trimethylethylene. Amylene may be satisfactorily obtained from commercial amyl alcohol under the following conditions: Amyl alcohol (1·5 litres) and concentrated sulphuric acid (100 c.c.) are heated to vigorous boiling under a reflux condenser in which the water is maintained at such a temperature (60°–90°) as to allow a considerable amount of vapour to distil out of the apparatus; the top of the condenser is connected with a second, efficiently cooled condenser, attached so as to permit downward distillation. The heating requires a maximum time of about eight hours. At first, water and amyl alcohol pass over, whilst subsequently amylene distils. The distillate is washed with sodium hydroxide to remove sulphur dioxide and the amylene isolated by fractionation. It appears to consist of *β*-methyl-Δ*α*-butylene and

β-methyl-Δ^{β}-butylene containing only a negligible amount of γ-methyl-Δ^{α}-butylene. The residue in the original flask contains amyl alcohol and *iso*amyl ether, which are recovered by distillation with steam and subsequent fractionation. About 250 c.c. of amylene 400 c.c. of *iso*amyl ether, and 500 c.c. of amyl alcohol are obtained from 1500 c.c. of the latter (Adams, Kamm, and Marvel, J. Amer. Chem. Soc. 1918, 40, 1950; Chem. Soc. Abstr. 1919, i. 61). Larger amounts of amylene are more conveniently obtained by the pyrogenic-catalytic method, using aluminium oxide as catalyst at 500°–540°, using a suitably electrically heated furnace (*cf.* Ipatieff, Abst. 1903, i. 593). The yield of amylene is 70–80 p.c. of the theoretical, and the product is about 98–99 p.c. pentene. The catalyst retains its activity for a long time. Pure trimethylethylene can be prepared by heating tertiary amyl iodide Me_2CIEt with alcoholic potash (J. Russ. Phys. Chem. Soc. 17, 294). It can also be formed by dropping tertiary amyl alcohol on to oxalic acid (D. R. P. 66866).

Other methods for obtaining ordinary amylene have been described by Balard (Ann. Chim. Phys. [3] 12, 320); Bauer (J. 1861, 659), and Linnemann (Annalen, 143, 350); Kondakoff (*l.c.*); Ipatieff (J. Russ. Phys. Chem. Soc. 30, 292); Tornöe (Ber. 21, 1282); Blaise and Courlot (Bull. Soc. chim. 35, 582).

Properties.—Amylene is a colourless liquid, b.p. 36°–38° and sp.gr. 0·6783 at 0° (Le Bel, Bull. Soc. chim. 25, 547); b.p. 36·8° at 752·7 mm. (Schiff, Annalen, 223, 65). It combines directly with a large number of substances: with nitric peroxide (Guthrie, Chem. Soc. Trans. 13, 129; Wallach, Annalen, 241, 291; 248, 161; Miller, Chem. Soc. Proc. 3, 108; Demganoff, Chem. Zentr. 1899, i. 1064); sulphur chloride and chlorine (Guthrie, Chem. Soc. Trans. 12, 112; 13, 45, 129; 14, 136; Kondakoff, J. Russ. Phys. Chem. Soc. 20, 141; 24, 381; Ber. 24, 929; Hell and Wildermann, *ibid.* 216); with bromine (Wurtz, Ann. Chim. Phys. [3] 55, 458; Hell and Wildermann, *l.c.*; Kondakoff, *l.c.*), and, when cautiously mixed with well-cooled sulphuric acid, sp.gr. 1·67 (2 vols. H_2SO_4 to 1 vol. water), in a freezing mixture, is converted into dimethylethyl carbinol, b.p. 101·6°–102°/762·2 mm., which has valuable hypnotic properties (J. Soc. Chem. Ind. 8, 1002; 9, 650, 889), and can be obtained, after neutralisation with sodium hydroxide; on distillation (Flavitzky, 175, 157) with sulphuric acid, sp.gr. 1·545 (2 pts. by weight H_2SO_4 to 1 pt. water), methyl*iso*propyl carbinol is obtained (Osipoff, Ber. 8, 542, 1240). Amylene forms compounds with metallic salts (Denigès, Compt. rend. 126, 1146; Kondakoff, J. Russ. Phys. Chem. Soc. 25, 35). When heated to high temperatures, benzene, naphthalene, acetylene, methane, carbon, and hydrogen are produced, the products depending on the temperature (Haber and Oechelhäuser (Chem. Zentr. 1897, i. 225). The action of nitrosyl chloride on amylene has been studied by Tilden and Sudborough (Chem. Soc. Trans. 1893, 482).

In addition to ordinary amylene, the following isomerides have been obtained:—*Normal amylene*, b.p. 39°–40° (Wurtz, Annalen, 123, 205; 127, 55; 148, 131; Zeidler, Annalen, 197, 253; Kondakoff, J. Russ. Phys. Chem. Soc. 24, 113; Flavitzky and Wyschnegradsky, *l.c.*); *isopropylethylene*, b.p. 21·1°–21·3° (Flavitzky and Wyschnegradsky, *l.c.*; Kondakoff, *l.c.*; Ipatieff, *l.c.*); *symmetrical methylethylethylene*, b.p. 36° at 740·8 mm. (Wagner and Saytzew, Annalen, 175, 373; 179, 302; Kondakoff, *l.c.*; Lissier, Bull. Soc. chim. 9, (3) 100); and *unsymmetrical methylethylethylene*, b.p. 31°–32°, sp.gr. 0·67 at 0° (Wyschnegradsky, *l.c.*; Le Bel, Bull. Soc. chim. 25, 546; Kondakoff, *l.c.* 25, 354); *Methyltetramethylene*, b.p. 39°–42° (Coleman and Perkin, Chem. Soc. Trans. 1888, 201); *pentamethylene*, b.p. 35° (Gustavson and Demganoff, J. Russ. Phys. Chem. Soc. 21, 344; Markownikoff, Ber. 30, 975; Young, Chem. Soc. Trans. 1898, 906; Wislicenus and Hanschel, Annalen, 275, 327); and *dimethyltrimethylene* (Gustavson and Popper, J. pr. Chem. 166, 458).

The action of hydrogen iodide on the amylenes has been investigated by Saytzew (Annalen, 179, 126); whilst Zeidler (Annalen, 186, 245) has examined the products obtained when various amylenes are oxidised with potassium permanganate in acid, neutral and alkaline solution, with chromic acid, and with potassium dichromate and sulphuric acid. The halogen derivatives of the various amylenes have been investigated (Lipp, Ber. 22, 2572; Hell and Wildermann, 23, 3210; Ipatieff, J. pr. Chem. 161, 257; Chem. Zentr. 1898, ii. 472; Brochet, Ann. Chim. Phys. 1897, 10, 381; Wassileef, Chem. Zentr. 1899, i. 775; Froebe and Hochstetter, Monatsh. 23, 1075; Kukuritschkin, J. Russ. Phys. Chem. Soc. 35, 873; Schmidt and Leipprand, Ber. 37, 532; Hamonet, Compt. rend. 138, 1609). Also the action of oxalic acid on various amylenes (Miklosheffsky, J. Russ. Phys. Chem. Soc. 22, 495), the nitrolamines (Wallach and Wohl, Annalen, 262, 324), and the nitrosites and nitrosates (Ipatieff, Chem. Zentr. 1899, ii. 178; Schmidt, Ber. 35, 2323, 2336, 3737; Hantzsch, 2978, 4120; Schmidt and Austin, Ber. 36, 1768).

The following polymerides of amylene have also been obtained, and can be prepared by heating ordinary amyl alcohol or amylene with zinc chloride:—*Diamylene* $C_{10}H_{20}$, b.p. 157°–157·5°/759 mm. (Balard, Annalen, 52, 316; Schneider, Annalen, 157, 207; Bauer, Jahresbericht. 1861, 660; Kondakoff, J. pr. Chem. 162, 442; Gasselin, Ann. Chim. Phys. 1894, 3, 5); *triamylene* $C_{15}H_{30}$ (Bauer, *l.c.*; Gasselin, *l.c.*); and *tetramylene* $C_{20}H_{40}$ (Bauer, *l.c.*). Also derivatives of diamylene (Schindelmeister, Chem. Zentr. 1896, ii. 354).

AMYLOCARBOL. · Trade name for a disinfectant, said to consist of carbolic acid 9 parts, amyl alcohol 160 parts, green soap 150 parts, water 690 parts.

AMYLOCOGULASE *v. Enzymes*, art. FERMENTATION.

AMYLOFORM. An antiseptic prepared by the action of formic aldehyde upon starch (Claassen, Pharm. Zeit. 41, 625) (*v.* SYNTHETIC DRUGS).

AMYRIN *v.* OLEO-RESINS.

ANACAHUITA. A wood of unknown botanical origin imported from Mexico; its preparations are said to be useful in pulmonary disorders. The wood contains a volatile oil, an iron-greening tannin, gallic acid, a yellowish resin, sugar, a tasteless volatile body crystallising in warty masses, and a bitter substance crystallising in white needles (J. 1861, 771).

ANACARDIUM NUT (Cashew Nut, Kajoo) is the fruit of *Anacardium occidentale* (Linn.), a tree indigenous to Brazil, Central America, and the West Indies. It has been transplanted to, and become naturalised in, many parts of India. The fruit rests on a fleshy edible peduncle, from which a spirit is distilled in Mozambique and in Western India. The nut is edible after it has been roasted to expel the cardol which it contains; the cardol thus obtained is used at Goa for tarring boats, and as a preservative of woodwork (Dymock, Pharm. J. [3] 7, 730). In addition to cardol, the nuts contain anacardic acid, and an oily matter which, by exposure to the air on linen, gives a brown stain, which is very permanent, but does not become black. It has been recommended as a marking ink, and is used for giving a black colour to candles (Böttger, Dingl. poly. J. 205, 490). From the stem of the plant a gum exudes which is said to be used by book-binders in South America.

The kernels contain 47·2 p.c. of a fatty oil, having the following characteristics:—Saponification value, 187; iodine value, 77–83·6; refraction in Zeiss' butyro-refractometer at 25°, 58·1–58·8 (Theopold, Pharm. Zeit. 1909, 1057).

J. L.

ANACARDIUM ORIENTALE (the 'marking nut tree') grows in the hotter parts of India, the West Indies, and in Northern Australia. It is now termed *Semecarpus anacardium*. As met with in commerce the nut is a black oval substance, from which, when cut, a black viscid juice exudes. This produces a light brown stain on linen, but gradually darkens on exposure to the air, and then resists the action of acids, alkalis, and chlorine. The native method of preparing marking ink, is to express the juice from the unripe fruit and to mix it with quicklime. The dried juice is also used in the preparation of a black varnish.

Kindt (Dingl. poly. J. 1859, 165, 158) prepared a marking ink from the nut by extracting it with a mixture of alcohol and ether, and evaporating the extract. This ink produced characters which, when moistened with a lime water or alkali solution, became black, and were then not completely removed when boiled with hydrochloric acid and potassium chlorate.

C. A. M.

ANÆSTHETICS. There are two principal types of anæsthesia, or loss of sensation sufficient to allow of surgical operations without pain. In *general* anæsthesia, total or partial insensibility and loss of muscular power are produced by the action of drugs on the brain, carried there in the circulation; extensive operations on any part of the body can then be done. In *regional* anæsthesia, insensibility to pain, with or without muscular paralysis, is produced by the action of anæsthetic drugs on the part where operation is contemplated. Regional anæsthesia can be produced (*a*) by the infiltration of the actual tissues to be lacerated with some substance which paralyses the endings of the nerves that convey painful sensations; (*b*) by a similar infiltration of the large or small nerve trunks supplying the field of operation; (*c*) by the injection into the spinal theca in the vertebral canal of a substance which paralyses the nerves, both sensory and motor, at their entrances into or exits from the spinal cord; (*a*) and (*b*) are usually classified together as *local* anæsthesia, while (*c*) is spoken of as *spinal* anæsthesia, which resembles general anæsthesia inasmuch as it causes loss of sensation and muscular power together over a wide region, and local anæsthesia in that consciousness is not lost and the anæsthetic is not diffused in the circulation.

Local anæsthetics. Very little is known of the action of these on the tissues with which they come in contact. They are all protoplasmic poisons which have a special preferential action upon nervous structures. Those in common use are: cocaine (methyl-benzoyl-ecgonine: $C_{17}H_{21}NO_4$); stovaine (hydrochloride of ethyl-dimethyl-amino-propinol benzoate); novocain (*p*-amido-benzoyl-diethyl-amino-ethenol-hydrochloride); tropacocaine (benzoyl-pseudo-tropeine-hydrochloride); β-eucaine (benzoyl-vinyl-diacetone-alkamine); β-eucaine lactate; alypin (hydrochloride of benzoyl-tetramethyl-diamino-ethyl-dimethyl-carbinol); quinine and urea hydrochloride; nirvanine (hydrochloride of diethyl-glycoll-*p*-amido-orthohydrobenzoic-methyl-ester); holocaine (hydrochloride of *p*-diethoxyethenyl-diphenyl-amidine); acoine (di-*p*-anisyl-mono-phenethyl-guanidine hydrochloride); orthoform (methyl-*p*-amino-meta-oxy-benzoate); anæsthone or anæsthesin (ethyl ester of *p*-aminobenzoic acid); apothesine (cinnamic ester of γ-diethyl-amino-alcohol hydrochloride).[1]

Braun has formulated postulates for appraising local anæsthetics. Omitting one which has not secured general assent, they are:

(1) Low toxicity in proportion to local anæsthetising power.

(2) Solubility in water to 2 p.c. at least; and stability of the solution, which should keep without deteriorating and be capable of sterilisation by boiling.

(3) Non-irritability to the tissues, and freedom from after-effects when absorbed into the circulation.

(4) Compatibility with suprarenal extract.

Acoine, holocaine hydrochloride, anæsthesine, and orthoform are more or less insoluble. Cocaine and eucaine are not soluble in water; but their salts, and the other drugs in the above list, are freely soluble and will keep without deteriorating. Cocaine solutions cannot be boiled, but stovaine, novocain, β-eucaine lactate, tropacocaine, alypin, and nirvanine can be thus sterilised, at 115° if necessary.

The most powerful anæsthetic action is that of stovaine. Next are cocaine, novocain, tropacocaine, alypin, and β-eucaine lactate, which are all about equal. The others have inferior actions in this respect. Experiments on mice and rabbits have resulted in the following table of relative toxicity, cocaine being taken as the unit[2]:—

Alypin, 1·25
Cocaine, 1·00
Nirvanine, 0·714
Stovaine, 0·625
Novocain, 0·490
β-eucaine lactate, 0·414

The irritant action of stovaine, tropacocaine, and β-eucaine lactate is greater than that of cocaine; that of novocain is less. All these five are compatible with suprarenal extract if the solutions are fresh mixed for each case. They are extensively employed; but novocain is evidently the best yet discovered for routine use.

---

[1] Sir F. W. Hewitt and Dr. Henry Robinson's Anæsthetics and their Administration, 5th edit.

[2] Le Brocq, Pharm. J. 1909, 674.

Local anæsthetics are used dissolved in water or in normal saline solution. It is not essential that they should be injected subcutaneously; where the surface tissues are delicate, as on the eye, larynx, tongue, tonsils, simple contact with a local anæsthetic in solution or in fine powder will destroy sensation sufficiently for many surgical procedures. But elsewhere the solution is injected with a hypodermic syringe into the tissues which are to be rendered anæsthetic. If suprarenal extract be mixed with the anæsthetic solution, contraction of all the minute blood-vessels in the locality takes place. Thus the drug is retained longer in the tissues about the site of injection, instead of being rapidly dissipated in the lymph-stream. Consequently a more intense and lasting, because more strictly local, action occurs. The presence of 0·4 p.c. of potassium sulphate also intensifies the action of some local anæsthetics, especially of novocain.

Local anæsthesia can also be obtained by freezing the superficial tissues. A fine jet of ether or ethyl chloride is directed on to the desired portion of the skin, and when the latter is frozen a cut can be made, as for a whitlow, boil, or other small abscess, without causing pain.

Spinal anæsthetics. Some of the same drugs which cause local anæsthesia are available for injection into the cerebro-spinal fluid with which the spinal cord is surrounded in the vertebral canal. Stovaine is most used in Britain, but novocain and tropacocaine also are popular in Europe. The method was introduced by Bier in Germany in 1899, and since 1907 has been very extensively tried all over the world. The balance of opinion is that for ordinary cases spinal anæsthesia is too dangerous to replace general anæsthesia; but that for certain cases where the latter entails especial risks, it is of undoubted utility. Barker[1] and McGavin,[2] who are the most prominent advocates of spinal anæsthesia in England, use a solution of stovaine in 5 p.c. glucose. Of late years solutions which are as light as the cerebro-spinal fluid (sp gr. 1·006 to 1·007) have been extensively used, in place of the heavy glucose solutions. Many anæsthetists use morphine with or without scopolamine (hyoscine) as a preliminary, injected hypodermically.

General anæsthetics. There are many substances which diminish or abolish the perception of pain; but only a few of these are freely used as general anæsthetics. The conditions which must be fulfilled to obtain admission to the list are[3]:

(1) To produce absolute insensibility to pain without causing any great discomfort during induction.

(2) To produce loss of all voluntary and many reflex movements.

(3) To be capable of being readily introduced into the system, and rapidly eliminated, after the completion of the operation, without injury to the patient.

(4) To act in a regular and constant way, so that the effects can be controlled by the administrator.

The general anæsthetics in use in Great Britain are four in number: nitrous oxide, ethyl chloride, ether, chloroform. Ethyl bromide, ethidene dichloride (dichlorethane), bichloride of methylene, and amylene (pental) are obsolete. Hedonal (methyl-propyl-carbinol-urethane) and urethane itself have also been used as general anæsthetics, by direct injection in solution in normal saline into the blood stream.[1] In America and on the Continent anæsthol, somnoform, and narcotile are also employed. Anæsthol is a mixture of chloroform, ether, and ethyl chloride, in molecular proportions; somnoform is ethyl chloride 60 parts, methyl chloride 35 parts, ethyl bromide 5 parts; narcotile has been stated to be a compound, but analysis has shown it to be a mixture of methyl chloride, ethyl chloride, and ether. Mixtures of ether and chloroform in various proportions are in common use everywhere. Morphine, chloral, cannabis indica, and many other drugs have analgesic and anæsthetic properties; some of them, morphine especially, are used to assist the action of the volatile anæsthetics.

The effects of a general anæsthetic are produced by the circulation in the blood of the drug employed. When it reaches the brain the phenomena of anæsthesia are exhibited: at first slightly, then with increasing doses more and more intensely, until with a sufficient quantity death results. The phenomena of general anæsthesia are the same whether absorption takes place through the lungs, rectum, skin, blood stream, or gastro-intestinal tract. Thus alcohol has a marked anæsthetic effect, familiar in the indifference of a drunken man to injury.

The easiest way of introducing into the blood any substance which is a gas or a volatile liquid is by means of the lungs. The blood thus charged with an anæsthetic is rapidly delivered to the nervous centres, in which the essential changes of general anæsthesia take place. The absorption of vapours in the lungs varies with numerous factors: barometric pressure, temperature of the vapour and of the blood, rate of respiration, and rate of blood-flow through the pulmonary system. But the process is also something more than simple solution by diffusion of gases through a thin membrane; there is at least an element which depends on the fact that the tissues concerned are living.

The lungs are also the chief, but not the only, medium for the elimination of inhaled anæsthetics. These are but little decomposed during their tour of the circulation, and the greater part is discharged unchanged after the administration is suspended. What change they undergo in the blood is very uncertain. Chloroform, which has hitherto received more attention in this respect than the others, is recoverable from the blood in fatal cases of chloroform anæsthesia, but it is believed that most of it circulates in the red corpuscles of the blood in combination with the lecithin and cholesterin which they contain.[1] Glycuronic acid not uncommonly appears in the urine after chloroform anæsthesia. Nitrogen and sulphur are also excreted in the urine in greater quantity, indicating a greater destruction of proteid; and the increase of chlorides is held to show that some chloroform is decomposed in the body. The affinity of cholesterin and lecithin for chloroform, chloral, ether, sulphonal, tetronal, trional, and chloralamide has been suggested as the explanation for the selective action of these narcotics on the central nervous system, which contains a larger proportion of cholesterin and lecithin than do the other organs. With regard to ether, Turnbull states that etherisation produces a marked diminution of the hæmoglobin of the blood[2]; and Reicher finds three times the normal quantity of fat present in the blood, together with an increased amount of acetone, due to the disintegration of fat and albuminoid bodies.[3] The chemical composition of the blood is often much modified during anæsthesia, because the air supply to the lungs is frequently curtailed to a greater or less extent, and the elimination of CO_2 hindered. The proportions of O and CO_2 in the circulating blood may thus be altered at the expense of the former, and an asphyxial element added to the narcotic effect of the anæsthetic. Some authorities believe that deprivation of oxygen is the method by which all anæsthetics produce their action on the nervous tissues.

The chemical changes which may be assumed to take place in the brain during anæsthesia are unknown, as indeed are those of natural sleep. It has been suggested that unstable compounds are formed between the anæsthetic and the protoplasm of the nerve cells, and some observers describe changes recognisable microscopically in those cells as a result of anæsthesia. Professor Hans Meyer holds that there is a loose physico-chemical combination with the lipoids of the cell. This causes inhibition of the normal metabolism until the loose reversible combination breaks up. A rare sequel of chloroform anæsthesia is known as delayed chloroform poisoning. The symptoms of this condition, which is sometimes fatal, arise about eighteen to seventy-two hours after the anæsthesia. They are attributed to 'acidosis,' that is to diminished alkalinity of the blood due to the presence of acetone and aceto-acetic acid, which can be detected in the urine and the breath. For the developed condition sodium bicarbonate in large doses is employed; as a preventive measure feeding on glucose for a day or two before operation is found to answer best. Very rarely indeed this acidosis has followed the administration of ether.

Nitrous oxide (Laughing gas).—The inhalation of from three or four to twenty or thirty gallons of this gas without any air produces anæsthesia. If the administration is then suspended, insensibility lasts on an average about thirty to forty-five seconds, during which time minor operations such as the extraction of teeth can be undertaken. A marked asphyxial element is nearly always present, owing to the replacement of oxygen by N_2O. If air be admitted for brief periods between successive doses of gas, anæsthesia can be maintained without great difficulty for several minutes. By delivering nitrous oxide mixed with pure oxygen for inhalation, anæsthesia can be prolonged for any desired period. The proportions of the two gases are varied to meet the requirements of individual cases, but roughly the mixture must contain about 80 p.c. by volume of N_2O. This method is well suited for operations on the limbs, but for abdominal operations it is difficult to get the complete muscular relaxation necessary. Nitrous oxide gas is the safest known general anæsthetic, and recovery takes place very rapidly (two or three minutes) without unpleasant after-effects. Nitrous oxide for anæsthetic purposes should be entirely free from other oxides of nitrogen, and from chlorine; small quantities of H_2O, O, and N are usually present as impurities, and are of no moment.

Ethyl chloride.—The vapour of 3 to 5 c.c. of this substance allowed to volatilise in a closed chamber, such as a rubber bag, into which an adult patient exspires and from which he inspires, produces anæsthesia very rapidly. If administration is then suspended, insensibility lasts from one to two minutes. By administering a further dose before recovery takes place from the first one, anæsthesia can be prolonged; it is preferable, however, to give ether or chloroform or nitrous oxide and oxygen if a longer anæsthesia is required. The after-effects of ethyl chloride are intermediate between those of nitrous oxide and those of ether and chloroform. Ethyl chloride given by an expert is safer than either of the latter, but not so safe as nitrous oxide. No impurities can be tolerated in ethyl chloride for use as a general anæsthetic; there is no difficulty in securing complete purity.

Ether.—About 30 p.c. of air and 70 p.c. of ethereal vapour will produce and maintain general anæsthesia. The vapour is so intensely irritating to the mucous membrane which lines the mouth, nose, and air-passages, that it must first be offered very dilute, and then in a gradually increasing percentage. Limitation of air supply renders it possible to procure anæsthesia with a much smaller quantity of ether than when fresh air is freely admitted, for a slight concurrent asphyxia helps the action of the ether. Such asphyxiation has disadvantages of its own if allowed to exceed a very moderate degree; it is usually present during anæsthesia under ether by the 'closed' methods. There is slightly more difficulty in producing anæsthesia by the 'open' method, in which air enters freely; the preliminary injection of small doses of morphine ($\frac{1}{6}$ to $\frac{1}{4}$ grain) with atropine ($\frac{1}{200}$ to $\frac{1}{100}$ grain) is often practised. Ether is much less dangerous to life than chloroform in the operating room; but part of this advantage is counterbalanced by the occasional development of bronchitis and broncho-pneumonia afterwards. Ether for anæsthetic purposes should have a sp.gr. between 0·720 and 0·722. Provided impurities have been removed, it is of no significance whether rectified spirit or methylated spirit is used in the manufacture.

Chloroform.—Much research has been carried out to determine the percentage of chloroform necessary to produce anæsthesia by inhalation.

Vernon Harcourt introduced early this century a chloroform inhaler capable of regulating this proportion up to 2 p.c. Experience showed that in occasional cases it is very difficult or impossible to induce anæsthesia with this amount, and a modification of the instrument allows air to be inspired containing 3 p.c. In practically every case anæsthesia, when fully established, can be maintained with a 2 p.c. vapour. Alcock, who has investigated the dosage of chloroform very carefully, finds[1] that for an ordinary adult it suffices to offer a percentage rising gradually to 2½ in three minutes; this as a rule produces complete surgical anæsthesia in eight or ten minutes. If a higher proportion is necessary, 3 p.c. may be allowed at the end of five minutes. He finds that within a few minutes after induction is complete 1·5 p.c., and after half an hour 1 p.c., will usually be enough. Several physiologists have estimated the amount of chloroform in the circulating blood during anæsthesia: their results vary from 0·035 to 0·07 p.c. Chloroform is the least safe of these four anæsthetics, especially in the hands of those whose experience as anæsthetists is small. Chloroform for anæsthetic purposes is found to keep better if it contains 0·2 to 0·5 p.c. of alcohol or of ethyl chloride. No other impurities are tolerable. It is also less liable to decomposition if kept in the dark. There are three commercial processes of manufacture, based respectively upon rectified spirit, methylated spirit, and acetone; there is no difference between the actions of the resulting chloroforms, provided they are duly purified. ANÆSTHESINE. Trade name for ethyl *p*-amino-benzoate 
ANAGYRINE *v.* CYTISINE.

ANALUTOS or **KALMOPYRIN.** Trade names for calcium acetyl salicylate.

ANALGESINE. Identical with antipyrine (*q.v.*).

ANALYSIS. Chemical analysis is the separation of a complex material into simpler constituents. It is *ultimate* when these component parts are elementary forms of matter, and *proximate* when the subdivision consists only in the separation of the original substance into less complicated compounds. The aim of chemical analysis is twofold: the first object is to ascertain the nature of the components of a mixture or complex substance; the second is to determine the proportions in which these constituents are present. All analytical operations may therefore be classified under the two main categories of *qualitative* and *quantitative* analysis, according as to whether these processes lead to the identification of the proximate or ultimate constituents of a complex substance, or to the determination of the relative proportions in which these constituents are present.

This article is written primarily from the technical point of view, and accordingly the descriptions given in the qualitative section are restricted mainly to those elements which find application in the arts and industries. Similarly, the estimations and separations outlined in the quantitative section are chiefly those required in the analysis of technically important materials.

The systematic investigation of the individual elements and their typical compounds has revealed the existence of many characteristic reactions which are exhibited by certain elements and compounds under widely varying conditions of combination or association. This circumstance leads to a simplification which is utilised extensively in both qualitative and quantitative analysis. In qualitative work, such characteristic reactions as are not generally interfered with by other substances enable the analyst to detect the presence of certain elementary or compound substances without undertaking the more laborious processes involved in isolating these constituents from the other ingredients of a mixture.

In quantitative analysis two essentially different methods of procedure are employed, the more fundamental one being *gravimetric* analysis, in which the elementary or complex constituent of a mixture is isolated and weighed in the form of a definite compound. By utilising quantitatively the above-mentioned distinctive reactions it is frequently possible to adopt the second procedure known as *volumetric* analysis, in which the relative amount of a certain constituent is estimated in the presence of other elements and compounds associated with this constituent in the mixture under examination.

For the purposes of scientific investigation the most accurate methods are essential, and these are, in the main, gravimetric in character; but for technical requirements extreme accuracy is rarely required, and rapid methods giving approximately correct results are preferred to more exact processes involving a longer time for their execution. It is in this direction that volumetric analysis has been most extensively developed, the general tendency in industrial laboratories being to replace gravimetric methods by quicker volumetric processes with very little loss in accuracy, provided that certain essential conditions be fulfilled.

General Operations.

Sampling.—It is of the highest importance that the sample under examination should be truly representative of the bulk of the substance. Discrepancies between the results of different analysts are usually attributed to faulty methods or inaccurate work, but in many cases they are really due to imperfect sampling. If the substance is a liquid, the contents of the vessel should be thoroughly mixed before the sample is withdrawn. If the substance is contained in several vessels, a proportional quantity should be taken from each, the different portions mixed together, and the final sample taken from the mixture.

In the case of solid products care must be taken to secure a proper proportion of large and small, hard and soft fragments. If a ship's cargo is to be sampled, portions should be taken from different parts of the bulk; if the substance is contained in railway trucks, portions should be taken from the ends and middle of each truck. When the substance is in bags or barrels, a long hollow auger is thrust to the bottom of each and then withdrawn, bringing with it a long core of the substance. If the material loses or gains moisture, or undergoes any other change on exposure to air, as in the case of soap or caustic soda, a proper proportion of the internal and external portions must be taken. In all cases the first samples are broken into small pieces, thoroughly mixed, and one-fourth taken for further treatment. This is ground to powder, again thoroughly mixed, and one-fourth taken. The subdivision is repeated, if necessary, and the final sample kept in well-closed bottles. This process of 'quartering' may also be effected by spreading out the finely powdered material in the form of a flattened cylinder dividing this radially into four parts, taking out the opposite sectors, mixing these thoroughly, and repeating the subdivision.

---

[1] N. H. Alcock. British Medical Journal, Feb. 6, 1909, 325.

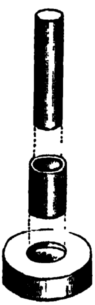

Fig. 1.

If the mixture is soft and friable, pulverisation is readily effected in a porcelain or earthenware mortar, but harder substances should be powdered in a cast-iron or steel mortar. When the substance is hard, and a very fine powder is required, an agate mortar should be used for the final operation, so that the powder may be completely sifted through fine muslin. Very hard substances, such as minerals, are first broken into small pieces by wrapping them in paper and striking with a hammer, and are then further crushed in a steel mortar (Fig. 1) consisting of a strong base with a circular recess into which fits a movable steel ring or guard, and inside this is a solid steel piston which acts as a pestle. A small quantity of the mineral is placed on the base of the mortar inside the guard-ring, the latter is held firmly down, and the piston is placed inside and struck smartly with a hammer, which drives it down upon the mineral. The final crushing is done in an agate mortar.

The mechanical ore-grinder described in Hillebrand's Analysis of Silicate and Carbonate Rocks, may likewise be employed in reducing hard minerals to a fine powder.

Drying.—Many substances absorb more or less moisture when exposed to the air, and in order to bring them into a definite condition for analysis, it is desirable that they should be dried, this operation being conducted at the ordinary or at a higher temperature according to circumstances. Substances which contain water in combination are usually dried by exposure to air or by pressure between folds of filter paper. In other cases where a higher temperature would be injurious the substance may be placed under a bell-jar which also incloses a dish containing sulphuric acid. The operation proceeds more quickly if the bell-jar is connected with an air-pump and thus rendered vacuous.

Substances which do not decompose at 100° are best dried in a copper oven provided with a jacket containing water which is heated to boiling, the water-level being kept constant by means of an overflow *a* and feeding arrangement at the side. The inside of the oven is fitted with a perforated shelf which supports dishes, funnels, &c. (Fig. 2).

When the substance is sufficiently stable it is advisable to dry at 115°–120°, since an increase of 10° or 20° often greatly reduces the time required For this purpose we use a copper oven without a jacket, heated by a lamp underneath; or toluene, boiling at 110°, may be used instead of water in the oven with a jacket, crude xylene will give a higher temperature (120°). Inside the oven at a little distance from the bottom is a shelf which supports the vessel containing the substance. At the top of the oven are two apertures, one of which serves to promote a current of air through the oven, whilst the other carries a thermometer the bulb of which is close beside the vessel which is being heated (*cf.* Huntly and Coste, J. Soc. Chem. Ind. 1913, 32, 62).

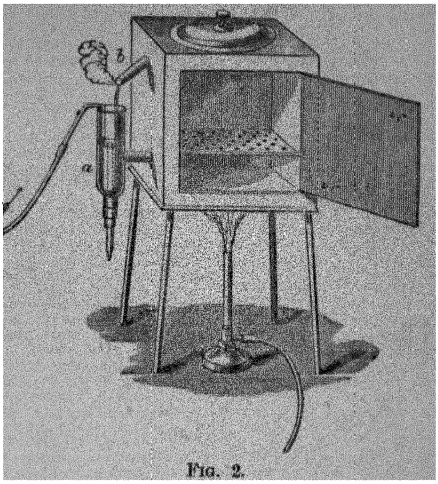

Fig. 2.

If it is desired to keep the temperature constant for a long time, the oven must be provided with a thermoregulator (*v.* THERMOREGULATORS).

Weighing.—The balance and the precautions to be observed in weighing form the subject of a special article (*v.* BALANCE). As a rule, substances taken for analysis should be weighed from tubes provided with well-fitting stoppers or corks, or from weighing bottles fitted with glass capsule stoppers, the difference between the weight of the tube or bottle before and after the removal of the substance giving the weight taken for analysis. The quantity required for an analysis will depend upon circumstances. When constituents present in minute quantity have to be estimated, a relatively large amount of the substance is required, but for the estimation of one or two constituents from 1 to 2 grams of the substance is usually sufficient. The smaller the quantity of matter operated upon, the shorter the time required for filtration, washing, &c., but also the greater the demands on the skill and accuracy of the operator.

Hygroscopic substances and precipitates must be kept under a *desiccator* (*q.v.*), *i.e.* a glass dish containing sulphuric acid or calcium chloride, fitted with a tray to support a crucible, &c., and provided with an air-tight glass cover, preferably bell-shaped. Crucibles containing non-hygroscopic precipitates may be allowed to cool with exposure to air, provided that the empty crucibles were allowed to cool under the same conditions before weighing.

Solution.—The solution of a substance is most conveniently effected in flasks or in somewhat deep beakers which are inclined at an angle in order to prevent possible loss by spurting. The operation may be accelerated by heat, and the reagent should be used in the most concentrated form possible and in the least possible excess, in order to avoid loss of time in evaporation, &c. Evaporation to expel excess of solvent should, where possible, be conducted in the same vessel.

Evaporation.—The evaporation of a liquid may be effected over an ordinary bunsen flame, or over a rose burner, care being taken that the liquid does not boil. If the operation is conducted in a flask or crucible, the latter should be inclined in order to prevent loss by ebullition, and the operation is accelerated in the first case by drawing a current of air through the flask, in the second by inclining the lid of the crucible (Fig. 3) across the mouth of the vessel and thus producing a circulation. The rate of evaporation, *cæteris paribus*, depends on the area of surface exposed, and hence the operation is effected most quickly in shallow dishes, especially if a current of air removes the vapour as fast as it is given off. During the process the contents of the dish should be protected from dust, &c., and this is really done by supporting at a distance of about six inches above the surface of the dish a triangle of glass rod or tubing on which is stretched a sheet of filter paper freed from soluble compounds by treatment with acid. When evaporation over a direct flame is impracticable, the dishes, &c., should be placed on a *water-bath*, that is, a vessel containing boiling water, in such a way that they are heated by the steam. The top of the water drying-oven already described (Fig. 2) may be provided with a series of rings of various sizes and thus serves two purposes. Ordinary tin cans or copper vessels of similar shape will answer, but in all cases it is desirable to have an arrangement for keeping the water at a constant level.

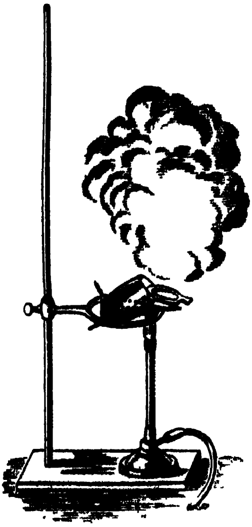

FIG. 3

Precipitation is conducted in beakers, dishes, or conical flasks, but not in ordinary round flasks because of the difficulty of removing the precipitate. Glass vessels, especially when new, are appreciably attacked and dissolved by water, and still more strongly by alkaline solutions, the action increasing with the concentration of the solution and the duration of contact. For quantitative work Jena glass vessels should be used, as these are least affected by alkalis. Acid liquids, with the exception of dilute sulphuric acid, have less solvent action. Porcelain vessels, especially after they have been used for a short time, are not appreciably attacked (Fresenius's Quant. Anal.). All precipitations involving long heating with alkaline liquids should be conducted in porcelain vessels or in platinum, silver, or nickel dishes. Silica-ware vessels can be used with all acid liquids excepting those evolving hydrogen fluoride (Zeitsch. anorg. Chem. 1905, 44, 221).

Unless circumstances forbid, the liquid and the reagent should be heated to boiling and mixed gradually with continual agitation, since under these conditions precipitation as a rule is more rapid and complete, and the precipitate is obtained in a dense and granular form and is readily separated and washed. Usually filtration may be commenced as soon as the supernatant liquid is clear, or at any rate after two or three hours. An unnecessary excess of reagent should always be avoided, but in all cases complete precipitation should be proved by adding a small quantity of the reagent to the clear liquid.

Filtration.—The separation of a precipitate from a liquid is usually effected by means of a specially prepared variety of blotting paper, known as filter paper. The Swedish paper made by J. Munktell has the oldest reputation, but that known as Whatman paper, made by W. & R. Balston, Ltd., is of excellent quality, and for many purposes answers better. The latter firm supply paper which has been treated with hydrochloric and hydrofluoric acids, and thus freed from almost all inorganic matter. It is desirable that all paper used in quantitative work should be free from soluble compounds, and this end is secured by soaking the ordinary filter paper for three or four hours in pure hydrochloric acid diluted with 15–20 times its volume of water, and then washing thoroughly to remove all traces of acid and soluble salts. The paper is conveniently kept in circular pieces of known radii (2, 4, 5, 6, 8 cm.), and the ash left by each size should be determined once for all by incinerating six filters of one of the medium sizes in the manner described under the treatment of precipitates, and weighing the ash which is left. This quantity divided by six gives the average amount of ash left by one filter of that size, and the amount left by the other sizes is readily calculated, the quantity of ash being proportional to the area of the paper.

Usually the filter paper is supported in a glass funnel which should have smooth even sides and an angle of 60°. The stem should be somewhat long and not too wide, with the lower end cut obliquely. A circular filter is folded in half, then in a quadrant, and when the quadrant is opened at one side it forms a hollow cone which should fit accurately into the funnel. The edge of the filter paper should be about 10 mm. below the edge of the funnel, and the size of the filter should be such that it is not more than three quarters filled by the precipitate. After placing the filter in position it is moistened with water, and fitted accurately to the glass, care being taken to remove all air bubbles from between the glass and the paper. Attention to these points greatly facilitates the subsequent filtration. The edge of the vessel containing the liquid to be filtered is slightly greased outside, and the liquid is directed into the filter by means of a glass rod, care being taken not to disturb the precipitate until most of the clear liquid has passed through. It is advisable to keep the filter well filled with the liquid, but the latter must not rise higher than 10 mm. below the top of the paper.

In order to accelerate filtration a glass tube about 3–4 mm. in diameter and not less than 20 cm. long, bent into a loop near its upper end, may be attached to the stem of the funnel by means of indiarubber tube.

Greater rapidity of filtration is obtained by using one of the numerous water pumps (*v.* Filter pump). In this case the liquid is filtered into a flask with stout walls, preferably of the conical form. The stem of the funnel passes through a cork which fits in the neck of the flask and also carries a tube connected with the pump, or the flask may be provided with a side tube for this latter purpose. When it is required to filter into a dish or beaker, the latter is placed under a tubulated bell-jar standing on a glass plate, the cork carrying the funnel, &c., being fitted into the tubulus of the bell-jar. If the reduction of pressure is considerable, it becomes necessary to support the apex of the filter. In the case of filters of medium size the necessary toughness is obtained by dropping into the apex of the dry filter, after it has been fitted into the funnel, two or three drops of the strongest nitric acid. After a minute or two the paper is washed and is ready for use. Bunsen's original method is to support the apex of the filter by means of a cone of platinum foil, which is made in the following way. A circular piece of thin platinum foil 3–4 cm. in diameter is cut in the manner shown in the diagram (Fig. 4), softened by heating in a flame, and then placed against a small metal cone of 60°, so that the point *a* coincides with the apex of the cone. The foil is then folded round the metal so that it also forms a small cone, which is finished by being pressed in a hollow conical mould into which the metal cone fits. It is then dropped into the funnel and the paper fitted in. The metal cones and moulds required can be purchased; Bunsen's method of making a cone and mould of plaster is described in Thorpe's Quantitative Analysis.

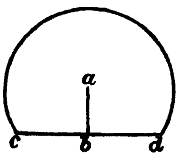

Fig. 4.

Carmichael has described a method of reverse filtration (Zeitsch. anal. Chem. 10, 83).

The Gooch crucible (Chem. News, 37, 181), which has a perforated bottom lined with a thin asbestos mat, has now become a recognised means of collecting precipitates. The asbestos makes an excellent filter, is not affected by ordinary acid and alkaline liquids, is readily dried, and does not alter in weight when ignited. The quality of the asbestos is of prime importance, a non-ferruginous amphibole being preferable to the cheaper hydrated varieties of serpentine which are appreciably soluble in acids. Silky asbestos is scraped into a short fine down, boiled with hydrochloric acid, well washed, and kept in water. A platinum or silica crucible, preferably of the low wide form, with the bottom perforated with a large number of minute holes, is fitted air-tight into an ordinary funnel by means of an indiarubber ring placed between the crucible and the wall of the funnel, which is fitted into a filtering flask. The pump is set in action and water containing the asbestos in suspension is poured into the crucible. A layer of asbestos felt is quickly formed, and when this is of sufficient thickness it is drained, dried, and ignited over a lamp, and the crucible is then weighed. It is desirable to have a non-perforated bottom to fit on the crucible during ignition, in order to protect the contents of the crucible from the flame gases. A Soxhlet tube, having a perforated porcelain or platinum disc covered with an asbestos layer and supported at the constricted part of the tube, is frequently used to collect precipitates. Neubauer recommends a perforated platinum crucible with a felted platinum mat (Zeitsch. anorg. Chem. 1901, 922; *cf.* Amer. Chem. J. 1909, 31, 456). The weighed crucible is replaced in the funnel, and filtration is conducted in the ordinary way, care being taken that the pump is set in action before any liquid is poured into the crucible. Drying and igniting the precipitate occupies but little time. For gelatinous precipitates the crucible may be replaced by a cone, the lower part of which is made of platinum gauze and the upper part of platinum foil.

Gooch has proposed (P. Am. A. 1885, 390; Zeitsch. anal. Chem. 24, 583) in special cases to replace the asbestos by anthracene, which after filtration can be dissolved in benzene or other suitable solvent, leaving the precipitate undissolved.

Not unfrequently it is necessary to keep the contents of a funnel hot during filtration. This is effected by placing the funnel inside a copper jacket filled with water which is heated to boiling by means of a side tube. A simpler plan is to coil lead pipe round the funnel and blow steam through the pipe (Richter, J. pr. Chem. (ii.) 28, 309).

Sometimes it is desirable to avoid contact with air during filtration. A convenient apparatus for this purpose has been described by Klobukow (Zeitsch. anal. Chem. 24, 395; J. Soc. Chem. Ind. 4, 756).

All precipitates require to be washed in order to remove soluble impurities, the liquid employed being water, dilute acid, dilute ammonia, alcohol, &c., as the case may require. The object in all cases is to reduce the impurity to the desired minimum in the shortest possible time with the least expenditure of liquid, and it can readily be shown that successive treatments with small quantities of the liquid are far more effectual than the same volume of liquid applied all at once (Bunsen, Annalen, 148, 269). When ever possible hot liquids should be used, and the precipitate should be washed so far as possible by decantation, only the washing liquid being poured on the filter. The soluble impurity collects round the top edge of the filter paper by reason of capillary action and evaporation, and hence, when washing is effected with the aid of an ordinary wash-bottle with a movable jet, it is important that the liquid should be directed on to the top edge of the filter. It is also important that each quantity of wash-water should be drained away as completely as possible before adding a fresh quantity, and it is obvious that this takes place most readily when a pump is used. In this case the liquid is poured into the funnel from an open vessel to a height of about 10 mm. above the edges of the paper. Care must be taken that the precipitate is not drained so far that channels are formed. It is always advisable to ascertain whether the washing is complete by testing a few drops of the last wash-water.

Drying and weighing precipitates.—Occasionally a precipitate must be dried without the application of heat, and this is accomplished in a desiccator over sulphuric acid, preferably in a vacuum. In other instances the substance is not injured by a temperature of say 120°, but cannot be ignited. In these cases the filter is carefully dried at the particular temperature, enclosed between a pair of watch-glasses, and weighed. It is then placed in the funnel and the operation proceeded with. After filtration the filter and the precipitate are thoroughly dried at the same temperature as before and again weighed, the increase being the weight of the precipitate. Tared filters can, however, be generally replaced by Gooch crucibles, Soxhlet tubes, &c. The majority of the precipitates usually met with can, moreover, be dried by heating them in a crucible over a lamp. In most cases it is not necessary that the precipitates should previously be dried. The greater part of the water is removed by draining in the funnel by means of the pump or by placing the filter and its contents on a porous tile or on a pad of filter paper. The filter is then introduced into a crucible, heated cautiously until quite dry and then heated more strongly until the weight is constant.

When the precipitate is not easily reducible it is not necessary to remove the paper before ignition. The wet paper enclosing the precipitate is placed in a platinum crucible, and the latter heated with a full flame; the water present assumes the spheroidal state and the paper smoulders away without spurting. If any slight reduction takes place, for example, with barium sulphate, it is easily remedied by adding a few drops of dilute sulphuric acid and again heating. In the case of magnesium pyrophosphate strong nitric acid serves a similar purpose. If, however, the precipitate is readily reduced in contact with organic matter, it must be removed from the paper as completely as possible by gentle friction, and transferred to the crucible, which should stand on a sheet of glazed paper. A carefully trimmed feather or a camel's-hair brush is useful to transfer scattered particles from the paper to the crucible. The filter paper is then folded with the portion to which the precipitate had adhered inside, wrapped in platinum wire which forms a sort of cage, and set on fire. Whilst burning it is held over the crucible, and *when completely burnt out*, the ash is heated with the tip of a Bunsen flame for a few minutes and then shaken into the crucible.

Precipitates which contain compounds of silver, lead, zinc, tin, and other easily reducible metals, should be heated in porcelain crucibles, since platinum vessels are liable to be attacked. Care should also be taken that platinum vessels are not heated with smoky or 'roaring' flames, and do not come in contact with brass crucible tongs or easily fusible metals whilst hot. After some time the surface of the metal may become dull, owing to the partial disaggregation of the platinum, but this defect can be remedied by polishing the metal with sea-sand or a burnisher.

Heating appliances.—The ordinary bunsen burner serves for most operations, but the argand bunsens introduced by Fletcher are more efficient, and the radial slit burner of the same inventor is perhaps the most efficient gas-burner for heating purposes that has yet been made. Glass vessels are more safely heated on a sheet of wire gauze or on a layer of sand in a metal tray. A most useful piece of apparatus in a technical laboratory is a large iron plate supported on iron legs, and heated by a burner underneath the middle. Vessels placed on the plate near its edges are subjected to a very gentle heat, but may be raised to a much higher temperature by being moved nearer to the middle.

A water-bath provided with a constant feeding arrangement is the most useful way of heating vessels at 100°. If higher temperatures are needed, a saturated solution of calcium chloride, melted paraffin, or oil may be used. Maumené (Compt. rend. 1883, 97, 45, and 215) has proposed to use fused mixtures of alkaline nitrates for temperatures between 140° and 250°. Brauner (Chem. Soc. Trans. 1885, 47, 887) has described a simple arrangement for heating substances in sulphur vapour.

Reagents.—The ordinary acids and ammonia are required in a dilute as well as in a concentrated form. Whenever possible the reagents should be made in solutions the strengths of which are multiples or submultiples of normal solutions. A convenient strength for the dilute mineral acids is twice normal, and the alkaline solutions should be of equivalent strength.

QUALITATIVE ANALYSIS.

The detection of the constituents of a mixture or chemical substance is based on the fact that almost every metallic or acidic radical will under suitable conditions give rise to a reaction which, under these conditions, is characteristic and thus enables one to distinguish this radical from all others. These tests may be applied directly to the solid substance, usually at high temperatures, when they are known as *dry reactions*; or they may be employed in solution, in which case they are described as *wet reactions*. The wet and dry reactions of metallic and acidic radicals are generally, but by no means invariably, independent of the acidic and

metallic radicals with which they are respectively combined.

Examination in the Dry Way.

The indications obtained from the dry reactions of a substance frequently afford very suggestive clues to its composition, but as these tests rarely, if ever, indicate the relative proportions in which the constituents exist in the mixture under examination, they must be regarded as being preliminary to the more systematic examination of the substance in solution. Moreover, negative results obtained from dry tests must not be accepted as final evidence.

In all cases, however, a preliminary examination of the substance should be made in the dry way, and if the substance is in solution a portion should be evaporated to dryness. The reactions of several substances in the dry way are interfered with and rendered inconclusive by the presence of certain other substances; but nevertheless an examination of this kind often gives much information in a short time.

The most convenient source of heat for this purpose is the ordinary bunsen burner. This consists of a metal tube at the base of which coal gas enters by means of a jet, the lower part of the tube being pierced with holes through which air is drawn and mixed with the coal gas. The mixture of 1 volume of coal gas with about 2½ volumes of air, which is thus produced, burns at the top of the tube with a non-luminous flame. When the supply of gas is turned low, it is necessary also to reduce the air supply by partially closing the inlet holes by means of a regulator. The upper part of the burner is generally fitted with a support carrying a cone to protect the flame from draughts.

The flame consists essentially of an inner dark zone containing unburnt gas mixed with air, and an outer zone or flame mantle in which combustion becomes complete. If the air holes are partially closed, a luminous cone appears at the top of the inner zone. Bunsen has shown, however, that several distinct zones exist, each of which can be utilised for producing particular reactions. The most useful of these are *a*, a comparatively cold zone at the base of the flame, which serves for the volatilisation of salts in order to obtain flame colourations; the *lower reducing flame* δ about one quarter of the way up and close to the edge of the dark zone; η, the *upper* and more powerful *reducing flame* at the top of the dark zone, obtained by closing the air holes until the tip of the inner zone just becomes luminous; β, the *zone of fusion* or highest temperature, at about one-third the height of the flame and half-way between the inner zone and the flame mantle; γ, the *lower* and hotter *oxidising flame* at the edge just below the zone of fusion; and ε, the *upper oxidising flame* at the extreme tip of the flame.

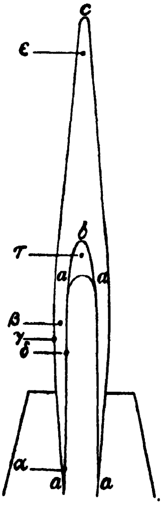

FIG. 5.

Instead of the bunsen burner, the flame obtained by means of a blowpipe may be used; a mouth blowpipe consists of a metal tube provided at one end with a mouthpiece, the other end fitting into a small metal box which serves to condense and retain the moisture of the breath. From the side of this box a second shorter and narrower tube projects at right angles to the first, and is provided with a nozzle or jet of brass or, better, of platinum. For general work the diameter of the bore of the jet should be 0·4 mm. In Black's blowpipe the larger tube is conical, the lower and wider end serving the same purpose as the box in the form just described. The art of keeping up a continuous blast of air through the blowpipe can only be acquired by practice. The necessary pressure is produced by distending the cheeks, breathing being carried on through the nostrils, whilst communication between the nostrils and the mouth is cut off by the pressure of the tongue against the palate. A convenient form of hand-blower for blowpipe work has been devised by Fletcher.

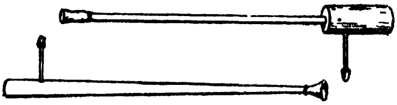

FIG. 6.

A good flame for blowpipe work is obtained by dropping into the tube of an ordinary bunsen burner a brass tube, the lower end of which descends to the bottom of the burner and cuts off the supply of air, whilst the upper end is flattened and cut off obliquely. The flame should be much smaller than when the burner is used in the ordinary way. Coal gas usually contains more or less sulphur, and consequently cannot be used when testing for this element.

A thick stearin candle answers well; but nothing is better than a lamp consisting of a low and rather wide cylindrical metal vessel, open at the top, with a somewhat broad and flat wick-holder attached to the side. The fuel used is solid paraffin, which is kept in a melted condition by the heat of the blowpipe flame, the wick being so arranged that the flame passes over the top of the paraffin. A metal cover protects the lamp from dust when not in use.

The nozzle of the blowpipe is introduced a short distance into the lamp flame at a short distance above the wick, and when the blast is produced the flame is deflected horizontally, becomes long and narrow, and is seen to consist of two parts, viz. an *outer* or *oxidising* flame, at the tip of which there is an excess of oxygen heated to a high temperature, and an *inner* or *reducing* flame, which contains carbonic oxide and hydrocarbons heated to a high temperature. If the blowpipe is held just at the edge of the flame and a moderate blast is used, a broader

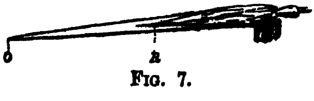

FIG. 7.

reducing flame can be obtained, which has a luminous tip containing solid particles of carbon.

The following appliances are required: a small pair of forceps with platinum points; short pieces of thin platinum wire; charcoal from some fine-grained compact wood; glass tubes about 3 mm. internal diameter, and 60–80 mm. long, closed at one end; and glass tubes of similar diameter 100–120 mm. long, open at both ends and bent slightly in the middle. The reagents used are borax, microcosmic salt ($NH_4NaHPO_4, 4H_2O$), potassium cyanide, sodium carbonate, potassium nitrate, cobalt nitrate solution, and potassium hydrogen sulphate.

The dry tests are conveniently performed in the following order:—

(1) *Heating in a dry closed tube.*—To avoid soiling the sides of the tube, the substance should be introduced by means of a roll of stiff paper. The following changes may be observed:

(*a*) Carbonisation with or without evolution of empyreumatic vapours = *organic compounds.*

(*b*) Condensation of moisture on cold parts of tube; neutral reaction = *hydrated salts and hydroxides*; acid reaction = *acids and acid salts*; alkaline reaction = *ammonium salts.*

(*c*) Fusion without change of colour = *alkaline salts, hydrated salts.*

(*d*) Fusion with change of colour = yellow hot, dark yellow cold = *bismuth oxide*; yellow hot, red cold = *lead oxide*. The chromates of lead and the alkali metals fuse and darken on heating.

(*e*) No fusion, but change of colour: dark yellow hot, pale yellow cold = *stannic oxide*; yellow hot, white cold = *zinc oxide*; black hot, reddish-brown cold = *ferric oxide*; black hot, bright red cold = *mercuric oxide*; brown darkening on heating = *cadmium oxide.*

(*f*) Gas evolved: oxygen = *oxides, peroxides, chlorates, bromates, perchlorates, iodates, periodates, persulphates,* and *nitrates*; carbon dioxide = *carbonates, bicarbonates, oxalates*; carbon monoxide (blue flame) = *formates, oxalates*; sulphur dioxide = *acid sulphites, sulphates of heavy metals* (together with sulphur trioxide); cyanogen = *cyanides of heavy metals*; ammonia = *ammonium salts*; phosphine = *phosphites, hypophosphites*; orange-brown vapours = *nitrates, nitrites, bromides*; violet vapours = *iodides*; colourless fuming gas = *hydrated chlorides.*

(*g*) Sublimate: white infusible = *arsenious oxide* (octahedra), *antimonious oxide* (needles), *selenium dioxide, ammonium chloride, ammonium sulphite* (from ammonium sulphate); white fusible = *mercuric chloride, tellurium dioxide, organic acids, molybdenum trioxide* (at very high temperatures); coloured, black, or reddish black = *selenium, mercuric sulphide*; yellow hot, red cold = *mercuric iodide*; reddish yellow = *arsenious sulphide*; yellow = *sulphur* and *sulphides*; black metallic mirror = *arsenic*; grey metallic globules = *mercury.* These metallic sublimates are often obtained more readily by heating the material with potassium cyanide.

Phosphorus compounds are detected by heating in a closed tube with magnesium ribbon and dropping the hot tube into water, when inflammable phosphine is evolved.

(2) *Heating in open tube.*—The tube being inclined, to promote a current of air through it, the changes observed are similar to the reactions in the closed tube, but sulphides burn evolving sulphur dioxide; arsenic is oxidised to arsenious oxide, and selenium and its compounds evolve a pungent odour of horseradish (dioxide), and give a grey or reddish sublimate.

(3) *Heating on platinum wire.—Flame colourations.*—The wire being cleaned by repeated dipping in hydrochloric acid and heating till it imparts no colour to the flame, a small quantity of the substance supported on the end of the wire is introduced into zone *a* of the bunsen flame. As a colouration is produced only if volatile compounds of the metals are present, the substance should be moistened with hydrochloric acid to produce the volatile chlorides. This result may also be attained by mixing the substance on an asbestos thread with moist silver chloride, a compound which, while imparting no colour to the flame, slowly yields chlorine, converting other metals into chlorides. The wire should be slowly moved into the hottest part of the blowpipe or bunsen flame, so that the colourations due to less volatile constituents may be successively developed.

Colourations: yellow = *sodium*; orange red = *calcium*; crimson = *strontium, lithium*; lavender = *potassium, rubidium, cæsium*; apple green = *barium*; bright green = *thallium, copper, boric acid*; pale blue = *lead, antimony*; deep blue becoming green = *copper halides*; deep blue = *selenium.*

The pocket spectroscope (direct vision) is a useful aid in examining flame colourations, particularly in the case of strontium and calcium, which exhibit respectively a characteristic blue and a yellowish-green line.

(4) *Heating on charcoal.*—The substance mixed with three times its weight of dry sodium carbonate or of a mixture of 2 parts sodium carbonate and 1 part potassium cyanide, is placed in a small shallow hole scooped out in charcoal, and heated in a reducing flame. The metallic bead obtained is examined as to colour, malleability, solubility, &c. Many metals yield films of oxide, which coat the charcoal at a greater or less distance from the flame, and the colour and appearance of which are more or less characteristic. These and similar films are best seen when the charcoal is supported on an aluminium plate (Ross). A piece of sheet aluminium 12 cm. by 5 cm. is bent in right angles at a distance of 2 cm. from one end, thus forming a ledge on which a small flat piece of charcoal is placed, the plate being held so that the surface rises vertically behind the ledge. Volatile oxides, &c., condense on the metallic surface (*v.* Hutchings, Chem. News, 1877, 36, 208, 217).

The reduction may also be effected by adding a fragment of sodium to the substance supported on charcoal (Parsons, J. Amer. Chem. Soc. 1901, 23, 159).

In order to obtain reduced metals with the bunsen flame, a match-stick is smeared with ordinary sodium carbonate (washing soda) which has been melted by holding it in the flame, and the wood thus prepared is carbonised by heating it in the flame. A small quantity of the substance is mixed in the palm of the hand with a small quantity of the fused washing soda, and the mixture is carefully placed on the charcoal splint, which is then heated in the lower or upper reducing flame. When reducting is complete, the match is allowed to cool inside the dark zone, and is then withdrawn, crushed in a mortar, and the lighter particles of charcoal removed by levigation with water, the heavy metallic particles being left.

By means of the bunsen flame reduced metals and their oxides can be obtained in the form of films on a porcelain surface. The substance is supported on a long slender piece of asbestos, and heated in the tip of a small oxidising or reducing flame, a small evaporating dish containing cold water being held momentarily just above the asbestos (*v.* Bunsen's Flammenreactionen, Heidelberg, 1880).

Incrustations on charcoal: white, very volatile = *arsenic*; white, less volatile = *antimony*; orange-yellow hot, pale yellow cold = *bismuth*; pale yellow hot, deep yellow cold, white edge = *lead*; yellow hot, white cold = *zinc, molybdenum*; reddish-brown or orange-yellow cold = *cadmium.*

Metallic beads or residues on charcoal: white malleable = *silver, tin, lead*; red malleable = *copper*; grey brittle = *antimony, bismuth*; grey powder, magnetic = *iron, cobalt, nickel*; non-magnetic = *molybdenum.*

(5) *Cobalt nitrate reactions.*—Certain *infusible* substances, when moistened with cobalt nitrate solution and strongly heated, acquire characteristic colours. These reactions are frequently, but not necessarily, carried out on a charcoal support:—blue infusible mass = *aluminium*; blue fusible = *certain phosphates, silicates, borates*; green = *zinc, titanium, tin*; pink = *magnesium.*

(6) *Heating with borax or microcosmic salt.*—A small loop is made at the end of a platinum wire, to which some borax or microcosmic salt is made to adhere, and heated in the flame until fused. The bead when cold must be quite transparent and colourless, otherwise it must be remelted, shaken off, and a fresh bead made. A *small* quantity of the substance is taken on the bead and heated first in the oxidising flame (O.F.) and then, after it has been examined, in the inner or reducing flame (I.F.). The colour of the bead should be observed both hot and cold. If too much substance is taken, the bead becomes opaque, and the colour cannot be distinguished.

These so-called borax and microcosmic beads owe their colour respectively to the formation of certain borates and phosphates of the heavy metals. Borax glass consists of anhydrous $Na_2B_4O_7$, and when heated with a metallic oxide or salt the excess of boric oxide present unites with the metallic oxide, forming the corresponding borate:

$$Na_2B_4O_7+CoO = Na_2B_2O_4+CoB_2O_4 \text{ (blue).}$$

Microcosmic salt on ignition yields the readily fusible sodium metaphosphate, and this salt combines with metallic oxides to form double orthophosphates:

$$NaPO_3+CuO = CuNaPO_4 \text{ (green).}$$

When a silicate is introduced into the molten metaphosphate, the latter withdraws the basic oxide from the former, setting free silica, which remains undissolved ('silica skeleton'):

$$CaSiO_3+NaPO_3 = CaNaPO_4+SiO_2.$$

Borax beads.—

Inner flame		Outer flame		Metal
Hot	Cold	Hot	Cold	
Green	Bottle-green	Yellow	Paler	*Iron*
Green	Green	Yellow	Green	*Chromium*
Green	Bottle-green	Yellow	Pale yellow	*Uranium*
Colourless	Colourless	Amethyst	Amethyst	*Manganese*
Blue	Blue	Blue	Blue	*Cobalt*
Grey	Grey	Violet	Reddish-brown	*Nickel*
Brownish	Emerald-green	Yellow	Greenish-yellow	*Vanadium*
Colourless	Brown	Green	Bluish-green	*Copper*
Colourless	Colourless	Orange-red	Colourless	*Cerium*
Brown	Brown	Yellow	Colourless	*Molybdenum*
Brownish-violet		Yellow	Colourless	*Titanium*
Yellow to brown		Yellow	Colourless	*Tungsten*

Microcosmic beads.—The colours produced are similar to those in the borax bead, but the reducing effects are less pronounced. In the I.F. molybdenum compounds give a green colour, and those of tungsten a greenish-blue tint. Chlorides and bromides evolve a blue and green flame when heated with a microcosmic bead saturated with copper oxide, and iodides give a green flame.

(7) *Other special dry tests.*—(*a*) Heating on charcoal with potassium (or cuprous) iodide and sulphur: crimson incrustation = *bismuth*; lemon yellow incrustation = *lead*; greenish-blue fumes = *mercury.*

(*b*) Heating on charcoal with (i.) fusion mixture (Na_2CO_3,K_2CO_3) alone and moistening with dilute acid, hydrogen sulphide evolved = *sulphur compounds*; (ii.) fusion mixture and sulphur, soluble mass giving coloured precipitate with dilute acid, yellow = *tin*; orange = *antimony.* The fused insoluble oxides SnO_2 and Sb_2O_4 can be thus characterised.

(*c*) Heating with fusion mixture and potassium nitrate: soluble green mass = *manganese*; yellow mass = *chromium.*

(*d*) Heating in closed tube with potassium hydrogen sulphate. Gas evolved: carbon dioxide = *carbonates, oxalates*; accompanied by charring of the residue = *tartrates, citrates,* &c.; carbon monoxide (blue flame) = *formates, oxalates*; sulphur dioxide = *sulphites, thiosulphates*; hydrogen sulphide = *sulphides* (not all); hydrogen chloride (fuming in air) = *chlorides* (not all); hydrogen fluoride (etching glass) = *fluorides*; bromine and hydrogen bromide = *bromides*; iodine = *iodides*; nitrous fumes = *nitrites, nitrates.*

Examination in the Wet Way.

The preparation of the solution requires some attention. A metallic substance is treated at once with moderately strong nitric acid. Tin and antimony form oxides which to a great extent remain undissolved; arsenic is oxidised to soluble arsenic acid; other metals (with the exception of gold and the platinum metals, which are not attacked) are converted into nitrates, which dissolve at once or on diluting.

If the substance is not a metal, it is first treated with hot water, and if anything is dissolved (which is ascertained by evaporating a few drops on platinum foil), the substance is boiled two or three times with fresh quantities of water. Any residue which may be left is treated with dilute hydrochloric acid, and afterwards, if necessary, with the concentrated acid. Care must be taken to observe if any gas is given off—*e.g.* carbon dioxide (effervescence), from *carbonates*; sulphur dioxide, from *sulphites* or *thiosulphates*; chlorine, from *peroxides* or *hypochlorites*; hydrocyanic acid, from *cyanides*; hydrogen sulphide, from *sulphides*. Many chlorides are insoluble in the strong acid, and hence the solution must be diluted before filtering. Silver, lead, and univalent mercury will be converted into insoluble chlorides.

Solvent action of the mineral acids (*v.* A. A. Noyes and W. C. Bray, J. Amer. Chem. Soc. 1907, 29, 137, 481).—In dealing with substances insoluble in water the following acidic solvents may be used: hydrochloric, nitric, sulphuric, and hydrofluoric acids. Although it is impossible to give a hard-and-fast rule as to the way in which these agents should be applied, the following considerations will indicate the relative advantages of one or other of these solvents:—

Hydrochloric acid.—(1) Advantages: (i.) Solutions on this acid do not yield a precipitate of sulphur on treatment with hydrogen sulphide; (ii.) the solvent action of this acid on the following oxides: lead peroxide, manganese dioxide, and the hydrated oxides of tin and antimony, is superior to that of nitric acid; (iii.) hydrated silica is readily precipitated on evaporating the hydrochloric acid solution.

(2) Disadvantages: (i.) This acid is comparatively useless for alloys; (ii.) evaporation of the hydrochloric acid solution leads to the volatilisation of arsenic, mercury, tin and selenium as chlorides.

Nitric acid.—(1) Advantages: (i.) The best general solvent for the metals and their alloys; (ii.) oxidises and dissolves insoluble compounds of arsenic, mercury, and selenium without the formation of volatile compounds of these elements; (iii.) does not cause the precipitation of silver or lead; (iv.) oxidises sulphides not attacked by hydrochloric and sulphuric acids.

(2) Disadvantages: (i.) This acid alters the state of combination of many elements, *e.g.* it oxidises mercurous, arsenious, antimonious, stannous, and ferrous salts; (ii.) its solution deposits much sulphur on treatment with hydrogen sulphide; (iii.) the oxidation of sulphides by nitric acid in the presence of barium, strontium, and lead leads to the precipitation of these metals as sulphates; (iv.) nitric acid is less efficacious than hydrochloric acid in rendering hydrated silica insoluble.

The nitric acid solution of an alloy when evaporated to dryness and heated at 120°-130° may yield the partially dehydrated hydroxides of silica, tin, antimony, titanium, and tungsten in an insoluble condition. When phosphorus or arsenic is present together with tin the so-called stannic phosphate or arsenate (phosphostannic or arsenostannic acid) may also be found in the insoluble residue.

Sulphuric acid.—The dilute acid is of little value as a solvent, but the hot concentrated acid has been found useful in certain cases. (i.) In bringing certain alloys into solution, *e.g.* white metals (*v.* Low, J. Amer. Chem. Soc. 1907, 29, 66); (ii.) destruction of organic matter; evaporation of a concentrated sulphuric acid solution of the substance is preferable to ignition, because the latter process renders certain compounds insoluble and leads to the loss by volatilisation of such elements as mercury, arsenic, selenium, &c. Very stable organic substances (*e.g.* paraffin and cellulose) can be destroyed completely by adding a little strong nitric acid and heating till the solution acquires a light yellow colour. When diluted considerably with water (20–30 vols.) this solution may yield a deposit containing silica and certain refractory silicates and fluosilicates, together with the sulphates of barium, strontium, lead, calcium, and chromium (an insoluble sulphate formed during the heating), basic sulphates of bismuth, antimony, and tin and the ignited oxides of the last two metals with those of aluminium and titanium. (iii.) Insoluble compound cyanides are decomposed by hot concentrated sulphuric acid, but may also be attacked by aqueous alkali hydroxides yielding soluble alkali cyanides and insoluble metallic hydroxides.

Hydrofluoric acid.—The insoluble residues from the preceding acids may be treated with a 40 p.c. solution of hydrogen fluoride, which is now obtainable in glass bottles lined with paraffin wax. (1) Advantages: (i.) Many insoluble silicates are readily decomposed, the silicon being eliminated completely as gaseous silicon fluoride; (ii.) the reducible metals and their compounds may be treated in platinum basins or crucibles providing that the solution is never evaporated to dryness.

(2) Disadvantages: (i.) Glass or silica-ware vessels cannot be used with hydrofluoric acid; (ii.) owing to the destructive action of hydrogen fluoride on animal tissues, all operations with solutions of this gas must be conducted in an efficient draught cupboard.

Aqua regia (concentrated hydrochloric acid 3 parts and nitric acid 1 part) may be employed in attacking substances not dissolved by hydrochloric or nitric acid, although it is of little use for colourless insolubles. It readily dissolves gold and platinum, but is less efficacious in rendering soluble the rarer noble metals (*e.g.* osmium and iridium).

Treatment of Insolubles.

The substances not dissolved by the foregoing acidic reagents are generally regarded as insolubles, although they are divisible into two classes: (i.) *pseudo-insolubles*, which are dissolved by certain specific solvents; (ii.) *true insolubles*, which are only broken up into soluble compounds by the agency of fused alkali carbonates.

Pseudo-insolubles.—*Silver chloride* and *bromide*, soluble in aqueous ammonia. (The three silver halides may be completely decomposed by treatment with zinc and dilute sulphuric acid, metallic silver and soluble zinc halide being produced.) *Insoluble fluorides* (those of the common and rare earth metals) are decomposed by heating with concentrated sulphuric acid. *Lead sulphate*, soluble in ammonium acetate solution; *oxides of antimony*, dissolved in hydrochloric and tartaric acids. *Anhydrous chromic sulphate* and *basic bismuth sulphate*, converted respectively into hydroxide and basic carbonate by boiling with aqueous sodium carbonate; these products are then dissolved in dilute mineral acids.

True insolubles.—These substances are fused with a mixture of sodium and potassium carbonates in equimolecular proportions (so-called fusion mixture). In the absence of reducible metals (*e.g.* silver or lead), insoluble sulphates (barium and strontium sulphates) and silicates may be heated with the fusion mixture in a platinum crucible. If any insoluble molybdenum sulphide is present (indicated by dry tests), a little nitre must be added to oxidise this sulphide, and thus prevent its corrosive action on the platinum. In the case of an insoluble silicate the fused mass is treated directly with hydrochloric acid, when the metals present pass into solution as chlorides, and the silica is rendered insoluble by evaporating down the acid solution. In the case of insoluble sulphates the fused mass is extracted with water to remove the soluble alkali sulphate, and the residue ($BaCO_3$,$SrCO_3$) is subsequently dissolved in dilute acid.

Silver iodide, bromide, and chloride are decomposed by 'fusion mixture,' yielding the soluble alkali halide; insoluble lead compounds are similarly decomposed. The strongly heated oxides of aluminium, chromium, titanium, tin, and antimony rank as insolubles; they are not readily attacked by 'fusion mixture,' but are rendered soluble by fusion with potassium hydroxide. The oxides of titanium and aluminium may be rendered soluble by fusion with potassium hydrogen sulphate; special methods for treating the insoluble oxides of chromium, tin, and antimony are indicated among the dry tests (7, *b* and *c*). The insoluble compounds of the easily reducible metals (*e.g.* Ag, Pb, Sn, Sb, &c.) can all be decomposed and reduced by fusion with sodium or potassium cyanide.

When both aqueous and acid solutions have been obtained from the same substance, the analyst must use his judgment as to whether they may be mixed or should be analysed separately. The latter course sometimes gives information as to the distribution of the acids and bases in the original substance. If the first course is adopted, it must be borne in mind that the hydrochloric acid solution may precipitate lead and silver, and possibly mercury, from an aqueous or nitric acid solution.

Systematic Method of Examination in the Wet Way.

The formation of a precipitate at the proper stage in the systematic separation is not sufficient proof of the presence of a particular substance; some characteristic confirmatory test should always be applied. The colour of the solutions at different stages in the operation is a valuable indication. Unnecessary excess of reagents should be avoided, but filtrates should always be tested to make sure that precipitation is complete. Many tests succeed only when the proper proportion of the reagent is added, and it should be a rule always to add the reagents very gradually. All precipitates which have to be subjected to the action of reagents should be carefully washed, but in qualitative analysis it is not as a rule desirable that all the washings should mix with the filtrate.

The reaction of the original solution towards litmus paper should be noted and a portion tested for ammonium compounds by heating with sodium hydroxide or by triturating in a mortar with soda-lime (dry sodium and calcium hydroxides).

In systematic qualitative analysis advantage is taken of certain *similarities* existing between the metallic radicals which enable these radicals to be divided into a limited number of groups, the members of which are subsequently either separated or identified by means of the *differences* between the properties of their respective compounds.

The metallic radicals are divided into six groups, according to their behaviour with the following reagents, which must be applied in the order given. It may be mentioned that some chemists prefer a division into five groups, and add the reagents of Groups III. and IV. successively *without* an intervening filtration. This process is conveniently adopted in the presence of the less commonly occurring metals (J. Amer. Chem. Soc. 1908, 30, 481).

Group I.—Reagent: hydrochloric acid in moderate excess. Precipitate: *silver*, *lead*, *thallium* (*thallous*), and *mercurous chlorides*; *tungstic acid*.

If the original solution is alkaline, the group precipitate may contain sulphides (*e.g.* As_2S_3, Sb_2S_3, SnS_2) which had been dissolved in aqueous alkali sulphide or hydroxide. This yellow or orange precipitate is examined under Group II. The group precipitate may also contain insoluble silver salts (*e.g.* AgBr, AgI) precipitated from solution in alkaline cyanides or thiosulphates; these are dealt with as insolubles. The filtrate from the Group I. precipitate or the solution itself in the absence of a precipitate, must be evaporated nearly to dryness if nitric acid or nitrates are present, since these compounds lead to the precipitation of sulphur in Group II.

Group II.—Reagent: hydrogen sulphide in acid solution. Thioacetic acid has been recommended as a substitute for hydrogen sulphide in qualitative analysis (Schiff and Tarugi, Ber. 1894, 27, 2437). Precipitate: the *sulphides* of *arsenic*, *antimony*, *tin*, *molybdenum*, *gold*, *platinum* (*the other platinum metals*), *bismuth*, *lead*, *mercury*, *copper*, and *cadmium*, together with *selenium* and *tellurium*, partly free and partly as *sulphides*. The solution should be dilute and not too acid, and it should be treated and saturated repeatedly with the group reagent, since prolonged treatment is required to precipitate molybdenum and the platinum metals.

The filtrate from the foregoing sulphides is boiled to expel hydrogen sulphide, and any iron present peroxidised by warming with nitric acid or bromine water. If organic matter is present, it is destroyed either by evaporation to dryness or treatment with hot concentrated sulphuric acid (*v. supra*). Silica or barium sulphate may be precipitated at this stage. A portion of the oxidised solution should now be tested for phosphate with nitric acid and ammonium molybdate.

Group III.—Reagents: ammonium chloride and ammonium hydroxide. Precipitate: (*a*) In absence of phosphates: *hydroxides* of *aluminium*, *iron*, *chromium*, *glucinum*, *titanium*, *zirconium*, *tantalum*, *columbium*, *thorium*, *cerium* (*and other rare earth metals*), and *uranium* as *ammonium diuranate*. Some manganese, zinc, and alkaline earth metals may be coprecipitated. (*b*) In presence of phosphates: *the phosphates of the preceding metals, together with those of Groups IV., V., and magnesium.*

Group IV.—Reagents: ammonium sulphide or hydrogen sulphide and ammonium hydroxide. Precipitate: *sulphides* of *zinc, manganese, cobalt, and nickel.* The precipitation is carried out in the boiling solution, and the filtrate, if brown, is slightly acidified with hydrochloric acid, when *vanadium* and a small portion of the nickel are precipitated as sulphides.

Group V.—Reagents. ammonium carbonate and ammonia. Precipitate: *barium, strontium,* and *calcium* as *carbonates.*

Group VI.—The filtrate from Group V. contains *magnesium, sodium, lithium, potassium, rubidium,* and *cæsium,* which are identified by special tests.

In the absence of the rarer metallic radicals, the group precipitates are examined in the following manner. Confirmatory tests are given under special reactions.

Group I.—The precipitate is boiled with water; the aqueous extract mixed with dilute sulphuric acid gives a white precipitate ($PbSO_4$), indicating *lead.* The insoluble portion is treated with aqueous ammonia; a black residue (NH_2Hg_2Cl or NH_2HgCl and Hg) indicates *mercury*; the ammoniacal filtrate acidified with nitric acid gives white silver chloride, indicating *silver.*

Group II.—The precipitate is washed with aqueous hydrogen sulphide and warmed with yellow ammonium sulphide [$(NH_4)_2S_x$], this extraction being repeated.

(A) The filtrate is acidified with dilute hydrochloric acid, the precipitate boiled with strong aqueous ammonium carbonate, and the solution filtered, the filtrate acidified yields a yellow precipitate (As_2S_3), denoting *arsenic.* The residue is dissolved in concentrated hydrochloric acid, the solution boiled, diluted, and treated with strips of platinum and pure zinc; a black stain on the platinum = *antimony.* The zinc is dissolved in hydrochloric acid and mercuric chloride added; a white precipitate (Hg_2Cl_2) becoming grey (Hg) = *tin.*

In the separation of arsenic, antimony, and tin by ammonium carbonate, this solvent dissolves an appreciable amount of stannic sulphide, which is reprecipitated by acids as a white oxysulphide (Schmidt, Ber. 1894, 27, 2739).

Boiling the mixed sulphides with concentrated hydrochloric acid effects a separation by dissolving the tin and antimony compounds, leaving nearly the whole of the arsenious sulphide undissolved. The mixed sulphides may also be dissolved in aqueous sodium peroxide, which produces sodium arsenate, antimonate, and stannate. On boiling this solution with excess of ammonium chloride, hydrated stannic oxide is precipitated (*v.* J. Walker, Chem. Soc. Trans. 1903, 83, 184; *cf.* Cavén, Chem. Soc. Proc. 1910, 26, 176).

(B) The precipitate insoluble in ammonium sulphide is boiled with nitric acid (1 vol. acid sp.gr. 1·20 : 2 vols. H_2O), the residue dissolved in aqua regia, excess of acid expelled, and stannous chloride added; a white precipitate (Hg_2Cl_2) indicates *mercury.* The nitric acid solution is evaporated to a small bulk with sulphuric acid, diluted with cold water and filtered; white residue ($PbSO_4$) indicates *lead.* The filtrate is rendered ammoniacal, blue colour = *copper*; white precipitate ($Bi(HO)_3$) = *bismuth,* confirmed by dissolving in hydrochloric acid and diluting considerably with water (BiOCl). The colour of the filtrate discharged by potassium cyanide (excess); the solution saturated with hydrogen sulphide, a yellow precipitate (CdS) = *cadmium* (confirmation is essential, since a yellow cyanogen derivative may be precipitated at this stage).

Group III. (phosphates absent).—The mixed hydroxides, suspended in water, are warmed with excess of sodium peroxide and filtered. A residue ($Fe_2O_3{\cdot}xH_2O$, which may contain some MnO_2) indicates *iron.* The filtrate is divided into two parts, (i.) boiled with excess of ammonium chloride, white gelatinous precipitate ($Al(OH)_3$) = *aluminium*; (ii.) acidified with dilute acetic acid and lead acetate added, yellow precipitate ($PbCrO_4$) = *chromium.*

Group III. (phosphates present).—If the original solution was acid, this group precipitate may contain phosphates insoluble in neutral or alkaline solutions. The sodium peroxide separation is applied to one-third of the precipitate; the remainder is dissolved in dilute hydrochloric acid, the solution nearly neutralised with pure sodium carbonate, and treated successively with ammonium acetate, acetic acid, and ferric chloride until no further precipitate is produced and the solution is deep red. The mixture is boiled and filtered hot; the filtrate is then examined for the metals of Groups IV. and V., and for magnesium. The precipitate, which is neglected, contains ferric phosphate and basic ferric acetate. Ammonium formate may be used instead of acetate in this separation (Tower, J. Amer. Chem. Soc. 1910, 32, 953).

The phosphoric acid may also be removed by evaporating the filtrate from Group II. to dryness with nitric acid and granulated tin, when an insoluble residue is obtained consisting of metastannic and phosphostannic acids.

Group IV.—The mixed sulphides, washed with hydrogen sulphide water, are dissolved in aqua regia, or hydrochloric acid and potassium chlorate. Excess of sodium hydroxide is added to the solution after expelling excess of acid; the precipitate collected and the filtrate treated with hydrogen sulphide; white precipitate (ZnS) = *zinc.* The precipitated hydroxides are dissolved in hydrochloric acid, excess of ammonium acetate added, and the solution saturated with sulphide. Any black precipitate is removed and the filtrate rendered ammoniacal; pink precipitate (MnS) = *manganese.*

The black precipitate is tested in the borax bead; a brownish-yellow colour indicates *nickel* present and cobalt absent. If the bead is blue (= *cobalt*), the precipitate is dissolved in hydrochloric acid, potassium chlorate added, excess of acid expelled, and the solution *nearly* neutralised with sodium carbonate; excess of potassium cyanide is then added, and the solution boiled in an open dish. An excess of sodium hypochlorite or freshly prepared sodium hypobromite is added to the warm solution; a black precipitate (Ni_2O_3,xH_2O) = *nickel*;

the filtrate contains potassium cobalticyanide ($K_3Co(CN)_6$).

A quicker separation of the Group IV. sulphides may be effected by digesting them with cold dilute hydrochloric acid (1 : 20). This treatment should bring the zinc and manganese into solution, leaving the sulphides of nickel and cobalt undissolved; but it is generally found that appreciable quantities of the latter metals are present in the filtrate. Alternative methods of detecting and separating nickel and cobalt are given under special reactions.

Group V.—Dissolve the washed precipitate in dilute acetic acid, add aqueous potassium chromate; yellow precipitate ($BaCrO_4$) = *barium*: filtrate boiled with concentrated aqueous ammonium sulphate; white precipitate ($SrSO_4$) = *strontium*: final filtrate treated with ammonium oxalate; white precipitate (CaC_2O_4,xH_2O) = *calcium*. Owing to their close relationship, a sharp separation of the three metals is extremely difficult. The following alternative process has been worked out (*v.* Bray, J. Amer. Chem. Soc. 1909, 31, 611).

The group precipitate, which may contain magnesium, is dissolved in 20 c.c. of 30 p.c. acetic acid, solution neutralised with ammonia, 3 c.c. of acetic acid added, diluted to 40 c.c., 10 c.c. of 20 p.c. potassium chromate slowly added, solution boiled for 2 minutes; yellow precipitate ($BaCrO_4$). Three c.c. of ammonia added to filtrate, diluted to 60 c.c., 50 c.c. of alcohol (95 p.c.) added; after 10 minutes yellow precipitate ($SrCrO_4$). Without washing this precipitate, 200 c.c. of water are added to filtrate, the solution boiled, and 40 c.c. of 4 p.c. ammonium oxalate added; after 10 minutes white precipitate (CaC_2O_4). *Magnesium* is precipitated in filtrate as a colourless crystalline precipitate ($Mg(NH_4)PO_4,6H_2O$) by adding ammonia and sodium phosphate.

Group VI.—A portion of the filtrate from V. examined for *magnesium* (*v. supra*), the remainder evaporated to dryness and ignited to expel ammonium salts. The residue dissolved in a small bulk of water, the solution filtered if necessary, examined by flame test and divided into two parts, (i.) platinic chloride added; yellow crystalline precipitate (K_2PtCl_6) = *potassium*; (ii.) potassium pyroantimonate added; colourless crystalline precipitate ($Na_2H_2Sb_2O_7,6H_2O$) = *sodium*.

Group Separation in the Presence of the Rarer Metals.

In the presence of the less commonly occurring elements, the ordinary group separations require, in certain instances, to be modified very considerably. A systematic attempt to deal with this problem has recently been made by A. A. Noyes and his collaborators, to whose original memoirs reference should be made for the exact working details of the necessarily somewhat complicated separations, an outline of which is given below (J. Amer. Chem. Soc. 1907, 29, 137; 1908, 30, 481; 1909, 31, 611).

It will be seen that the greater number of the rarer elements are precipitated by the reagents of Groups II., III., and IV. of the foregoing analytical classification; but in the scheme devised by Noyes, Groups III. and IV. are merged into one, and it is chiefly in this comprehensive group that the additional complications are to be found.

Group I.—The precipitate may contain *thallous chloride* and *tungstic acid*. The former is extracted by hot water, any lead separated as sulphate, when the filtrate treated with potassium iodide gives a yellow precipitate (TlI) = *thallium*. The hydrated tungstic acid, precipitated by hydrochloric acid from alkali tungstates, remains in the residue, and may be separated from lead and silver by fusion with sodium carbonate. The aqueous solution of alkali tungstate is boiled with zinc and hydrochloric acid, when the development of a blue colouration = *tungsten*.

Group II.—Selenium, tellurium, molybdenum, gold, platinum and its allies, are precipitated by hydrogen sulphide in acid solution. Extraction of the group precipitate with yellow ammonium sulphide carries the greater part of these elements into the tin sub-group, but the separation is not quite sharp, for small but appreciable quantities of molybdenum, gold and the platinum metals remain in the insoluble sulphides of the copper sub-group.

A. *Copper sub-group.*—The precipitate boiled with dilute nitric acid (1 vol. of sp.gr. 1·20 : 2 vols. water) partially dissolves; the solution contains lead, copper, cadmium, and bismuth, while the residue contains mercury, gold, platinum, and a trace of tin. The insoluble portion is oxidised with bromine water, potassium chloride and hydrochloric acid are added and the solution concentrated; a yellow crystalline precipitate (K_2PtCl_6) = *platinum*. The excess of acid is expelled from the solution, which is then rendered alkaline and boiled with excess of oxalic acid; a brownish-black precipitate = *gold*.

B. *Tin sub-group.*—The sulphides are reprecipitated by dilute acid from their solution in ammonium sulphide, and digested for 10 minutes with nearly boiling hydrochloric acid (sp.gr. 1·20); the solution contains tin and antimony, and the residue arsenic and the rarer elements. The residue is dissolved by strong hydrochloric acid and potassium chlorate; the solution concentrated to the crystallising point yields a yellow precipitate (K_2PtCl_6)=*platinum*. The filtrate, treated successively with ammonia and magnesia mixture ($MgCl_2,2NH_4Cl$ with $NH_4{\cdot}OH$), yields a colourless crystalline precipitate ($Mg(NH_4)AsO_4,6H_2O$) = *arsenic*. The filtrate from the double arsenate is evaporated to remove ammonia, and then boiled with oxalic acid, and the brownish-black precipitate (*gold*) extracted with hydrochloric acid to dissolve any co-precipitated tellurous acid. The filtrate from the gold is concentrated and acidified with strong hydrochloric acid, and after removing any precipitated potassium chloride, sodium sulphite (in *slight* excess) is added when a red precipitate = *selenium*. The filtrate from selenium is diluted and treated successively with potassium iodide and solid sodium sulphite (excess); the double iodide, K_2TeI_6, becomes reduced, and a black precipitate = *tellurium*. The final filtrate is boiled with hydrochloric acid to expel sulphur dioxide, and to the cooled solution 10 p.c. potassium thiocyanate and stannous chloride (or a scrap of zinc) are successively added, when a red colouration ($MO(CNS)_4$) soluble in ether = *molybdenum*.

GROUPS III. and IV.—The filtrate from Group II. is boiled to expel hydrogen sulphide, treated with moderately strong ammonia, the colour of the precipitate being noted, and the ammoniacal mixture heated nearly to boiling and treated with ammonium sulphide, or preferably, in the presence of nickel, with hydrogen sulphide to saturation. In the presence of vanadium the filtrate has a reddish colour, and on adding hydrochloric acid brown vanadium sulphide is precipitated. The acid filtrate is boiled to expel hydrogen sulphide, and treated with ferric chloride and ammonia to precipitate last traces of vanadium. The presence of this metal in the sulphide and ferric hydroxide precipitates is confirmed by dissolving in nitric acid (sp.gr. 1·20), diluting and adding hydrogen peroxide, when an orange-yellow colouration = *vanadium*.

The group precipitate is dissolved in hydrochloric acid (sp.gr. 1·12), adding, if necessary, some nitric acid or bromine water. The solution is then boiled with hydrochloric acid to remove nitric acid, and treated in a platinum dish with 40 p.c. hydrofluoric acid, and evaporated to dryness. An insoluble residue indicates the fluorides of the rare earth metals (thorium, cerium, yttrium, erbium, &c.); the aqueous extract, which contains all the other metals of this analytical group, is evaporated successively with hydrochloric and nitric acids. The insoluble fluorides are decomposed by hot sulphuric acid, and the resulting sulphates of the rare earth metals subjected to special tests for these elements.

The nitric acid solution of the other metals of the group is treated successively with caustic soda solution, dry sodium peroxide, and aqueous sodium carbonate, when a precipitate B and a filtrate A are obtained. This treatment separates these metals into two sub-groups, and the method is valid even when phosphates are present.

A. *The aluminium sub-group* (may contain sodium glucinate, zincate, aluminate, vanadate, chromate, and peruranate). The solution is acidified with nitric acid (sp.gr. 1·42) and diluted considerably, solid sodium hydrogen carbonate added in moderate excess and the mixture heated in a stoppered bottle. The precipitate (containing zinc, glucinum, and aluminium) is dissolved in hydrochloric acid, and the solution rendered ammoniacal; the zinc remains in solution, while the hydroxides of glucinum and aluminium are precipitated. These hydroxides are dissolved in strong hydrochloric acid, ether (1·5 vols.) is added, and the cooled solution saturated with hydrogen chloride, white crystalline precipitate ($AlCl_3,6H_2O$) = *aluminium*. The ethereal filtrate is evaporated, treated with ammonia, any precipitate dissolved in 10 p.c. sodium hydrogen carbonate, the solution saturated with hydrogen sulphide; the filtrate from any precipitated sulphide is acidified, boiled, and rendered ammoniacal, when a white flocculent precipitate ($Gl(OH)_2$) = *glucinum*.

The filtrate obtained from the first treatment with sodium hydrogen carbonate is acidified with nitric acid, and just neutralised with caustic soda; 2 c.c. of nitric acid (sp.gr. 1·20 and 20 c.c. of 20 p.c. lead nitrate are added; yellow precipitate = *chromium*. The lead is removed with hydrogen sulphide, the excess of gas boiled off, vanadyl salts oxidised to vanadates with bromine, any excess of this reagent being removed by boiling. The solution, after neutralisation with ammonia, is treated successively with 5 c.c. of 30 p.c. acetic acid, 2 grams of ammonium sulphate (or nitrate), and 2 grams of sodium phosphate; the mixture is heated to boiling, when a white precipitate ($UO_2(NH_4)PO_4$) = *uranium*. The final filtrate is rendered ammoniacal, saturated with hydrogen sulphide, acidified with acetic acid, and boiled; dark precipitate = *vanadium*.

B. *The iron-manganese sub-group* (may contain the hydroxides and phosphates of iron, manganese, cobalt, nickel, zinc (traces), titanium, and zirconium, together with calcium, strontium, barium, and magnesium, as carbonates and phosphates). The precipitated hydroxides, &c., are dissolved in hydrochloric acid, the solution evaporated down with strong nitric acid, and treated with 0·5 gram of solid potassium chlorate; brown precipitate = *manganese*. A portion of the filtrate tested for phosphoric acid, when, if present, the remainder is treated with ammonium hydroxide till nearly alkaline, and boiled with ferric chloride and ammonium acetate. The filtrate contains the ordinary metals of Groups III. and IV., together with magnesium; the precipitate consists of the hydroxides, phosphates, and basic acetates of iron, zirconium, titanium, and possibly thallium (tervalent). This precipitate is dissolved in hydrochloric acid (sp.gr. 1·12), and the solution shaken with an equal volume of ether. The ethereal extract contains ferric and thallic chlorides; the hydrochloric acid solution the zirconium and titanium. The latter is evaporated down with sulphuric acid until the hydrogen chloride is expelled, the residue taken up with water and treated with hydrogen peroxide and subsequently with sodium phosphate; orange-yellow colouration (TiO_3) = *titanium*; white flocculent precipitate ($Zr(OH){\cdot}PO_4$) = *zirconium*. The final filtrate is reduced with sulphurous acid, when a white flocculent precipitate ($Ti(OH){\cdot}PO_4$) confirms *titanium*.

GROUPS V. and VI.—In the presence of lithium it is preferable to precipitate magnesium in the calcium group. The filtrate from Groups III. and IV. is concentrated to 10 c.c. and treated with 30 c.c. of 20 p.c. ammonium carbonate and 30 c.c. of 95 p.c. alcohol. After 30 minutes the precipitation is complete, the magnesium being present as the double carbonate ($MgCO_3,(NH_4)_2CO_3,4H_2O$). The treatment of the group precipitate has already been described under Group V. (*v. supra*). The filtrate is evaporated to dryness and ignited. The residue is taken up with 10 c.c. of water, and one-third tested for lithium by adding 0·5 c.c. of 10 p.c. caustic soda and 2 c.c. of 10 p.c. sodium phosphate, heating to boiling and adding 1 c.c. of alcohol, white precipitate (Li_3PO_4) = *lithium*. The filtrate from this phosphate is tested for potassium by adding acetic acid and sodium cobaltinitrite. The remaining two-thirds of the solution, containing the alkali metals, are tested for sodium by potassium pyroantimonate after removing the lithium as fluoride by ammonia and ammonium fluoride.

Examination for Acids.

Although it is not possible to separate the acidic radicals into a limited number of groups, each having a group reagent, yet the reactions may be divided into (i.) preliminary tests made on the original solution or substance; and (ii.) systematic tests made on suitably prepared solutions. The reactions may be conveniently carried out in the following order:—

I. *Preliminary tests* (compare dry reactions).

1. The original substance or solution is warmed with dilute hydrochloric or sulphuric acid. A gas is evolved, carbon dioxide, turning lime water milky = *carbonate*; sulphur dioxide = *sulphite*; hydrogen sulphide, blackening lead acetate paper = *sulphide* (not all); nitrous fumes = *nitrite*; hydrogen cyanide, odour of bitter almonds = *cyanide*.

2. The original substance or solution warmed slowly with strong solution of sodium dichromate slightly acidified, carbon dioxide evolved, confirms *carbonate* in presence of sulphite.

3. *Heating with concentrated sulphuric acid.*—The foregoing gases may be evolved, and in addition the following:—

(*a*) *Colourless*:

Fuming acid gas etching glass = *fluoride*; fuming acid gas not etching = *chloride*; odour of vinegar = *acetate*; carbon monoxide, blue flame = *formate, ferrocyanide*; carbon monoxide and dioxide = *oxalate*; sulphur dioxide and sulphur sublimate = *thiosulphate*.

(*b*) *Colour*.

Orange vapour, bromine = *bromide*; violet vapour and hydrogen sulphide = *iodide*; nitrous fumes = *nitrite, nitrate*; oxides of carbon and sulphur with charring = *tartrate, citrate, malate*; yellow explosive chlorine oxide = *chlorate*.

4. *Heating with alcohol and concentrated sulphuric acid*, green flame = *borate*. Before performing this test chlorates must be decomposed by igniting the original substance, otherwise an explosion may result.

5. *Heating with concentrated sulphuric acid and sand*, a colourless gas (SiF_4), giving a gelatinous precipitate on moist rod, confirms *fluoride*.

II. *Systematic tests.*—Before testing a solution for acids, boil with excess of pure sodium carbonate to remove heavy metals, filter, and carefully neutralise with nitric acid.

1. *Barium chloride* in neutral solution yields: (*a*) a white precipitate, insoluble in hydrochloric acid = *sulphate, silicofluoride*; (*β*) a white precipitate, soluble in hydrochloric acid = *sulphite, carbonate, phosphate, oxalate, borate, fluoride, silicate, tartrate*; (*γ*) a yellow precipitate = *chromate*.

2. To a portion of the neutral solution add *calcium chloride* in excess, allow to stand for some time with occasional shaking, and filter. A white precipitate (*a*) insoluble in acetic acid = *oxalate* (*sulphate* in strong solutions); (*β*) soluble in acetic acid = *phosphate, borate*, and other acids precipitated by barium chloride.

Calcium *tartrate* after washing is soluble in potash, and is re-precipitated on diluting and boiling.

The filtrate from the precipitate in the cold is boiled for some time and filtered hot; a white precipitate = *citrate* (*malate* in strong solutions). The filtrate from this precipitate is allowed to cool and then mixed with excess of alcohol; a white precipitate = *succinate, malate*.

3. *Silver nitrate* in neutral solution yields:

(*a*) A precipitate soluble in nitric acid.

(1) White = *oxalate, borate, tartrate, benzoate*, &c.

(2) Yellow = *phosphate, arsenite*.

(3) Brick-red = *arsenate*.

(4) Dark-red = *chromate*.

(*β*) A precipitate insoluble in nitric acid.

Soluble in ammonia: White = *chloride* (*hypochlorite*), *cyanide, thiocyanate*; yellowish-white = *bromide*; orange-red = *ferricyanide*; white = *ferrocyanide* (sparingly soluble).

Insoluble in ammonia: Yellow = *iodide* black = *sulphide*.

4. *Ferric chloride* in neutral solutions yields:

(*a*) A colouration: blood-red = *acetate, formate* (precipitate on boiling), *thiocyanate* (no precipitate on boiling); violet = *salicylate, thiosulphate* (fugitive); bluish-black = *tannate, gallate*; greenish-brown = *ferricyanide* (dark-blue precipitate on adding stannous chloride).

(*β*) A precipitate: buff = *benzoate, carbonate*; reddish-brown = *succinate*; white = *phosphate*; black = *sulphide*; bluish- or greenish-black = *tannate, gallate*.

Sulphur acids. (1) Detect *sulphate* by barium chloride, and *sulphide* by lead acetate, &c. Make part of the solution slightly alkaline with potash, add zinc sulphate in considerable excess, and filter. Test one part of the filtrate for *thiosulphate* by means of hydrochloric acid; to the other part add acetic acid till *faintly* acid, sodium nitroprusside in small quantity, and potassium ferrocyanide; a pink precipitate indicates a *sulphite*.

(2) Separation of soluble sulphates, sulphites, sulphides, and thiosulphates in neutral solution. Precipitate *sulphide* as CdS, PbS, or ZnS by adding cadmium carbonate or lead carbonate sludge or zinc chloride solution. Add strontium nitrate and leave for 12 hours; the precipitated strontium *sulphate* and *sulphite* separated by hydrochloric acid, the filtrate contains the *thiosulphate*, decomposed by strong hydrochloric acid, giving sulphur and sulphur dioxide (Autenrieth and Windaus, Zeitsch. anal. Chem. 1898, 37, 295).

Chloride, bromide, and iodide. (1) Place the substance in a small flask connected with a small bulb U-tube containing a little starch paste and placed in a beaker of water. Add water and ferric sulphate solution to the substance in the flask, and heat to boiling. If iodine is present, the starch paste becomes blue. Remove the cork, boil with fresh additions of ferric sulphate till all iodine is expelled. Now add a few crystals of potassium permanganate, connect with a bulb tube containing chloroform, and again boil. If bromine is present, the chloroform is coloured brown. Boil with addition of more permanganate until all bromine is expelled, filter and test filtrate for chlorine (Hart, Amer. Chem. J. 1884, 6, 346).

(2) After iodine has been detected by means of nitrogen oxides in sulphuric acid, evaporate part of the solution to dryness with sodium

carbonate, fuse with ten times its weight of potassium dichromate till all iodine is expelled, place in a small dry retort, and heat with strong sulphuric acid. Part of the distillate is agitated with water and carbon disulphide; if bromine is present, the latter becomes orange-red. The remainder of the distillate is neutralised with ammonia, and tested for chromic acid by acidifying with acetic acid and adding lead acetate. The presence of chromic acid indicates the presence of chlorine in the original substance.

(3) A neutral solution of the three halides is treated with potassium iodate and dilute acetic acid; as iodine is liberated, more iodate is added and the solution boiled until all the iodine is eliminated. The solution is mixed with half its volume of $5N$-nitric acid, bromine is evolved and the solution boiled till colourless A little potassium iodide added to destroy the iodate in excess, and the solution boiled till colourless, then an equal volume of strong nitric acid and a few drops of silver nitrate are added, when a white precipitate indicates a chloride: The strong nitric acid holds in solution any trace of silver iodate. If thiocyanic acid is present, the test for iodine must be made in a small portion of the original solution, adding sodium acetate as well as acetic acid to depress the dissociation of the latter (Benedikt and Snell, J. Amer. Chem. Soc. 1903, 25, 809).

Other acids must be detected by special tests. Iodine, and ferrocyanides and ferricyanides must be removed before testing for nitrates.

To remove iodine, ferrocyanic, ferricyanic, and thiocyanic acids, add excess of a mixture of cupric and ferrous sulphates, and filter. To remove excess of copper and iron (which is not always necessary) heat to boiling, add slight excess of *pure* caustic potash or soda, and filter.

To remove bromine and iodine, acidify with dilute sulphuric acid, and boil with successive additions of potassium permanganate until the liquid has a faint permanent pink tinge; filter.

To remove hypochlorous and nitrous acids, acidify with dilute sulphuric acid, and boil. Nitrous acid can also be decomposed by boiling with a strong solution of ammonium chloride.

For an alternative classification of the acidic radicals into analytical groups, compare T. Milobendski (J. Russ. Phys. Chem. Soc. 1909, 41, 1301).

SPECIAL REACTIONS.

In the following lists only the most characteristic and useful reactions have been given; negative reactions, and others not particularly characteristic, have, as a rule, been omitted (*see also* Dry reactions).

METALS.

The metals are arranged in the order of their occurrence in the systematic separation.

Silver.

Hydrochloric acid, a white precipitate (AgCl), insoluble in hot water and in nitric acid; soluble in ammonia and reprecipitated by nitric acid in excess. *Potassium chromate*, a dark-red precipitate (Ag_2CrO_4); soluble in mineral acids and decomposed by caustic alkalis. *Potassium cyanide*, white precipitate (AgCN) soluble in excess to $KAg(CN)_2$.

Lead.

Hydrochloric acid, a white precipitate ($PbCl_2$), soluble in hot water, from which it crystallises on cooling; insoluble in ammonia. *Hydrogen sulphide*, a black precipitate (PbS), insoluble in ammonium sulphide (in presence of hydrogen halides, intermediate red compounds are produced, *e.g.* PbS,4PbI_2, J. Amer. Chem. Soc. 1895, 17, 511; 1901, 23, 680); soluble in nitric acid. *Sulphuric acid*, a white precipitate ($PbSO_4$), soluble in hot hydrochloric acid; insoluble in dilute sulphuric acid; soluble in ammonium acetate (Noyes and Whitcomb, J. Amer. Chem. Soc. 1905, 27, 747). *Potassium chromate*, yellow precipitate ($PbCrO_4$), insoluble in acetic acid; soluble in potassium hydroxide.

Thallium.

Hydrochloric acid, white precipitate (TlCl), only slightly soluble in hot water. *Potassium iodide*, pale-yellow precipitate (TlI), even in dilute solutions. *Sulphuric acid*, no precipitate (diff. from Pb). *Sodium cobaltinitrite* gives red crystalline precipitate ($Tl_3Co(NO_2)_6$) (J. Russ. Phys. Chem. Soc. 1910, 42, 94).

Tungsten.

Hydrochloric acid, a yellowish-white precipitate (H_2WO_4), insoluble in excess of the dilute acid; soluble in the concentrated acid and in tartaric acid; fragments of zinc added to this solution produce a blue colouration. *Stannous chloride*, a yellow precipitate, which becomes blue if mixed with hydrochloric acid and heated. *Ammonium sulphide*, no precipitate with sodium tungstate, but on acidifying, light-brown precipitate (WS_3), insoluble in hydrochloric acids, soluble in ammonium sulphide.

Mercury.

Mercurous compounds. Hydrochloric acid, white precipitate (Hg_2Cl_2), insoluble in hot water; insoluble in ammonia, but blackened (NH_2Hg_2Cl). *Stannous chloride*, grey precipitate (Hg). *Metallic copper*, becomes coated with mercury, which can be sublimed.

Mercuric compounds. Hydrogen sulphide, white precipitate, becoming yellow, red, and then black (HgS); insoluble in ammonium sulphide; appreciably soluble in alkali sulphides ($Hg(SNa)_2$), insoluble in nitric acid; soluble in aqua regia. *Stannous chloride*, white precipitate (Hg_2Cl_2), becoming grey (Hg) with excess of the reagent. *Potassium iodide*, scarlet precipitate (HgI_2), soluble in excess. *Metallic copper*, as mercurous salts. For detection of minute traces of mercury, as in toxicological inquiries by electrolytic and spectroscopic methods, *see* Browning (Chem. Soc. Trans. 1917, 111, 236).

Bismuth.

Hydrogen sulphide, brown precipitate (Bi_2S_3), insoluble in ammonium sulphide; soluble in nitric acid. *Ammonia*, white precipitate ($Bi(HO)_3$), soluble in hydrochloric acid. *Water* in large excess (with previous addition of ammonium chloride if chlorides are absent), white precipitate (BiOCl), soluble in hydrochloric acid; insoluble in tartaric acid. *Reducing agents* (sodium stannite, hypophosphites, hydrosulphites, formaldehyde in alkaline solution) reduce bismuth compounds to elemental bismuth.

Copper.

Hydrogen sulphide, black precipitate (CuS), insoluble in ammonium sulphide and in dilute sulphuric acid; soluble in nitric acid and in potassium cyanide. *Ammonia*, blue precipitate, soluble in excess to dark-blue solution. *Potassium ferrocyanide*, chocolate-brown precipitate, insoluble in dilute acids; in very dilute solutions colouration only; decomposed by sodium hydroxide, yielding blue copper hydroxide.

Cadmium.

Hydrogen sulphide, yellow precipitate (CdS), insoluble in ammonium sulphide and potassium cyanide; soluble in nitric acid and hot dilute sulphuric acid. *Ammonia*, white precipitate (CdH_2O_2), readily soluble in excess. *Caustic potash* or *soda*, white precipitate (CdH_2O_2) insoluble in excess. An ammoniacal solution of ammonium perchlorate precipitates white double perchlorate ($Cd(ClO_4)_2{\cdot}4NH_3$).

Tin.

Stannous compounds. Hydrogen sulphide, dark-brown precipitate (SnS), soluble in yellow but not in colourless ammonium sulphide. *Mercuric chloride*, white precipitate (Hg_2Cl_2), becoming grey (Hg).

Stannic compounds. Hydrogen sulphide, yellow precipitate (SnS_2), soluble in ammonium sulphide; appreciably soluble in ammonium carbonate (Ber. 1894, 27, 2739); soluble in concentrated hydrochloric acid; dissolves in aqueous caustic soda. *Stannic chloride*, boiled with copper becomes stannous chloride. When *zinc* and *platinum* are placed in the solution, no black stain on the platinum; crystals of tin on the zinc.

Antimony.

Hydrogen sulphide, orange precipitate (Sb_2S_3), soluble in ammonium sulphide and in concentrated hydrochloric acid; insoluble in ammonium carbonate. *Water* in excess (with ammonium chloride if chlorides are absent), white precipitate (SbOCl), soluble in hydrochloric acid and in tartaric acid. *Zinc* and *platinum*, a black stain on the platinum (Sb), soluble in nitric acid and in ammonium sulphide.

Arsenic.

Hydrogen sulphide, yellow precipitate, soluble in ammonium sulphide and in ammonium carbonate; insoluble in concentrated hydrochloric acid. *Metallic copper*, boiled with the liquid after acidifying with hydrochloric acid, is covered with a shining grey deposit (As_2Cy_3), which, when heated in a tube, yields a sublimate of arsenious oxide (Reinsch's test) (Clark, Chem. Soc. Trans. 1893, 63, 884, 886). *Nascent hydrogen* produced from zinc and dilute sulphuric acid reduces arsenic compounds to volatile arsine (AsH_3), which decomposes on gently heating, giving an arsenic deposit soluble in aqueous hypochlorites. Antimony compounds under these conditions also give a black deposit (antimony), insoluble in hypochlorites (Marsh's test). Zinc and caustic soda reduce arsenic compounds, liberating arsine, which produces a yellow-to-brown stain on mercuric chloride paper (Gutzeit's test, Chem. Soc. Trans. 1901, 79, 715).

Arsenites. Ammonio-silver nitrate, yellow precipitate (Ag_3AsO_3), soluble in nitric acid and ammonia. *Ammonio-cupric sulphate*, bright-green precipitate ($CuHAsO_3$), turns red by boiling with caustic soda.

Arsenates. Ammonio-silver nitrate, brick-red precipitate (Ag_3AsO_4), soluble in nitric acid and ammonia. *Ammonium chloride, ammonia,* and *magnesium sulphate*, white crystalline precipitate (NH_4MgAsO_4). *Ammonio-cupric sulphate*, pale-blue precipitate, turned black by boiling with caustic soda.

When arsenic acid or arsenates are present, they should be reduced by heating with sulphurous acid or ammonium iodide or hydriodic acid (Bull. Soc. chim. Belg. 1909, 23, 88) before applying hydrogen sulphide or Reinsch's test (Usher and Travers, Chem. Soc. Trans. 1905, 87, 1370).

Platinum.

Hydrogen sulphide, brown precipitate (PtS_2) on heating, soluble in ammonium sulphide. *Ammonium chloride* or *potassium chloride*, yellow crystalline precipitate (M_2PtCl_6), less soluble in presence of alcohol. *Potassium iodide*, in dilute solution red colouration (K_2PtI_6), very delicate test. *Stannous chloride*, in dilute solution, brownish-red colouration, delicate test.

Palladium.

Hydrogen sulphide, black precipitate (PdS), insoluble in ammonium sulphide; soluble in hot hydrochloric acid and in aqua regia. *Potassium iodide*, black precipitate (PdI_2), somewhat soluble in excess. *Mercuric cyanide*, yellowish white, gelatinous precipitate ($PdCy_2$), readily soluble in ammonia. *Ammonium chloride*, no precipitate (diff. from Pt); on addition of chlorine water, orange precipitate ($(NH_4)_2PdCl_6$). *Potassium chloride*, precipitate ($2KCl{\cdot}PdCl_2$) only in very concentrated solutions.

α-Nitroso-β-naphthol dissolved in 50 p.c. acetic acid gives a voluminous red-brown precipitate in solutions containing only as little as 1 part palladium in 1,000,000.

Iridium.

Hydrogen sulphide, decolourisation followed by brown precipitate (Ir_2S_3), soluble in ammonium sulphide. *Caustic potash*, a greenish colouration which, on heating with exposure to air, changes slowly to azure blue (diff. from Pt). *Ammonium chloride* or *potassium chloride*, dark-brown or red precipitate (double chloride), insoluble in a saturated solution of the precipitant. Both salts become olive green with potassium nitrite and other reducing agents, especially in hot solutions. *Strong sulphuric acid* and *ammonium nitrate*, on heating, blue colouration.

Osmium.

Hydrogen sulphide, in acid but not in neutral solution, black precipitate (OsS_4), insoluble in ammonium sulphide. *Nitric acid* on boiling oxidises osmium compounds to osmic tetroxide (OsO_4), characteristic odour and yellow solution in caustic soda.

Ruthenium.

Hydrogen sulphide, blue solution followed by brown precipitate of ruthenium sulphide. *Sodium thiosulphate* in ammoniacal solution to dilute solutions of ruthenium, a purplish-red colouration. *Zinc* reduces $RuCl_3$, giving a blue solution and then precipitating ruthenium.

Rhodium.

Hydrogen sulphide, on warming, black precipitate (Rh_2S_3), insoluble in ammonium sulphide; soluble in boiling nitric acid. *Potassium nitrite*, warmed with sodium rhodium chloride, gives orange-yellow precipitate ($K_3Rh(NO_2)_6$)

Gold.

Hydrogen sulphide, black precipitate (Au_2S_3) in cold, brown precipitate (Au_2S) in hot, solution; soluble in yellow ammonium sulphide. *Oxalic acid* or *ferrous sulphate*, brown or purple precipitate, yellow and lustrous when rubbed. *Stannous* and *stannic chlorides*, purplish precipitate, insoluble in hydrochloric acid. *Hydrogen peroxide*, in very dilute alkaline solution, liberates finely divided gold having a beautiful blue shimmer.

A solution of colourless *m*-phenylenediamine (5 : 1000) gives an immediate violet colouration with a dilute solution of a gold salt.

Molybdenum.

Hydrogen sulphide, brownish-black precipitate (MoS_3) on heating, soluble in ammonium sulphide. *Sodium phosphate*, in presence of nitric acid, yellow precipitate on heating, soluble in ammonia and in excess of the alkaline phosphate. *Potassium thiocyanate* and zinc or stannous chloride, red colouration due to $Mo(CNS)_4$ soluble in ether. *Concentrated sulphuric acid*, when strongly heated with molybdenum compounds, develops a deep-blue colouration. *Phenylhydrazine*, in 50 p.c. acetic acid, red colouration (Ber. 1903, 36, 512).

Hydrogen peroxide, in presence of ammonia gives a cherry-red colouration.

Selenium.

Hydrogen sulphide, yellow precipitate, becoming dark on heating, soluble in ammonium sulphide. *Sulphurous acid*, in presence of hydrochloric acid, a red precipitate, which becomes grey on heating, and is soluble in potassium cyanide. *Stannous chloride* and other reducing agents behave in a similar manner. *Barium chloride*, (i.) white precipitate ($BaSeO_3$), soluble in dilute hydrochloric acid; (ii.) white precipitate ($BaSeO_4$), insoluble in dilute hydrochloric acid; soluble in the strong acid, evolving chlorine. *Concentrated sulphuric acid*, green colouration.

Tellurium.

Hydrogen sulphide, brown precipitate (TeS_2) at once from tellurites, but from tellurates only after boiling with hydrochloric acid. *Potassium iodide*, to tellurite in acid solution, black precipitate (TeI_4). *Reducing agents* ($SnCl_2$,Zn), black precipitate (Te). *Concentrated sulphuric acid*, carmine colouration.

Aluminium.

Ammonia, white gelatinous precipitate (AlH_3O_3), insoluble in excess and in ammonium carbonate; soluble in acids. *Caustic potash* or *soda*, white gelatinous precipitate (Al_3HO_3), soluble in excess; reprecipitated on adding ammonium chloride and heating.

Chromium.

Chromic salts. Ammonia, greenish or purplish precipitate (CrH_3O_3), soluble in acids; insoluble in ammonium carbonate. *Caustic potash* or *soda*, green precipitate (CrH_3O_3), soluble in excess, but reprecipitated on boiling.

Chromates. Hydrogen sulphide in acid solution, reduction to chromic salt with change of colour to green. *Lead acetate*, bright yellow precipitate ($PbCrO_4$), insoluble in acetic acid. *Silver nitrate*, dark-red precipitate (Ag_2CrO_4), soluble in nitric acid.

Iron.

Ferrous salts. Ammonium sulphide, black precipitate (FeS), soluble in acids. *Ammonia* or *caustic potash* or *soda*, white precipitate, rapidly becoming green and then brown. *Potassium ferrocyanide*, white precipitate, gradually becoming dark blue. *Potassium ferricyanide*, dark-blue precipitate ($Fe_3(FeCy_6)_2$). *Potassium thiocyanate*, no reaction.

Ferric salts. Ammonium sulphide, black precipitate ($2FeS + S$, or Fe_2S_3), soluble in acids. *Ammonia* or *caustic potash* or *soda*, reddish-brown precipitate (FeH_3O_3), soluble in acids. *Potassium ferrocyanide*, dark-blue precipitate ($Fe_4(FeCy_6)_3$), insoluble in dilute acids. *Potassium ferricyanide*, no precipitate; greenish-brown colouration. *Potassium thiocyanate*, blood-red colouration; not affected by boiling or by hydrochloric acid.

Thorium.

Ammonia, *caustic soda*, or *potash*, white gelatinous precipitate ($Th(OH)_4$), insoluble in excess. *Ammonium* or *sodium carbonate*, white precipitate, basic carbonate; soluble in excess. *Oxalic acid*, white precipitate ($Th(C_2O_4)_2,2H_2O$), insoluble in excess and insoluble in mineral acids, but soluble in ammonium oxalate. *Potassium fluoride* or *hydrofluoric acid*, white precipitate (ThF_4). *Potassium sulphate*, white crystalline precipitate ($2K_2SO_4,Th(SO_4)_2,2H_2O$).

Cerium.

Ammonia, white precipitate of basic salt, insoluble in excess. *Caustic potash* or *soda*, white precipitate ($Ce(OH)_3$), insoluble in excess; becomes yellow when exposed to air. *Oxalic acid*, white precipitate ($Ce_2(C_2O_4)_3$), insoluble in excess, but soluble in a large quantity of hydrochloric acid. *Potassium sulphate*, white precipitate even in somewhat acid solutions ($CeK_3(SO_4)_3$), insoluble in saturated solution of potassium sulphate. *Hydrogen peroxide*, in ammoniacal solution, orange-brown precipitate.

Glucinum.

Ammonia, white precipitate (GlH_2O_2), insoluble in excess. *Caustic potash* or *soda*, the same precipitate, soluble in excess, but reprecipitated on boiling (diff. from Al). *Ammonium carbonate*, white precipitate, easily soluble in excess (diff. from Al).

Glacial acetic acid dissolves $Gl(OH)_2$ or $GlCO_3$, and the residue, after evaporating to dryness, is the basic acetate ($Gl_4O(CH_3{\cdot}CO_2)_6$), readily soluble in chloroform, ether, acetone, the alcohols, and other organic media; dissolves unchanged in glacial acetic acid; it melts at 283°–284°, and can be sublimed without decomposition. *Sodium hydrogen carbonate*, 10 p.c. dissolves $Gl(OH)_2$; dilution to 1 p.c. causes reprecipitation.

Uranium.

Ammonia, *caustic potash*, or *soda*, yellow precipitate, insoluble in excess, but readily soluble in ammonium carbonate. *Ammonium sulphide*, brown precipitate, readily soluble in ammonium carbonate. *Potassium ferrocyanide*, chocolate-brown precipitate, readily decomposed by alkalis, yielding yellow alkali diuranates.

Titanium.

Ammonia, *caustic potash*, or *soda*, or *ammonium sulphide*, white precipitate (H_2TiO_3), insoluble in excess; soluble in dilute sulphuric and hydrochloric acids. *Potassium ferrocyanide*, dark-brown precipitate. *Sodium thiosulphate*, complete precipitation on boiling. *Hydrogen peroxide*, to a slightly acid solution of titanium sulphate; orange-red colouration; weakened by fluorides. A solution of thymol in acetic acid mixed with sulphuric acid gives a more intense colouration, also bleached by fluorides. *Reduc-*

ing agents ($SnCl_2$ or Zn and HCl) produce a violet colouration ($TiCl_3$).

Catechol added to dilute solutions of titanic or titanous salts, yellowish-orange colouration, very delicate test, but interfered with by mineral acids or alkalis (Ber. 1909, 42, 4341).

Zirconium.

Ammonia, ammonium sulphide, caustic soda, white gelatinous precipitate, dissolving in dilute acid, but less readily after boiling; precipitation prevented by tartaric acid. *Oxalic acid*, white precipitate ($Zr(C_2O_4)_2$), readily soluble in ammonium oxalate or in excess of oxalic acid. *Hydrogen peroxide*, white milky precipitate (Zr_2O_5), evolving chlorine when boiled with hydrochloric acid. *Turmeric paper*, moistened with acid solution of zirconium salt, becomes reddish-brown on drying.

Zinc.

Ammonium sulphide, white precipitate (ZnS), soluble in dilute hydrochloric acid; insoluble in acetic acid and in alkalis. *Caustic potash* or *soda*, white precipitate (ZnH_2O_2), soluble in excess. *Potassium ferrocyanide*, white precipitate, insoluble in dilute hydrochloric acid (Zn_2FeCy_6).

Manganese.

Ammonium sulphide, pink precipitate (MnS), soluble in dilute hydrochloric acid and in acetic acid. *Caustic potash* or *soda*, white precipitate (MnH_2O_2), insoluble in excess, becoming brown on exposure to air. Boiled with dilute *nitric acid* and *lead peroxide* (in absence of chlorine), a purplish crimson solution of permanganic acid.

Nickel.

Ammonium sulphide, black precipitate (NiS), somewhat soluble in excess; insoluble in cold dilute hydrochloric acid; soluble in strong acids. *Caustic potash* or *soda*, pale-green precipitate (NiH_2O_2), insoluble in excess. *Potassium cyanide*, precipitate ($NiCy_2$), soluble in excess, forming $NiCy_2,2KCy$, which is not altered when boiled with exposure to air. This solution, heated with excess of sodium hypochlorite solution, or mixed with bromine in the cold, yields a precipitate of black nickelic hydroxide (NiH_3O_3). *Dimethylglyoxime* ($CH_3·C(NOH)·C(NOH)·CH_3$) (Tschugaeff, Ber. 1905, 38, 2520), added to ammoniacal or acetic acid solution of nickel salts, scarlet precipitate (distinction from cobalt). *Dicyanodiamidine* (H. Grossmann and W. Heilborn, Ber. 1908, 41, 1878) added to ammoniacal solutions of cobalt and nickel salts containing excess of sucrose, yellow crystalline precipitate ($Ni(N_4H_5C_2O)_2,2H_2O$), the presence of cobalt indicated by the reddish-violet colour of the solution.

An alcoholic ammoniacal solution of α-benzildioxime gives an intense red precipitate $C_{28}H_{22}N_4O_4Ni$ (Tschugaeff, Zeitsch. anorg. Chem. 1905, 46, 144; Atack, Analyst, 1913, 316).

Cobalt.

Ammonium sulphide, black precipitate (CoS), insoluble in cold dilute hydrochloric acid; soluble in strong acids. *Caustic potash*, pale-blue precipitate (CoH_2O_2), slightly soluble in excess, forming a blue solution. *Potassium cyanide*, precipitate ($CoCy_2$), soluble in excess, forming $CoCy_2,4KCy$, and when this solution is boiled with exposure to air it is changed to K_3CoCy_6, which is not precipitated by sodium hypochloride or bromine. *Potassium nitrite* to dilute acetic acid solutions, yellow crystalline precipitate ($K_3Co(NO_2)_6$). *Nitroso-β-naphthol* $NO·C_{10}H_6·OH$ (Ilinski and Knorre, Ber. 18, 699) dissolved in dilute acetic acid added to feebly acid solutions of cobalt and nickel, brick-red precipitate ($Co(NO·C_{10}H_6·O)_3$); solution examined for nickel (Chaplin, J. Amer. Chem. Soc. 1907, 29, 1029).

Vanadium.

Ammonium sulphide, dark-brown solution, which when acidified yields a brown precipitate (V_2S_4). *Ammonium chloride*, white precipitate of ammonium meta-vanadate (NH_4VO_3). *Potassium ferrocyanide*, in acid solution, a green precipitate. If a solution of an alkaline vanadate is agitated with *hydrogen peroxide* and *ether*, the solution acquires a deep purplish-red colour, but the ether remains colourless. *Mild reducing agents* (SO_2, H_2S, HBr, alcohol, &c.) reduce vanadates in acid solutions to blue divanadyl salts. *Strong reducing agents* (zinc and aluminium with acids) produce a series of colour changes—blue, green, and violet.

Columbium.

Hydrogen fluoride and *potassium fluoride* produce potassium columbo-fluoride, which when boiled in aqueous solution yields potassium columbium oxyfluoride (K_2CbOF_5,H_2O) (solubility 1 in 12·5 cold water). *Mineral acids*, partial precipitation of columbic acid from alkali columbates: *zinc* and *acid*, blue colouration, turning brown; *potassium ferrocyanide*, greyish-green precipitate.

Tantalum.

Hydrogen fluoride and *potassium fluoride* produce potassium tantalofluoride (K_2TaF_7) (solubility 1 in 154 cold water), separating in colourless needles. *Mineral acids*, white precipitate of tantalic acid. *Potassium ferrocyanide*, reddish-brown precipitate (*v.* Weiss and Landecker, Zeitsch. anorg. Chem. 1909, 64, 65).

Calcium.

Ammonium carbonate, white precipitate ($CaCO_3$), soluble in acids. *Sulphuric acid*, white precipitate only in very concentrated solutions. *Ammonium oxalate*, white precipitate (CaC_2O_4), insoluble in acetic and oxalic acids, but soluble in hydrochloric acid.

Strontium.

Ammonium carbonate, white precipitate, soluble in acids ($SrCO_3$). *Ammonium sulphate*, white precipitate, especially on boiling. *Ammonium oxalate*, white precipitate (SrC_2O_4), soluble in hydrochloric acid; insoluble in acetic acid. *Sulphuric acid* or *calcium sulphate*, white precipitate ($SrSO_4$), forming slowly.

Barium.

Ammonium carbonate, white precipitate ($BaCO_3$), soluble in acids. *Ammonium oxalate*, white precipitate (BaC_2O_4), soluble in hydrochloric acid; insoluble in acetic acid. *Sulphuric acid* or *calcium sulphate*, an immediate white precipitate, insoluble in acids and alkalis. *Potassium chromate*, yellow precipitate ($BaCrO_4$), insoluble in acetic acid.

Magnesium.

Sodium phosphate, in presence of ammonia and ammonium chloride, white precipitate, rapidly becoming crystalline ($NH_4MgPO_4 6H_2O$). Forms slowly in dilute solutions, formation being accelerated by agitation and by rubbing the sides of the beaker with a glass rod; soluble in acids.

Potassium.

Chloroplatinic acid H_2PtCl_6, yellow crystalline precipitate (K_2PtCl_6), somewhat soluble in water, insoluble in alcohol. *Sodium hydrogen tartrate*, in neutral or feebly acid solutions, a white crystalline precipitate ($KHC_4H_4O_6$), forming slowly in dilute solutions. If the solution contains free mineral acids, nearly neutralise with soda and add sodium acetate (*cf.* Winkler, Zeitsch. angew. Chem. 1913, 26, 208; Analyst, 1913, 295).

Sodium cobaltinitrite in acetic acid solution, yellow precipitate ($K_2NaCo(NO_2)_6$). *Sodium 1-amino-β-naphthol-6-sulphonate* (eikonogen) in 5–10 p.c. solutions, crystalline precipitate ($KSO_3{\cdot}C_{10}H_5(NH_2){\cdot}OH$); negative results with ammonium and magnesium salts (Alvarez, Chem. Soc. Abstr. 1905, ii. 355).

Ammonium.

Ammonium salts are readily volatile. *Heated with lime, caustic potash,* or *soda,* ammonia gas is given off, and is recognised by its smell and its action on test paper.

Chloroplatinic acid, yellow crystalline precipitate ($(NH_4)_2PtCl_6$), slightly soluble in water: insoluble in alcohol. *Sodium hydrogen tartrate*, white crystalline precipitate ($NH_4HC_4H_4O_6$), forming slowly in dilute solutions.

Nessler's reagent (K_2HgI_4 and KOH), brownish-red precipitate or colouration (NHg_2I,H_2O), very delicate test. Equally delicate is the blue colouration which is developed when an ammonium compound is treated with a solution of phenol and a hypochlorite (eau de Javel).

Sodium.

Flame colouration, intense yellow.

Although all sodium salts are more or less soluble, some dissolve only sparingly, *e.g.* sodium oxalate and sodium *a*-naphthylamine-8-sulphonate.

Potassium pyroantimonate, white crystalline precipitate ($Na_2H_2Sb_2O_7{\cdot}6H_2O$) (J. Amer. Chem. Soc. 1909, 31, 634); from neutral or slightly alkaline solutions.

Dihydroxytartaric acid, colourless precipitate ($CO_2Na{\cdot}C(OH)_2{\cdot}C(OH)_2\,CO_2Na$) (Fenton, Chem. Soc. Trans. 1895, 67, 48). *Solution of bismuth nitrate in 50 p.c. potassium nitrite containing cæsium nitrite*, yellow crystalline precipitate ($5Bi(NO_2)_3,9CsNO_2,6NaNO_2$); very delicate test, not interfered with by lithium and metals of alkaline earths (Ball, Chem. Soc. Trans. 1909, 95, 2126). Sodium chloride, obtained by slow evaporation of a solution acidified with hydrochloric acid, crystallises in distinct cubes.

Lithium.

Chloroplatinic acid, no precipitate.

Sodium phosphate, in alkaline solution; white precipitate (Li_3PO_4), soluble in hydrochloric acid, not reprecipitated by ammonia except on boiling. Lithium chloride is soluble in ethyl or amyl alcohol, and in pyridine. *Ammonium hydrogen fluoride*, white precipitate (LiF).

Cæsium.

Flame colouration, violet.

Chloroplatinic acid, yellow crystalline precipitate (Cs_2PtCl_6), insoluble in boiling water, *Tartaric acid*, crystalline precipitate, somewhat soluble in water. *Stannic chloride*, white precipitate (Cs_2SnCl_6). *Lead chloride dissolved in chlorine water*, yellow precipitate (Cs_2PbCl_6). Cæsium carbonate is soluble in alcohol (diff. from K, Rb).

Rubidium.

Flame colouration, violet.

Chloroplatinic acid, yellow crystalline precipitate (Rb_2PtCl_6), insoluble in boiling water. *Tartaric acid*, white crystalline precipitate, less soluble than the cæsium compound (Reactions of Cs and Rb, *v.* Wells, Amer. J. Sci. [3] 43, 17 and 46, 186, and 265).

ACID RADICALS.

The acid radicals are arranged partly in the order of the systematic separation and partly with a view to bring together those acids which are commonly associated or which resemble one another in their reactions. In all cases, unless otherwise specified, it is important that the solution should be neutral.

Sulphates.

Barium chloride, white precipitate ($BaSO_4$), insoluble in acids and alkalis.

Sulphites.

Hydrochloric acid, sulphur dioxide evolved, but no sulphur precipitated. *Barium chloride*, white precipitate ($BaSO_3$), soluble in hydrochloric acid. *Iodine solution*, sulphites are converted into sulphates. Neutralise, then *slightly* acidify with acetic acid; add excess of *zinc sulphate*, a small quantity of *sodium nitroprusside* and *potassium ferrocyanide*. The precipitate of zinc ferrocyanide has a pink colour.

Strontium chloride, white precipitate ($SrSO_3$), different from thiosulphate SrS_2O_3, being much more soluble.

Hyposulphites ('hydrosulphites,' *e.g.* $Na_2S_2O_4$, $2H_2O$) owe their technical application to their reducing action on indigotin and its sulphonic acids—the colour is discharged (indigo-white). *Silver nitrate*, black precipitate (Ag). *Mercuric chloride*, black precipitate (Hg). *Copper sulphate*, reddish precipitate (Cu and Cu_2H_2), in very dilute solution, colloidal copper.

Thiosulphates.

Hydrochloric acid, sulphur dioxide evolved and sulphur precipitated. *Silver nitrate*, white precipitate ($Ag_2S_2O_3$), rapidly changing to black (Ag_2S), soluble in excess of alkaline thiosulphate, forming a much more stable solution. With *sodium nitroprusside, zinc sulphate,* and *potassium ferrocyanide*, the precipitate is white. *Iodine solution* converts soluble thiosulphates into tetrathionates, which give no precipitate with barium chloride. *Ferric chloride*, transient violet colouration ($Fe_2(S_2O_3)_3$).

Persulphates (*e.g.* $K_2S_2O_8$).

The dry salts evolve oxygen on heating. *Barium chloride*, no precipitate in the cold, on warming oxygen evolved and $BaSO_4$ precipitated. *Silver nitrate*, black precipitate (silver peroxide). *Other metallic salts* (Pb, Mn, Co, and Ni) yield their hydrated peroxides.

Monopersulphuric acid (*Caro's acid*) $HO{\cdot}SO_2{\cdot}O{\cdot}OH$, produced by adding a persulphate to cold concentrated sulphuric acid, and pouring the mixture on to ice. *Aromatic amines* (*e.g.* $p\text{-}Cl{\cdot}C_6H_4{\cdot}NH_2$) give coloured oxidation products with persulphates and nitroso- compounds (*e.g.* $Cl{\cdot}C_6H_4{\cdot}NO$) with Caro's acid.

Thionic acids (*v.* Chem. Soc. Trans. 1880, 608).

Sulphides.

Hydrochloric acid, in most cases evolution of hydrogen sulphide, especially on heating. *Lead nitrate* or *acetate,* black precipitate (PbS). *Silver nitrate,* black precipitate (Ag_2S), insoluble in ammonia, sodium thiosulphate, and potassium cyanide. *Sodium nitroprusside,* in alkaline solutions an intense but somewhat fugitive violet colouration.

Phosphates.

Barium chloride, white precipitate $Ba_3(PO_4)_2$, soluble in dilute acids. *Calcium chloride,* white precipitate ($Ca_3(PO_4)_2$), soluble in acetic acid. *Silver nitrate,* yellow precipitate (Ag_3PO_4), soluble in nitric acid and in ammonia. *Pyrophosphates* and *metaphosphates* give white precipitates of their silver salts with silver nitrate, but metaphosphates alone, unlike ortho- and pyro-phosphates, coagulate albumin. *Magnesium sulphate,* in presence of ammonium chloride and ammonia, white crystalline precipitate ($NH_4MgPO_4 6H_2O$), soluble in acids. *Ammonium molybdate,* in nitric acid solution, on heating, a yellow precipitate ($((NH_4)_3PO_4 \cdot 12MoO_3)$) soluble in ammonia, and soluble in excess of an alkaline phosphate.

Phosphites.

Barium chloride, white precipitate ($BaHPO_3$), soluble in hydrochloric acid. *Silver nitrate,* precipitate of metallic silver, especially in presence of ammonia, and on heating. *Mercuric chloride,* white precipitate (Hg_2Cl_2), becoming grey (Hg). Heated with *nitric acid,* phosphites are converted into phosphates. Heated alone, phosphites evolve phosphine. *Copper sulphate,* pale blue precipitate.

Hypophosphites.

Heated alone, evolve phosphine. *Barium chloride,* white precipitate only in strong solution ($Ba(H_2PO_2)_2$). *Silver nitrate,* metallic silver precipitated. *Copper sulphate,* brown precipitate, cuprous hydride (Cu_2H_2).

Carbonates.

Hydrochloric acid, effervescence, with evolution of carbonic anhydride, which turns lime water turbid. *Barium chloride,* white precipitate ($BaCO_3$), soluble in acids with effervescence. *Mercuric chloride,* red precipitate (basic carbonate); bicarbonates give only a yellowish opalescence. *Calcium sulphate,* white precipitate, immediately with carbonate, but only after standing with bicarbonate (Leys, J. Pharm. Chim. 1897, (vi.) 6, 441).

Borates.

Barium chloride, white precipitate in not too dilute solutions, soluble in acids. *Silver nitrate,* in strong solution, white precipitate ($AgBO_2$) in dilute solution, dark-grey deposit (Ag_2O).

Mix the solid substance with concentrated sulphuric acid in a small crucible, add alcohol, and ignite; the alcohol flame is green, especially at the edges. Mix the solid substance with three parts potassium hydrogen sulphate and one part powdered fluorspar, and heat on platinum wire in the cold area of the flame; a bright-green colouration (due to BF_3) is observed. *Turmeric paper,* moistened with acid solution of boric acid, becomes reddish brown on drying.

Silicates.

Solutions of silicates heated with acids, ammonium chloride, or ammonium carbonate, deposit silicic acid. Dilute solutions must be evaporated to dryness, and on treating the residue with dilute hydrochloric acid insoluble silica is left.

Most silicates are insoluble in water; some are decomposed by acids; others are only decomposed by fusion with about four times their weight of a mixture of equal parts of sodium and potassium carbonates.

Silicofluorides.

Concentrated sulphuric acid, in leaden or platinum capsule, hydrogen fluoride and silicon fluoride are evolved. *Barium chloride,* colourless crystalline precipitate $BaSiF_6$. Silicofluorides on heating evolve silicon fluoride, leaving residues of metallic fluorides.

Thorium nitrate precipitates hydrofluosilicic acid quantitatively from soluble hydrofluosilicates.

Oxalates.

Barium chloride or *calcium chloride,* white precipitate, insoluble in acetic acid, but soluble in hydrochloric acid.

Acidify with sulphuric acid, and add potassium permanganate; the colour of the latter is rapidly and completely discharged.

Heat the solid substance with concentrated sulphuric acid; carbonic anhydride and carbonic oxide are evolved. The latter burns with a blue flame.

Fluorides.

Barium chloride, white precipitate (BaF_2), soluble in hydrochloric acid. *Silver nitrate,* no precipitate with soluble fluorides. *Concentrated sulphuric acid,* especially when heated, produces hydrogen fluoride, which attacks glass. The substance and acid are placed in a small leaden or platinum crucible, which is covered with a watch-glass protected by a thin coating of wax, part of which has been scratched away so as to expose the glass.

Thorium nitrate added to a solution of an alkali fluoride acidified with acetic or nitric acid gives a gelatinous precipitate of thorium fluoride ThF_4.

Chlorides.

Silver nitrate, a white precipitate (AgCl), insoluble in nitric acid, soluble in ammonia; darkens when exposed to light. *Manganese dioxide* and *sulphuric acid,* evolution of chlorine on heating. *Potassium dichromate* and *strong sulphuric acid,* evolution of chromyl chloride on heating. This forms with ammonia a yellow solution of ammonium chromate.

Bromides.

Silver nitrate, yellowish-white precipitate (AgBr), insoluble in nitric acid; moderately soluble in ammonia; readily soluble in potassium cyanide or sodium thiosulphate. *Manganese dioxide* and *sulphuric acid,* orange vapours of bromine, which turn starch paste orange. *Chlorine water* liberates bromine, which dissolves in ether or carbon disulphide, forming an orange-brown solution. Bromides heated with *potassium dichromate* and *strong sulphuric acid* yield bromine, which forms a colourless solution with ammonia.

Iodides.

Silver nitrate, yellow precipitate (AgI), insoluble in nitric acid or ammonia; soluble in potassium cyanide or sodium thiosulphate. *Manganese dioxide* and *sulphuric acid* yield violet vapours of iodine, which colour starch paste blue. *Chlorine water, bromine water*, or *potassium dichromate in presence of hydrochloric acid*, liberates iodine, which turns starch paste an intense blue. The colour disappears on heating, and reappears on cooling. The liberated iodine may be agitated with carbon disulphide or chloroform, when it yields a violet solution. *Nitrogen oxides in sulphuric acid* likewise liberate iodine, but do not liberate bromine unless added in large excess.

Cyanides.

Silver nitrate, white precipitate (AgCN), insoluble in nitric acid, but soluble in ammonia, sodium thiosulphate, or excess of the alkaline cyanide.

Add ferric chloride and ferrous sulphate; make alkaline with caustic potash or soda, and then acidify with hydrochloric acid. A dark blue precipitate of Prussian blue is formed.

Evaporate the solution with an excess of yellow ammonium sulphide to complete dryness on a water-bath; dissolve in very dilute hydrochloric acid, and add ferric chloride; a blood-red colouration is produced.

Most cyanides evolve hydrocyanic acid, recognisable by the smell, when treated with hydrochloric or sulphuric acid.

Mercuric cyanide cannot be recognised by these tests. It yields cyanogen when heated in a closed tube, and is decomposed when heated with strong sulphuric acid.

Ferrocyanides.

Silver nitrate, white precipitate (Ag_4FeCy_6), insoluble in nitric acid and sparingly soluble in ammonia; soluble in potassium cyanide. *Ferric chloride*, dark-blue precipitate ($Fe_4(FeCy_6)_3$). *Ferrous sulphate*, white precipitate, rapidly becoming blue. *Copper sulphate*, chocolate-brown precipitate (Cu_2FeCy_6), or in very dilute solution a brown colouration.

Ferricyanides.

Silver nitrate, orange precipitate (Ag_3FeCy_6), soluble in ammonia; insoluble in nitric acid. *Ferrous sulphate*, dark-blue precipitate ($Fe_3(FeCy_6)_2$), insoluble in dilute acids; decomposed by alkalis. *Ferric chloride*, a greenish-brown colouration.

Thiocyanates.

Silver nitrate, white precipitate (AgCNS), soluble in ammonia; insoluble in nitric acid. *Ferric chloride*, blood-red colouration, not affected by boiling nor by hydrochloric acid; decolourised by mercuric chloride. *Copper sulphate*, a black precipitate changing to white ($Cu_2(CNS)_2$) on standing or addition of a reducing agent. *Moderately strong sulphuric acid* evolves carbon oxysulphide, which burns to carbon dioxide and sulphur dioxide. *Cobalt chloride* and the solution shaken up with ether and amyl alcohol, azure-blue colouration ($K_2Co(CNS)_4$).

Cyanates.

Cobalt chloride, in aqueous alcoholic solution, blue soluble double salt ($K_2Co(CNO)_4$), decomposed by excess of water.

Nitrates.

Sulphuric acid evolves nitric acid on heating; if metallic copper is added, red-brown nitrogen oxides are given off.

The neutral solution is mixed with ferrous sulphate, and concentrated sulphuric acid is poured down the side of the tube so as to form a layer at the bottom; a dark-brown ring is formed at the junction of the two liquids. Iodine and bromine must be removed before applying this test, and the liquid must be cold. Nitrate in presence of nitrite: destroy nitrite by boiling acetic acid solution with urea or hydrazine sulphate; then add potassium iodide, starch, and a fragment of zinc; then colouration denotes nitrate.

Nitrites.

Silver nitrate, a white precipitate in concentrated solutions.

Mix the solution with potassium iodide and starch and acidify with acetic acid; a deep-blue colouration is produced, owing to the liberation of iodine. Nitrites heated with dilute acids evolve nitrogen oxides. *Metaphenylenediamine hydrochloride*, Bismarck brown colouration.

A dilute solution of *a-naphthylamine* and *sulphanilic acid* acidified with acetic acid; a red colouration of azo- compound (*cf.* Zeitsch. angew. Chem. 1900, 235).

Dimethylaniline hydrochloride, added to an acidulated solution containing nitrous acid, gives a yellow colour depending on the formation of paranitrosodimethylaniline (Miller, Analyst, 1912, 37, 345).

Hypochlorites.

Silver nitrate, a white precipitate of silver chloride. *Lead nitrate*, a white precipitate becoming orange-red, finally brown. *Manganous salts*, a brown precipitate (MnO_2,xH_2O). *Indigo solution*, decolourised even in an alkaline solution.

Chlorates.

Warm a small quantity of the solid with concentrated sulphuric acid; a yellow explosive gas is produced with detonations.

Acidify the solution with sulphuric acid, add indigo solution, and then sulphurous acid or a sulphite drop by drop; the colour of the indigo is discharged.

Perchlorates.

Concentrated sulphuric acid, no explosive gas. *Titanous sulphate*, perchlorates reduced to chlorides.

Bromates.

Silver nitrate, white precipitate, $AgBrO_3$, decomposed by hot hydrochloric acid with evolution of bromine. *Barium chloride*, white precipitate $Ba(BrO_3)_2$. *Sulphurous acid*, bromine liberated.

Iodates.

Silver nitrate, white curdy precipitate ($AgIO_3$), soluble in ammonia; reduced to yellow silver iodide by sulphurous acid. *Barium chloride*, white precipitate ($Ba(IO_3)_2$). *Sulphurous acid*, iodine liberated.

Periodates.

Silver nitrate, yellowish-white, red, or brown precipitate depending on the acidity of the periodate solution. *Barium chloride*, white precipitate. *Manganous sulphate*, red precipitate Mn_2HIO_6, turning brown. *Reducing agents* (H_2SO_3, $Ti_2(SO_4)_3$, Zn, etc.) convert periodates readily into iodides. *Mercuric nitrate*, orange-red precipitate $5HgO,I_2O_7$, different from iodates, which give white $Hg(IO_3)_2$.

Tartrates.

Calcium chloride, in excess, a white precipitate ($CaC_4H_4O_6$), soluble in acids and in potash solution. Complete precipitation requires time, and is promoted by vigorous agitation. *Potassium acetate*, in presence of free acetic acid, a white crystalline precipitate ($KHC_4H_4O_6$), forming slowly in dilute solutions. *Silver nitrate*, a white precipitate, soluble in nitric acid or ammonia. If the washed precipitate is dissolved in the least possible quantity of dilute ammonia, and the solution heated, the test-tube is coated with a mirror of metallic silver. *Ferrous sulphate*, followed by few drops of hydrogen peroxide and excess of caustic soda, bluish-violet colouration.

Citrates.

Calcium chloride, or *lime-water*, in excess in neutral solution, a white precipitate,

$$(Ca_3(C_6H_5O_7)_2)$$

only on boiling. *Potassium salts*, no precipitate. *Cadmium chloride*, gelatinous white precipitate $(Cd(C_6H_5O_7)_2)$, insoluble in hot water; soluble in acetic acid (diff. from tartrates). *Mercuric sulphate* (5 p.c.), following by potassium permanganate, white turbidity, mercuric acetonedicarboxylate (halogens should be absent) (Denigès).

Malates.

Calcium chloride, no precipitate even on boiling, except in strong solutions; precipitate in dilute solutions on adding alcohol. *Lime water*, no precipitate even on boiling. *Silver nitrate*, white precipitate $(Ag_2C_4H_4O_5)$, which becomes grey on boiling. *Lead acetate*, white precipitate $(PbC_4H_4O_5)$, which when washed melts in boiling water.

Succinates.

Barium chloride, or *calcium chloride*, no precipitate except after addition of alcohol. *Ferric chloride*, reddish-brown precipitate $(Fe_2(C_4H_4O_4)_3)$, soluble in acids; decomposed by ammonia.

Benzoates.

Hydrochloric acid, white crystalline precipitate of benzoic acid, slightly soluble in water. *Ferric chloride*, a buff precipitate $(Fe_2(C_4H_7O_5)_6)$, soluble in hydrochloric acid with liberation of benzoic acid; decomposed by ammonia. *Concentrated sulphuric* acid and *alcohol* on heating produce ethyl benzoate, distinctive odour. *Soda lime*: benzoates heated with this reagent are decomposed, evolving benzene.

Salicylates.

Ferric chloride, intense purple colour; not affected by glycerol; interfered with by alkalis, dilute mineral acids, tartaric, citric, and oxalic acids, and certain other substances such as borax, sodium phosphate, ammonium and sodium acetates. *Silver nitrate*, white precipitate in neutral solutions. *Bromine water*, white precipitate, which with sodium amalgam yields phenol. *Concentrated sulphuric acid* and *methyl alcohol* on heating give methyl salicylate ('oil of winter-green'). *Diazotised aniline* or *sulphanilic acid* gives an orange azo- compound.

Acetates.

Ferric chloride, a dark-red colouration, discharged on boiling, with precipitation of a basic ferric acetate. Also discharged by hydrochloric acid. Heated with *strong sulphuric acid*, acetic acid is evolved. If alcohol is added, ethyl acetate is formed and is recognised by the smell.

Formates.

Silver nitrate, a white precipitate in concentrated solutions; the solution or precipitate rapidly becomes black (Ag), especially on heating. *Ferric chloride*, a red colour, discharged on boiling, with precipitation of basic ferric formate; also discharged by hydrochloric acid.

A solid formate mixed with concentrated sulphuric acid gives off carbonic oxide even in the cold, but no carbonic anhydride.

Gallic acid.

Ferric chloride, in neutral solutions, a bluish-black precipitate or colouration. *Gelatin* or *albumin*, no precipitate. *Potassium cyanide*, red colouration, which disappears on standing, but reappears on agitation in presence of air. *Caustic soda*, green colouration gradually darkening, and with excess becoming brownish-red. *Lime water*, bluish-grey precipitate.

Tannic acid.

Ferric chloride, bluish-green or bluish-black precipitate or colouration. *Gelatin* or *albumin*, yellowish-white precipitate. *Potassium cyanide*, no colouration. *Caustic soda*, reddish-brown colouration gradually darkening. *Lime water*, grey precipitate.

Phenol.

Ferric chloride, violet colouration, destroyed by acids. *Bromine water*, white precipitate (tribromophenol and tribromophenol bromide). *Concentrated sulphuric acid* and a fragment of *sodium nitrite*, on gently warming, greenish blue solution, turned red when poured into water, and changed again to blue by caustic alkali.

Pyrogallol.

Silver nitrate or *Fehling's solution*, readily reduced. *Caustic alkalis*, brown solutions, rapidly darkening owing to absorption of oxygen. *Formaldehyde* and *strong hydrochloric acid*, white precipitate becoming red, and finally purple.

Uric acid.

Alkali urates reduce *silver nitrate*, and when heated with solid caustic soda, ammonia is evolved, and an alkali cyanide is produced. *Nitric acid*: evaporate solution to dryness on water-bath, reddish colouration, rendered violet by ammonia, and turned blue by caustic soda (Murexide test).

Quantitative Analysis.

GRAVIMETRIC METHODS.

A few metals are separated and weighed in the metallic condition, but the majority of metallic and acidic radicals are weighed in the form of one or other of their compounds. In order that a compound may be available for the determination of one of its constituents, it should be of perfectly definite composition and not highly hygroscopic or otherwise liable to alter; it must be insoluble in the liquid in which it is formed, and insoluble in an excess of the reagent; it must be easily freed from impurities, and capable of being brought into the proper condition for weighing without tedious and complicated operations. It is also desirable that the compound should contain only a small proportion of the constituent to be estimated, since the effect of the unavoidable error of experiment is thus minimised. An estimation of chlorine in the form of silver chloride is more accurate than an estimation of silver in the same way, since only one-fourth of the error of experiment represents chlorine, whilst three-fourths represent silver.

A description will first be given of a few typical gravimetric methods; then an alphabetical list of metals and acid radicals, with a summary of methods available in each case;

followed by a series of methods of separation of general applicability. Special methods for the analysis of technical products will be found in the articles dealing with these materials.

GENERAL METHODS OF ESTIMATION.

I *As Sulphides.*

(*a*) *With previous precipitation by hydrogen sulphide.* The solution should be moderately dilute and distinctly acidified with HCl, but any large quantity of this acid must be avoided. Nitric acid and nitrates, which should be absent as far as possible, may be removed by repeated evaporation with strong hydrochloric acid, but this treatment is not admissible if the metals present form volatile chlorides; if present, a much higher degree of dilution is necessary. In most cases precipitation is accelerated and the precipitate rendered more granular by keeping the liquid warm. A current of washed hydrogen sulphide is passed through the solution until it is thoroughly saturated, and the flask is closed and left in a warm place until the precipitate has settled. Molybdenum and the metals of the platinum group are only completely precipitated after prolonged treatment with the gas. The precipitate is protected from air as far as possible during filtration, and the liquid used for washing should contain hydrogen sulphide in order to prevent oxidation.

When arsenic is present, the liquid should be heated with pure sulphurous acid to reduce arsenic acid, and the excess of sulphurous acid expelled before treatment with hydrogen sulphide. In presence of antimony, tartaric acid should be added to prevent co-precipitation of basic antimony chloride.

When copper is precipitated as sulphide in presence of zinc, the copper sulphide should be washed once or twice with dilute hydrochloric acid of sp.gr. 1·05 containing hydrogen sulphide, and then with water also containing the gas.

(*β*) *With previous precipitation by ammonium sulphide.* Add to the warm solution a considerable quantity of ammonium chloride, which is found to promote precipitation and render the precipitate more granular, then ammonia to alkaline reaction, and a slight excess of ammonium sulphide. Close the flask and allow to stand in a warm place until the precipitate has settled. Protect from air as far as possible during filtration, and wash with water containing ammonium chloride and a little ammonium sulphide or hydrogen sulphide.

The precipitated sulphide is treated in one of two ways: it is collected on a weighed filter, dried at a definite temperature and weighed; or heated with sulphur in a current of hydrogen, and then weighed.

In the first case it is essential to ensure the absence of co-precipitated sulphur, and for this purpose the dried precipitate is treated with pure carbon disulphide and again dried, or, in the case of cadmium, mercury, or bismuth, the moist precipitate is treated with a warm concentrated solution of sodium sulphite, again washed, and dried.

When the sulphide is stable at a moderately high temperature and is not reduced by hydrogen, Rose's method is employed. The dry precipitate is separated from the filter, which is then burnt, and the precipitate and filter ash are introduced into a porcelain crucible and mixed with pure finely powdered sulphur. The crucible is provided with a perforated lid, through which passes a porcelain tube connected with a hydrogen apparatus. A current of purified and dried hydrogen is passed into the crucible, which is gradually heated to full redness until excess of sulphur is expelled, allowed to cool in a current of hydrogen, and weighed

Non-volatile sulphides may be collected in a wide Soxhlet tube and dried *in situ* over a ring burner at 300°, while a current of pure dry carbon dioxide is conducted through the tube. This treatment removes both moisture and co-precipitated sulphur (Cahen and Morgan, Analyst, 1909, 34, 3).

II. *As Oxide.*

(*a*) *With previous precipitation as hydroxide.* The solution is mixed with ammonium chloride, heated to boiling, and ammonia added in slight excess. A large excess of ammonia will partially redissolve some of the precipitate, and must be expelled by boiling. The precipitate is washed with hot water.

If ammonia is inadmissible, pure caustic potash or soda is used as the precipitant. Excess of alkali must be avoided, and the precipitate must be very thoroughly washed, since small quantities of alkali are somewhat firmly retained.

In both cases it is better to precipitate in a porcelain or platinum vessel than in glass.

Non-volatile carbon compounds, such as sugar, glycerol, alkaline, tartrates, and citrates, &c., more or less completely prevent precipitation of hydroxides by ammonia or caustic potash, or soda, and hence must first be removed by calcination. Moderately strong nitric acid attacks filter paper, forming soluble products, which prevent the precipitation of metallic hydroxides.

(*β*) *With previous precipitation as carbonate.* The solution is nearly neutralised, heated to boiling, and mixed with a slight excess of sodium carbonate, boiling being continued until all carbon dioxide is expelled. The precipitate is washed with hot water. Ammonium carbonate can be used in some cases, and has the advantage of not introducing a fixed alkali. In these cases the precipitate should be washed with water containing a little ammonia and ammonium carbonate.

The precipitated hydroxide or carbonate is placed in a crucible (with previous separation from the filter paper if the metal is easily reducible), and is gradually heated to full redness, care being taken that no reducing gases from the flame enter the crucible. Oxides of reducible metals must be heated in a porcelain crucible, but in other cases a platinum crucible may be used with advantage. If carbonates (or oxalates) are being converted into oxides, it is important to secure a circulation of air in order to remove carbon monoxide and carbon dioxide as fast as they are given off, and thus accelerate decomposition. This is done by inclining the crucible and placing the lid across the mouth in a slanting position.

III. *As reduced Metals.*

(*a*) In some cases the metal is precipitated as oxide, which is then dried and heated in hydrogen as in Rose's method for sulphides, the reduced metal being cooled in hydrogen and weighed. This method is especially valuable when, as in the case of cobalt, the oxide obstinately retains small quantities of alkali, which, however, can readily be removed from the reduced metal by washing with water.

(β) The other method is to mix the oxide, carbonate, &c., with five or six times its weight of ordinary potassium cyanide, and heat in a capacious porcelain crucible, at first cautiously and afterwards to complete fusion. When reduction is complete, the crucible is allowed to cool, and is tapped occasionally to promote the collection of the reduced metal in a single button. The cyanide is removed by treatment with water, the metal washed, dried, and weighed. Care should be taken that the metallic button does not contain small fragments of porcelain resulting from the corrosion of the crucible.

IV. *As Sulphate.*

Barium, strontium, and lead are precipitated from solutions in the ordinary way, but other metals are converted into sulphate by treatment with the strong acid, the method being only available when a single metal is present in combination with a volatile acid. The highly concentrated solution, or better, the solid substance, is mixed cautiously with concentrated sulphuric acid in a platinum crucible and then gently heated to expel excess of acid, the crucible being inclined and the lid placed in a slanting position across its mouth. A large excess of acid should be avoided, and care must be taken that the temperature is sufficient to expel the excess of free acid but not sufficient to decompose the sulphate. Sulphates of the alkalis and alkaline earths may be heated to redness. Bismuth sulphate and zinc sulphate decompose if heated above 400°; magnesium sulphate is not decomposed at 450°, nor barium or lead sulphate at 500° (G. H. Bailey). A temperature of about 350° is required to expel the last traces of free sulphuric acid. With lead or bismuth sulphate a porcelain vessel must be used.

GRAVIMETRIC DETERMINATION OF METALS AND ACID RADICALS.

Details of operations will be found under *General Methods of Estimation*, and electrolytic and volumetric methods will be indicated under appropriate headings.

Aluminium.

(*a*) As *oxide*, with previous precipitation with ammonium sulphide, ammonium carbonate, or as basic acetate (*v. Methods of separation*). The aluminium hydroxide is maintained in its insoluble hydrogel form by washing with dilute aqueous ammonium nitrate. The hydroxide may also be precipitated in a form suitable for filtration by boiling the solution of the aluminium salt with potassium iodide and potassium iodate (Stock, Ber. 1900, 33, 548; Compt. rend. 1900, 130, 175); or with bromine water (Jakob, Zeitsch. anal. Chem. 1913, 52, 651), when the precipitate is compact and not gelatinous.

(*b*) As *phosphate*. The solution is nearly neutralised, mixed with sodium acetate and a small quantity of acetic acid, heated to boiling, sodium phosphate added in excess, and the precipitate washed with hot water, heated, and weighed as aluminium phosphate ($AlPO_4$).

Ammonium.

(*a*) As *platinichloride* $(NH_4)_2PtCl_6$ (*v. Potassium*). The platinic chloride solution should be added before the liquid is heated, and evaporation should not quite be carried to complete dryness.

(*b*) By distillation (*v.* ACIDIMETRY).

Antimony.

(*a*) As *sulphide* Sb_2S_3. The precipitate is collected (i.) in a weighed Soxhlet tube on an asbestos mat, and dried at 280°–300° in a current of carbon dioxide (Analyst, 1909, 34, 3); or (ii.) in a Gooch crucible and dried in an air-oven in an atmosphere of carbon dioxide. An aliquot part is then placed in a porcelain boat, and heated in a glass tube in a current of dry carbon dioxide until it becomes black, and all admixed sulphur is expelled. The loss of weight is calculated to the whole quantity and deducted from the weight at 100°.

(*b*) As *oxide* Sb_2O_4, with previous precipitation as sulphide. The sulphide is placed in a porcelain crucible and treated with fuming nitric acid boiling at 86° until completely oxidised, the excess of acid expelled, and the residue heated with partial exposure to air until the weight is constant. The sulphide may also be mixed with 30 to 50 times its weight of precipitated mercuric oxide and heated cautiously until of constant weight. A deep capacious crucible with a lid having a side tube for the exit of vapours has been devised for this and similar estimations.

For a method of estimating small quantities of antimony, as in urine, *see* Schidrowitz and Goldsbrough (Analyst, 1911, 36, 101); Beam and Freak (*idem.* 1919, 44, 196).

Arsenic.

(*a*) As *trisulphide* As_2S_3, which is dried at 100°. The dry precipitate should volatilise completely when heated.

(*b*) As *pentasulphide* As_2S_5. The arsenic is oxidised to arsenic acid by chlorine in alkaline solution, and the precipitation then effected in warm acid solution after decomposing all the chlorate (Brauner and Tomicek, Monatsh. 1887, 8, 642; and Neher, Zeitsch. anal. Chem. 1893, 32, 45).

(*c*) Arsenic acid is estimated as *magnesium pyroarsenate* $Mg_2As_2O_7$, in the same way as phosphoric acid (*which see*). The filter paper is moistened with a solution of ammonium nitrate and dried before burning, in order to prevent reduction (*v.* Ducru, Compt. rend. 1900, 131, 886; *cf. also* Friedheim and Michaelis, Zeitsch. anal. Chem. 1895, 34, 505).

Or the ammonium magnesium arsenate precipitate after washing with dilute ammonia, then with alcohol to remove free ammonia, is titrated with N/2-acid, using methyl-orange as indicator. Each c.c. of N/2-acid is equivalent to 0·01875 gram of arsenic.

Barium.

(*a*) As *sulphate* $BaSO_4$, by precipitation with sulphuric acid (*v. Sulphuric acid*).

(*b*) As *carbonate* $BaCO_3$, which may be dried at a temperature below dull redness after moistening the filter ash with ammonium carbonate (*v. General Methods of Estimation*).

(*c*) As *silicofluoride* (*v. Methods of Separation*).

(*d*) As *bromide* (Thorne, Zeitsch. anal. Chem. 1905, 43, 308).

Bismuth.

(*a*) As *oxide* Bi_2O_3, after precipitation with a slight excess of ammonium carbonate. In presence of chlorides or sulphates the precipitate will contain basic chloride or sulphate, and in this (or in any other) case the bismuth may be precipitated as sulphide, which is oxidised in the crucible by fuming nitric acid boiling at 86°, and then heated.

(*b*) As *sulphide* Bi_2S_3, which is dried at 100° and weighed at intervals of 20-30 minutes. The weight first decreases owing to loss of water, and then increases owing to oxidation; the minimum weight is taken as correct.

(*c*) As *metallic bismuth*. Bismuth is precipitated as metal by adding to slightly acid solutions of its salts, formaldehyde and excess of caustic soda, boiling and filtering through a Gooch crucible, the precipitate being washed with alcohol and dried at 105° (Vanino and Treubert, Ber. 1898, 31, 1303).

(*d*) Other methods: *phosphate* (Stahler and Scharfenberg, Ber. 1905, 38, 3862), *double molybdate* $(Bi(NH_4)(MoO_4)_2$ (Miller and Cruser, J. Amer. Chem. Soc. 1905, 27, 16); and benzildioxime (Atack) (*cf.* Strebinger, Chem. Zeit. 1918, 42, 242).

Cadmium.

(*a*) As *sulphide* CdS, which is dried at 100°, or dissolved in hydrochloric acid, and the solution evaporated to dryness with sulphuric acid, the residue gently ignited and weighed as $CdSO_4$.

(*b*) As *oxide*, after precipitating as basic carbonate from boiling solutions by potassium (not sodium) carbonate and collecting in a Gooch crucible (Amer. J. Sci. 1906, 20, 456).

Calcium.

(*a*) As *oxide* CaO, after precipitation with ammonium carbonate or ammonium oxalate (*v.* Utz, Oest. Chem. Zeit. 1904, 7, 510). In the latter case the solution is made alkaline with ammonia, heated to boiling, and mixed with excess of ammonium oxalate. The precipitate is washed with hot water, and strongly heated until its weight is constant.

(*b*) As *sulphate* $CaSO_4$, by igniting the carbonate or oxalate with pure sulphuric acid; or by heating it with a mixture of ammmonium sulphate and chloride (Willis and Macintire, Analyst, 1918, 102).

Cerium. *V.* Brinton and James, J. Amer. Chem. Soc. 1919, 41, 1080.

Chromium (in chromic salts).

(*a*) As *oxide* Cr_2O_3, after precipitation by ammonia, or better, ammonium sulphide; or by potassium iodide and iodate (Stock and Massaciu, Ber. .1901, 34, 467). When precipitated as chromic hydroxide and weighed after ignition as chromic oxide, care should be taken to avoid oxidation. Ignition in a Rose crucible in a current of hydrogen gives exact results.

(*b*) As *phosphate*, in the same way as aluminium.

Chromium (in chromic acid and chromates).

(*a*) As *oxide* Cr_2O_3. The solution is neutralised, heated to boiling, and mixed with excess of a neutral solution of mercurous nitrate free from nitrous acid. The precipitate is washed with hot water containing mercurous nitrate, and heated to redness in a porcelain crucible until all mercurial vapours are expelled. The mercurous chromate yields chromic oxide.

(*b*) As *chromate*, by precipitation with barium chloride in acetic acid solution (*cf.* Winkler, Zeitsch. angew. Chem. 1918, 31, 46).

Cobalt.

(*a*) As *metallic cobalt*, after precipitation as cobaltic hydroxide by caustic soda or potash with bromine. The solution must be free from ammonium salts, or all ammonia must be expelled by boiling. The precipitate retains traces of alkali, and in accurate estimations the reduced metal should be washed with water, dried, and again heated in hydrogen.

(*b*) As *sulphate* $CoSO_4$, after precipitation as sulphide, which is treated with nitric acid and then with sulphuric acid. If the heated sulphate is at all black, it must be treated again with sulphuric acid.

Copper.

(*a*) As *cuprous sulphide* Cu_2S, using Rose's method, with previous precipitation as cupric sulphide by hydrogen sulphide or sodium thiosulphate (Chem. Zeit. 1895, 19, 1591).

(*b*) As *oxide*, after precipitation by caustic potash or soda in absence of ammonium salts.

(*c*) As *cuprous thiocyanate* CuCNS (Rivot, Compt. rend. 1854, 38, 868; also Amer. J. Sci. 1902, 13, 20 and 138). The warm solution, which must contain no free nitric acid, is slightly acidified with hydrochloric acid, and mixed gradually with an excess of a moderately strong solution of equal parts of ammonium or potassium thiocyanate and ammonium hydrogen sulphite. When cold, the precipitate is collected in a weighed Gooch crucible, washed with cold water and 20 p.c. alcohol, and dried at 110°–120°. The precipitate may also be converted into cuprous sulphide by Rose's method. Cuprous thiocyanate is not quite insoluble, especially in presence of much free acid.

Copper salts are reduced by hypophosphorous acid, or alkaline hypophosphites on warming, and the reduced copper may be washed, dried, and weighed (Dallimore, Windisch).

Glucinum.

As *oxide* GlO, with previous precipitation in the cold by slight excess of ammonia or ammonium sulphide in presence of ammonium chloride, but not caustic soda or potash, or ammonium carbonate. The *basic acetate of glucinum* $[GlO_4(CH_3CO_2)_3]$ is readily soluble in chloroform, and can be distilled unchanged.

Gold.

As *metallic gold*. Nitric acid is removed by evaporation with hydrochloric acid. The solution is acidified with hydrochloric acid, mixed with a large excess of ferrous sulphate solution, and heated gently for a few hours; or it is acidified with sulphuric acid, mixed with oxalic acid, and allowed to stand in a warm place for several hours. Formaldehyde and hydrogen peroxide in alkaline solution can be used as precipitants (Ber 1899, 32, 1968). Nitrous acid is also suggested (Jameson, J. Amer. Chem. Soc. 1905, 27, 1444). The precipitate is collected on a weighed filter, washed and dried.

Iron.

(*a*) As *ferric oxide* Fe_2O_3, after precipitation by ammonia, caustic potash or soda, potassium iodide and iodate (*v. Chromium*), or as basic carbonate, basic acetate or formate. The oxide is heated to redness until its weight is constant; if heated at a higher temperature, it is partially converted into ferroso-ferric oxide Fe_3O_4.

(*b*) Ferrous and ferric salts can be separated and estimated gravimetrically by means of barium carbonate and ammonium chloride, when the ferric salt is decomposed, precipitating ferric hydroxide, and the ferrous salt remains in solution.

Lead.

(*a*) As *sulphate* $PbSO_4$. The solution, which should not be dilute, is mixed with dilute sulphuric acid and twice its volume of alcohol, and allowed to stand, and the precipitate washed with alcohol. If the addition of alcohol is inadmissible, the solution is evaporated with a large excess of dilute sulphuric acid, till fumes are evolved. The residue is taken up with cold water and quickly filtered on a Gooch crucible; and the precipitate is washed with dilute sulphuric acid and afterwards with alcohol to remove all free acid.

(*b*) As *sulphide* PbS, by hydrogen sulphide and Rose's method.

(*c*) As *oxide* PbO, after precipitation by ammonium carbonate, avoiding an excess of ammonium salts.

(*d*) As *metal*.

(*e*) Other methods. As *chromate* and *iodate*.

Magnesium.

(*a*) As *pyrophosphate* $Mg_2P_2O_7$. The solution is mixed with ammonium chloride in sufficient quantity to prevent precipitation by ammonia, made strongly alkaline with ammonia, and then mixed with excess of sodium phosphate, or, better, ammonium phosphate or microcosmic salt. Care should be taken to avoid rubbing or scratching the sides of the vessel. The liquid is allowed to remain for a few hours, filtered, and the precipitate washed with a mixture of strong ammonia (1 part) and water (5 parts) until the washings give only a faint opalescence with silver nitrate after acidifying with nitric acid. The precipitation of the double phosphate is greatly accelerated and a granular non-adherent product obtained by shaking the mixed solutions in a stoppered cylinder. The precipitate is dried, *cautiously* heated in a platinum crucible until all ammonia is expelled, and then heated to redness until the weight is constant. If the precipitate is black, owing to partial reduction, it is moistened with a few drops of strong nitric acid, and again heated until perfectly white.

(*b*) As *oxide* MgO, after precipitation as hydroxide by barium hydroxide, or mercuric oxide, or as double carbonate $MgCO_3(NH_4)_2CO_3$ (Zeitsch. anorg. Chem. 1908, 58, 427), the precipitate being strongly ignited (*v.* Zeitsch. anorg. Chem. 1901, 26, 347).

(*c*) As *pyroarsenate* (*v. Pyrophosphate*, and Amer. J. Sci. 1907, 23, 293).

Manganese.

(*a*) As *sulphide* MnS, by Rose's method after precipitation by ammonium sulphide.

(*b*) As *oxide* Mn_3O_4, after precipitation by sodium carbonate, or ammonium carbonate (Tamm, Zeitsch. anal. Chem. 1872, 11, 425). The hydrated peroxide precipitated by bromine and ammonia, on prolonged ignition yields Mn_3O_4.

(*c*) As *pyrophosphate* $Mn_2P_2O_7$. Ammonium chloride and microcosmic salt are added in considerable excess to the cold manganese solution followed by a slight excess of ammonia. The mixture is then heated till the precipitate becomes silky and crystalline. After cooling for 30 minutes, the precipitate is collected on the Gooch, washed with very dilute ammonia, and ignited (Gooch and Austin, Amer. J. Sci. 1898, 6, 150).

(*d*) As *sulphate* (Gooch and Austin, Amer. J. Sci. 1898, 5, 209).

Mercury (in mercurous compounds).

As *mercurous chloride* Hg_2Cl_2. The dilute cold solution is mixed with a solution of sodium chloride in slight excess, and the precipitate is collected on a weighed filter and dried at 100°.

Mercury (in mercuric compounds).

(*a*) As *sulphide* HgS, which is dried at 100° after precipitation by hydrogen sulphide.

(*b*) As *mercurous chloride* Hg_2Cl_2. The solution is mixed with excess of hydrochloric acid and phosphorous acid (made by allowing phosphorus to oxidise slowly in moist air), and allowed to remain in a warm place for twelve hours. The precipitate is collected on a weighed filter and dried at 100°.

For the estimation of mercury as metal by the dry method, *see* Cumming and Macleod (Chem. Soc. Trans. 1913, 103, 513). For its reduction by zinc filings, *see* Francois (Compt. rend. 1918, 166, 950; Chem. Soc. Abst. 1918, ii. 276).

Molybdenum.

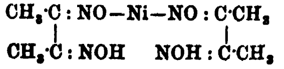
(*a*) As *lead molybdate* $PbMoO_4$. The solution is heated to boiling, mixed with excess of lead acetate, and boiled for a few minutes. The precipitate is washed with hot water, dried at 100°, and heated to low redness in a porcelain crucible.

(*b*) As the *oxide* MoO_3. The solution is neutralised with nitric acid, mixed with excess of a neutral solution of mercurous nitrate, the precipitate washed with mercurous nitrate solution, dried, and heated until the weight is constant. The metal is precipitated as sulphide either in acid solution, or an ammoniacal solution is saturated with hydrogen sulphide and then acidified. The precipitate, collected in a Gooch crucible, is roasted to oxide. The temperature during ignition should not exceed 425°. The conversion of the sulphide into trioxide is complete at 400°; no further change takes place between 400° and 450°, but above 450° the trioxide sublimes. The correct temperature (400°-425°) is most readily attained by using an electric furnace (Wolf, Zeitsch. angew. Chem. 1918, 31, i. 140). Molybdenite is roasted to form trioxide; this is extracted with ammonia, and the filtrate evaporated and residue ignited (Analyst, 1906, 31, 312).

Nickel.

(*a*) As *oxide* NiO, after precipitation as nickelic hydroxide ($Ni(OH)_3$) by caustic potash or soda with the addition of bromine in absence of ammonium salts; or after precipitation by ammonium sulphide thoroughly saturated with hydrogen sulphide, the nickel sulphide being dissolved in aqua regia and the solution precipitated by caustic soda or potash.

(*b*) As *dimethylglyoximate*



$$\begin{array}{l} CH_3{\cdot}C : NO-Ni-NO : C{\cdot}CH_3 \\ \qquad\ | \qquad\qquad\qquad\qquad\quad | \\ CH_3{\cdot}C : NOH \quad NOH : C{\cdot}CH_3 \end{array}$$

(Ni = 20·31 p.c.). A 1 p.c. alcoholic solution of dimethylglyoxime (J. pr. Chem. 1908, 77, 44) is added to a hot dilute hydrochloric acid solution of nickel followed by ammonia in slight excess. The red precipitate, after standing for about an hour, is collected on a Gooch crucible, washed with hot water and dried at 110°–120° (Brünck, Zeitsch. angew. Chem. 1907, 20, 834; *ibid.* 1914, 27, 315).

(*c*) As *nickel dicyanodiamidine* $Ni(N_4H_6C_2O)_2$. Dicyanodiamidine sulphate and caustic alkali are added to an ammoniacal solution of nickel salt, the yellow precipitate collected and dried at 115°. If cobalt is present, hydrogen peroxide is first added to the ammoniacal solution. Aluminium and iron are kept in solution by means of tartaric acid (Grossmann and Schück, Chem. Zeit. 1907, 31, 335, 911).

(*d*) Small quantities of nickel may conveniently be estimated by means of *a-benzildioxime*. For details, *see* Atack (Analyst, 1913, 318). The method is available in presence of cobalt, iron, manganese, zinc, magnesium, and chromium (*cf.* Strebinger, Analyst, 1918, 361).

Platinum.

As *metal*. The solution of platinic chloride free from excess of acid is precipitated by ammonia, or, better, potassium chloride (*v. Potassium*), and the precipitate is filtered by Gooch's method or through a plug of thoroughly dried asbestos contained in a weighed tube The precipitate is dried, heated to redness in a current of hydrogen, washed with water to remove alkaline chloride, again dried, and weighed. The metal is also precipitated by reducing agents (*e.g.* formic acid, alcohol in alkaline solution); and by metals such as magnesium or zinc (Chem. Zeit. 1905, 29, 293).

Potassium.

(*a*) As *platinichloride* K_2PtCl_6. The solution, which must contain the potassium in the form of chloride and be free from acid, is mixed with excess of platinic chloride and evaporated to dryness on the water-bath. The crystalline residue is washed with strong alcohol, without breaking the crystals, until the washings (which at first must be orange, showing the presence of excess of platinum) are colourless. The precipitate is left in the evaporating dish, and the washings are poured through a small filter. When washing is complete, the precipitate is transferred to a weighed porcelain crucible by means of a jet of alcohol from a wash-bottle, and the alcohol is decanted off through the filter. The precipitate in the crucible is dried first at 70° till most of the alcohol is expelled, and then at 100° for half an hour. The filter is dried, and any precipitate is detached from the paper as far as possible and added to the contents of the crucible, which is then weighed. The filter is burnt, and the ash allowed to fall into the crucible, which is again weighed. The increase in weight is filter ash and metallic platinum. The amount of platinichloride corresponding with the latter is calculated and added to the weight of the precipitate (*v.* J. Amer. Chem. Soc. 1895, 17, 453; and Zeitsch. anal. Chem. 1906, 45, 315; Chem. Zeit. 1906, 30, 684). Or the precipitate of platinichloride is collected, washed with alcohol-ether water mixture, then dissolved in boiling water, and the solution boiled with an excess of sodium formate; after a few minutes hydrochloric acid is added, the heating continued until the reduced platinum has flocculated, when the platinum is collected, washed, ignited, and weighed (Steel, Analyst, 1918, 43, 348).

(*b*) As *perchlorate* $KClO_4$. The solution containing potassium and sodium as chlorides is evaporated down with excess of dilute perchloric acid until all the hydrogen chloride is expelled. The residue is taken up with alcohol, the precipitate collected on a Gooch crucible, washed with alcohol, and dried at 130° (Amer. J. Sci. 1897, 2, 263; *cf.* Davis, Analyst, 1913, 38, 47; Thin and Cumming, Trans. Chem. Soc. 1915, 107, 361; Baxter and Kobayashi, J. Amer. Chem. Soc. 1917, 39, 249; Gooch and Blake, Amer. J. Sci. 1917, 44).

As *cobaltinitrite*. The solution is evaporated and the residue mixed with 3 c.c. of a 50 p.c. cobaltous chloride solution and 3 c.c. of a 50 p.c. sodium nitrite solution, and, after stirring, mixed with 2 c.c. 50 p.c. acetic acid. After standing the precipitate is collected on a filter, washed, and treated in a beaker with excess of N/50 potassium permanganate, warmed, 15 c.c. sulphuric acid (1 : 1) added, and the excess of permanganate titrated with oxalic acid solution. The precipitate has the formula $K_2CoNa(NO_2)_6$, and according to theory, 1 c.c. of N/50 permanganate = 0·000156 gram K_2O; experiment shows a better factor is 0·000172 (Van der Horn van der Bos, Analyst, 1913, 294; *cf.* Mitscherlich and Fischer, Analyst, 1912, 37, 588; Haff and Schwartz, Analyst, 1917, 372). Bennett (Analyst, 1916, 165) combines the two methods by separating the potassium as the cobaltinitrite and weighing it as perchlorate.

Selenium.

As *selenium*. The solution is strongly acidified with hydrochloric acid, mixed with excess of sulphurous acid or sodium hydrogen sulphite, and boiled for about fifteen minutes. The precipitate is collected on a weighed filter and dried at a temperature below 100°. Solutions of selenium containing hydrochloric acid cannot safely be concentrated by evaporation except in presence of a large quantity of alkaline chlorides, which prevent the volatilisation of the selenium as chloride.

Hypophosphorous acid in alkaline solution, and potassium iodide in acid solution, have also been recommended as reducing agents (Zeitsch. anorg. Chem. 41, 448; and Amer. J. Sci. 1896, [4] 1, 416). For a review of methods for estimating selenium, *see* Zeitsch. anorg. Chem. 1904, 41, 291).

Silver.

As *chloride* AgCl, or *bromide* AgBr. The solution is acidified with nitric acid, heated to boiling, and mixed with a slight excess of sodium chloride or potassium bromide. Estimation as bromide is to be recommended, since silver chloride is not quite insoluble in pure water. The precipitate is washed with hot water, dried, detached from the paper as far as possible, transferred to a porcelain crucible, and dried at 150°, or heated slowly until it shows signs of fusion at the edges, and weighed. The filter is burnt and the ash added to the crucible, which is again weighed. The increase in weight is filter ash and metallic silver. The quantity of bromide or chloride corresponding with the latter is calculated and added to the weight of the precipitate.

Sodium is weighed in the form of chloride together with any potassium which may be present, and is estimated by difference, or it may be estimated directly as sulphate or chloride if potassium is absent.

The following reagent precipitates sodium even from very dilute solutions, and is not interfered with by the other alkali metals or by magnesium and the metals of the alkaline earths. Three grams of bismuth nitrate and 30 grams of potassium nitrite are dissolved in water containing sufficient nitric acid to remove any turbidity, about 1·6 grams of cæsium nitrate are added, and the solution diluted with water to 100 c.c. The precipitation should be carried out in a stoppered bottle in an inert atmosphere. The precipitate, $5Bi(NO_2)_3,9CsNO_2,6NaNO_2$, contains 3·675 p.c. sodium (*v.* Ball, Chem. Soc. Trans. 1910, 97, 1408).

Strontium.

(*a*) As *sulphate* $SrSO_4$. The solution, which must contain but little free acid, is mixed with excess of dilute sulphuric acid and at least an equal volume of alcohol, and the precipitate is washed with alcohol. If alcohol cannot be used, a much larger excess of sulphuric acid is added and the precipitate is washed with cold water, but the results are less exact.

(*b*) As *carbonate* $SrCO_3$ (which must not be heated too strongly) after precipitation by ammonium carbonate.

According to Winkler (Zeitsch. angew. Chem. 1918, 31, i. 80), the most convenient and exact method of estimating strontium is to precipitate it as *oxalate* by the addition of a 10 c.c. solution of potassium oxalate and washing with saturated strontium oxalate solution. The precipitate is dried at 100°, and weighed as SrC_2O_4,H_2O, or at 132°, and weighed as SrC_2O_4.

Tellurium.

(*a*) As *tellurium*, by reducing solutions of ellurous or telluric compounds with sulphur ioxide and hydrazine hydrochloride (Lenher, . Amer. Chem. Soc. 1908, 30, 387). Other reducing agents have been employed: sulphur dioxide nd potassium iodide, hypophosphorous acid, nd grape sugar in alkaline solution.

(*b*) As *dioxide* TeO_2 (*v.* Amer. J. Sci. 1909, v.) 28, 112).

Thallium.

(*a*) As *thallous iodide* TlI. The solution is eated with sulphurous acid to reduce all the hallium compounds to thallous salts, allowed to ool, and then mixed with excess of potassium odide. The precipitate is washed with dilute lcohol, and dried on a weighed filter at 170° v. Baubigny, Compt. rend. 1892, 113, 544).

(*b*) As *thallous platinichloride*. This salt is ery insoluble, but is difficult to filter (Crookes, elect Methods, 4th ed. p. 172).

Tin.

As *oxide* SnO_2, which is obtained when tin r one of its alloys is treated with nitric acid. The solution is boiled for ten minutes to ensure omplete precipitation, and the precipitate is igested for an hour with dilute nitric acid 1 : 6) at 100° to remove other metals, washed with hot water, and ignited.

In other cases the tin is precipitated as ydrated oxide. If the solution contains stannous alts, the latter are oxidised by chlorine or by ydrochloric acid and potassium chlorate, ammonia added until a slight precipitate forms, nd hydrochloric acid until the precipitate just redissolves. The solution is then mixed with a moderately large quantity of a strong solution of ammonium nitrate or sodium sulphate, and boiled for some time. The precipitate is washed with hot water by decantation and on the filter, dried, and heated. To ascertain if precipitation is complete, a small quantity of the filtrate is added to a hot solution of ammonium nitrate or sodium sulphate.

If the tin has been precipitated as stannic sulphide, the latter is washed with a solution of sodium chloride, and finally with a solution of ammonium acetate, dried, and roasted in a porcelain crucible until the weight is constant. Decomposition is facilitated by adding a small quantity of ammonium carbonate.

In all cases the filter is burnt separately and the ash dropped into the crucible.

Titanium.

As *dioxide* TiO_2, after precipitation by ammonia. Usually the substance is dissolved in sulphuric acid, or is fused with potassium hydrogen sulphate and dissolved in water. The solution is diluted largely and boiled for some time, when all titanium is precipitated as hydrated oxide, which is rendered anhydrous by ignition. The solution should contain 0·5 p.c. of free sulphuric acid; if less, the precipitate is impure, if more, precipitation is incomplete (Lévy). In presence of iron the results are always somewhat too high.

Baskerville recommends fusing titaniferous iron ores with potassium hydrogen sulphate containing some sodium fluoride. The product is boiled with water containing nitric acid and then neutralised with ammonia. The precipitate is dissolved in dilute hydrochloric acid, avoiding any excess. The liquid is then saturated with sulphur dioxide and boiled, the precipitate being collected, ignited, and weighed as TiO_2 (J. Soc. Chem. Ind. 1900, 19, 419; also J. Amer. Chem. Soc. 1903, 25, 1073; and 1910, 32, 957).

Tungsten.

As *tungstic anhydride* WO_3. The solution containing the tungsten as an alkaline tungstate is neutralised with nitric acid and precipitated with a neutral solution of mercurous nitrate. The precipitate is washed with a solution of mercurous nitrate, dried, and heated in a porcelain crucible, when tungstic anhydride is left.

Fused lead tungstate, when boiled with strong hydrochloric acid, gives a precipitate of tungstic acid (Brearley, Chem. News, 1899, 79, 64).

Uranium.

(*a*) As the *oxide* U_3O_8. The solution, oxidised if necessary by nitric acid, is heated to boiling and mixed with a *slight* excess of ammonia. The precipitate of acid ammonium uranate is washed with ammonium chloride solution, dried, and strongly heated.

(*b*) As the *pyrophosphate* $(UO_2)_2P_2O_7$, obtained by precipitating uranyl ammonium phosphate $(UO_2)(NH_4)PO_4$ with ammonium phosphate in the presence of ammonium acetate and igniting the precipitate at low redness. For the application of this process to uranium minerals, see Low's Technical Methods of Ore Analysis, 3rd ed. p. 223; and J. Amer. Chem. Soc. 1901, 23, 685.

Vanadium.

(*a*) As *barium pyrovanadate* $2BaO{\cdot}V_2O_5$. The solution is neutralised with ammonia, heated to boiling, mixed with excess of barium chloride, agitated, and cooled quickly out of contact with air. The precipitate is washed and heated.

(*b*) As *manganese pyrovanadate* $2MnO\cdot V_2O_5$. The solution is mixed with a slight excess of ammonium chloride and ammonia, manganese chloride or sulphate mixed with ammonium chloride is added in excess, and the liquid is boiled two or three minutes and allowed to cool out of contact with the air. The precipitate, which should be brownish yellow and free from oxidation products, is washed with cold water and heated.

(*c*) As *pentoxide* V_2O_5, obtained (i.) by precipitating barium or lead vanadate, decomposing with sulphuric acid, filtering, evaporating the filtrate, and igniting; (ii.) by precipitating and igniting mercury vanadate; (iii.) by precipitating ammonium vanadate by ammonium chloride and igniting the precipitate.

For other methods of estimating and separating vanadium, *v.* A. Carnot, Compt. rend. 104, 1803 and 1850; Chem. Soc. Abstr. 1887, 896; Chem. Zeit. 1905, 29, 392; Amer. J. Sci. 1910, 30, 220.

Zinc.

(*a*) As *oxide* ZnO, with previous precipitation by sodium carbonate in absence of ammonium salts.

(*b*) As *sulphide* ZnS, by Rose's method after precipitating with ammonium sulphide.

The filtration of the zinc sulphide may be promoted by precipitating in the presence of ammonium acetate or thiocyanate, and washing with a 5 p.c. solution of either of these salts. If mercuric chloride is added to the solution, the mixed precipitate of mercuric and zinc sulphides filters much better than the latter alone; the former is expelled on ignition.

Zirconium.

Zirconium is quantitatively precipitated by ammonium phosphate from solutions which are either neutral or contain up to 20 p.c. of sulphuric acid. The precipitate is calcined and weighed as pyrophosphate, the factor for conversion to ZrO_2 being 0·487. The method may be used for the estimation of zirconium in presence of iron, chromium, and aluminium, but an acidity equal to 20 p.c. sulphuric acid is necessary if the first two are present, or 10 p.c. if only aluminium is present, in order to avoid simultaneous precipitation of these metals (Nicolardot and Reglade, Compt. rend. 1919, 168, 348).

ACID RADICALS.

Carbonic acid.

The estimation of carbon in carbonates may be made by a loss in weight method. The carbonate is weighed into an apparatus fitted with a stoppered dropping funnel containing acid to decompose the carbonate, and an exit tube containing strong sulphuric acid to dry the escaping gas. The apparatus is weighed with the acids, &c., after the carbonate has been introduced. The acid is then allowed to drop on the carbonate until the decomposition is complete, and the liquid boiled to expel dissolved carbon dioxide. The apparatus is again weighed and the loss of weight gives the amount of carbon dioxide. The apparatus is figured in most treatises on quantitative analysis. More accurate results are obtained by weighing the carbon dioxide directly by absorbing it in weighed tubes containing soda lime or in bulbs containing aqueous caustic potash. For a complete form of apparatus for this estimation, *see* Thorpe's Quantitative Analysis, 9th ed. p. 86, and Clowes and Coleman's Analysis, 8th ed. p. 104.

When carbonates and sulphides occur together, the gases evolved on treatment with acid are passed into a solution of copper acetate acidified with acetic acid and heated to boiling. Hydrogen sulphide is absorbed, with formation of copper sulphide, and carbon dioxide passes on.

For a convenient apparatus for determining small quantities of carbon dioxide, *see* Sinnatt (Analyst, 1913, 136). As shown by Morgan a solution of phosphoric acid may conveniently replace the hydrochloric or sulphuric acid usually employed (Proc. Chem. Soc. 1904, 20, 167).

For the estimation of carbon dioxide in the presence of nitrites, sulphides, and sulphites, *see* Marle, Chem. Soc. Trans. 1909, 1491; and Wolkowitz, Zeitsch. angew. Chem. 1894, 165.

Chloric acid.

Any chlorine present as chloride is determined, the chlorate reduced by a zinc-copper couple, and the chlorine again determined. The difference is the amount of chlorine existing as chlorate (Thorpe, Chem. Soc. Trans. 1873, 541). Thin granulated zinc is washed with caustic soda solution, then with dilute sulphuric acid, which is allowed to act for a short time, and finally with water. It is then covered with about 100 c.c. of a 3 p.c. solution of copper sulphate heated to 40°-50°. When most of the copper has been deposited, the liquid is carefully poured off, and treatment repeated with a fresh quantity of solution. The zinc-copper couple is now very carefully washed with distilled water by decantation, not more than 0·5 gram of potassium chlorate, or the equivalent quantity of any other chlorate, is weighed out into the beaker and dissolved in about 25 c.c. of warm water, which should just cover the couple. The liquid is heated gently for half an hour, then boiled for half an hour, dilute sulphuric acid added drop by drop until the white precipitate of zinc hydroxide and oxychloride just dissolves, filtered, the filtrate neutralised with pure calcium carbonate, and the chlorine estimated by standard silver nitrate solution (Chem. Soc. Trans. 1888, 166).

This reduction may also be effected by Devarda's alloy (Al 45, Zn 5, Cu 50). Jannasch recommends hydroxylamine sulphate and excess of nitric acid as a suitable reducing agent for chlorates while bromates and iodates are best reduced by hydroxylamine in ammoniacal solution (Ber. 1905, 38, 1576). Formaldehyde in dilute nitric acid reduces chlorates in 30 minutes and bromates in 2½ hours; iodates are not reduced (Grützner. Arch. Pharm. 1896, 294, 634; compare Brunner and Mellet, J. pr. Chem. 1908, 77, 33).

Hydrobromic, hydrochloric, and hydriodic acids.

As silver salts (AgBr, AgCl, AgI). The solution is mixed with excess of silver nitrate, acidified with nitric acid, and heated to boiling. The precipitate is treated exactly as in the estimation of silver.

Hydrofluoric acid.

(*a*) As *calcium fluoride* CaF_2, in the case of soluble fluorides. The solution is mixed with a moderate excess of sodium carbonate, heated to boiling, and mixed with excess of calcium chloride. The precipitate is washed, dried, and heated to redness in a platinum crucible, then treated with excess of acetic acid, evaporated to dryness, and heated to expel excess of acid. The product is now heated with water, and the insoluble calcium fluoride filtered off, washed, and heated.

(*b*) Indirectly as *silicon fluoride* SiF_4. The finely powdered solid substance is placed in a deep platinum crucible and covered with three or four times its weight of pure precipitated silica, the weight of which is accurately known. Sulphuric acid is then added, and the crucible gently heated for half an hour. The temperature is raised to expel most of the sulphuric acid, the residue treated with hydrochloric acid, washed, dried, and heated. The hydrofluoric acid is calculated from the loss in weight of the silica: $4HF = SiO_2$. The amount of silica in the substance must be known, and its weight added to that of the admixed silica.

(*c*) By *distillation and weighing as calcium fluoride.* The fluoride is decomposed by concentrated sulphuric acid in a platinum apparatus; the hydrogen fluoride carried off in a current of air and carbon dioxide and absorbed in a solution of pure caustic soda contained in a platinum dish. Calcium chloride is added to this solution and the precipitate ($CaCO_3$ and CaF_2) washed, ignited, and treated with dilute acetic acid in moderate excess. After evaporation to expel this excess of acid, the residue is taken up with water and the insoluble calcium fluoride collected, washed, and ignited (Jannasch and Röttgen, Zeitsch. anorg. Chem. 1895, 9, 267). The apparatus employed is figured in Jannasch's Praktischer Leitfaden der Gewichtsanalyse, 2nd ed. 411 (compare also J. Amer. Chem. Soc. 1901, 23, 825; and Chem. News, 1905, 92, 184).

(*d*) Directly as *silicon fluoride* (Fresenius). The mineral is finely powdered and intimately mixed with ignited quartz and heated with concentrated sulphuric acid in a dry U-tube at 150°–160°. A current of dry air free from carbon dioxide is drawn through the decomposition tube and thence through a series of five U-tubes. The first of these is empty and cooled by immersion in cold water; the second contains glass-wool, or, if the substance contains chlorine, half is filled with pumice impregnated with anhydrous copper sulphate, and the other half with pure dry calcium chloride. The third and fourth tubes are weighed and serve to absorb the silicon fluoride; the third contains pumice moistened with water, and the fourth contains soda lime and calcium chloride. The fifth tube is a guard tube containing the same reagents as the fourth. After one or two hours the decomposition of the fluoride is complete, and the gain in weight of the absorption tubes represents the amount of silicon fluoride generated. This process may be rendered volumetric (*v. Volumetric section*).

Hydrogen sulphide (sulphides).

Insoluble sulphides are decomposed by hydrochloric acid in a flask similar to that used in the gravimetric estimation of carbonic acid, and the gas evolved is led into two or three bulb U-tubes containing a solution of bromine in dilute hydrochloric acid, which converts the hydrogen sulphide into sulphuric acid. When decomposition is complete, the liquid in the flask is boiled, and the last traces of the gas are drawn through the bulbs by means of an aspirator. The contents of the bulb tubes are transferred to a beaker, heated to expel bromine, and the sulphuric acid precipitated by barium chloride.

Sulphides which are not decomposed by hydrochloric acid may be oxidised with aqua regia, hydrochloric acid and bromine, or hydrochloric acid and potassium chlorate, the sulphuric acid formed being weighed as barium sulphate.

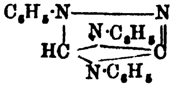
Nitric acid.

(*a*) Indirectly, as ammonia, by means of the zinc-copper couple (Thorpe). A zinc-copper couple (*v. Chloric acid*) is made in a flask into which is weighed a quantity of the nitrate corresponding with not more than 0·5 gram of potassium nitrate, and sufficient water is added to just cover the couple. The flask is attached to a condenser, the other end of which is connected with a U-tube or flask containing hydrochloric acid, as in the estimation of ammonia. The liquid is gently heated for some time, and then distilled nearly to dryness. After cooling, a further quantity of water is added to the couple, and distillation repeated. The ammonia in the distillate is estimated as platinichloride, or is received in a measured volume of standard acid and titrated. The reduction can also be conveniently effected by the use of Devarda's alloy (*v. Chloric acid*) in alkaline solution (Analyst, 1910, 35, 307).

(*b*) *Schloesing's method.* When a solution of a nitrate is heated with an acid solution of a ferrous salt, the nitrate is decomposed, the whole of the nitrogen being evolved as nitric oxide, which is measured. The difficulty lies mainly in obtaining the nitric oxide free from air. The apparatus employed consists of a *small* distilling flask provided with a side tube which terminates under a gas-collecting tube in a mercurial trough. The neck of the flask is fitted with a cork, which carries a tube funnel provided with a stop-cock and another tube connected with a carbon-dioxide apparatus. Carbon dioxide *free from air* is passed into the apparatus until all air is expelled and the gas issuing from the exit tube is completely absorbed by caustic potash. The substance containing the nitrate, which must be in the solid condition, is dissolved in 2 or 3 c.c. of concentrated ferrous chloride solution, mixed with 1 c.c. of strong hydrochloric acid, and introduced into the flask by means of the funnel tube, care being taken that no air enters. The dish and the funnel are rinsed with very small quantities of acid, the object being to use as little liquid as possible. The contents of the flask are then rapidly boiled to dryness, the evolved gas being collected in the tube over mercury, and carbon dioxide is driven through the apparatus to expel all nitric oxide. The mixture of nitric oxide and carbon dioxide is transferred to an apparatus for gas analysis; the latter absorbed by caustic potash, and the former mixed with oxygen and absorbed by alkaline pyrogallol. Nitrites are converted into nitrates by addition of hydrogen peroxide during evaporation of the original solution (*v.* Warington, Chem. Soc. Trans. 1880, 468, and 1882, 345).

(c) *By standard indigo solution* (Warington, Chem. News, 35, 45, and Chem. Soc. Trans. 1879, 578).

(*d*) **As** 1 : 4-*diphenyl*-3 : 5-*endanilodihydrotriazole nitrate* $C_{20}H_{16}N_4,HNO_3$. A 10 p.c. solution of the base 1 : 4-diphenyl-3 : 5-endanilohydrotriazole 'Nitron,'



in 5 p.c. acetic acid produces a voluminous white precipitate in dilute nitric acid or nitrate solution. Nitrites interfere by giving a sparingly soluble salt with this base; they are removed by hydrazine sulphate. Bromides, iodides, chlorates, perchlorates, and chromates, are also precipitated by nitron, and must be removed. Organic matters do not seriously affect the method, which has been tested successfully with solutions containing 0·5 p.c. of gelatine, and 2 p.c. of dextrin (Busch, Ber. 1905, 38, 861). The method gives favourable results for nitrates in water or fertilisers (Collins, Analyst, 1907, 32, 349).

(*e*) Howard and Chick have shown that cinchonamine gives a very insoluble nitrate and can be used in estimating nitric acid and its salts (J. Soc. Chem. Ind. 1909, 28, 53).

Oxalic acid.

As *calcium oxalate*. The method is already indicated under *Calcium*.

Phosphoric acid.

As *magnesium pyrophosphate* $Mg_2P_2O_7$. The operation is conducted as in the estimation of magnesium. If magnesium sulphate is used as the precipitant, the precipitate may be contaminated with basic magnesium sulphate; it is therefore advisable to employ a solution of the chloride, which is made as follows: 85 grams of crystallised magnesium sulphate are dissolved in boiling water, acidified with 5 c.c. of hydrochloric acid, mixed with an aqueous solution of 82 grams of crystallised barium chloride, boiled, and filtered. A few drops of magnesium sulphate solution are added to be sure that there is no excess of barium, then 165 grams of pure ammonium chloride, and 260 c.c. of ammonia, and the solution diluted to 1 litre. After two or three days the solution is filtered. In many cases the phosphoric acid is first separated by ammonium molybdate (*v. Methods of separation*).

Silicic acid.

As *silica* SiO_2. Soluble silicates are acidified with hydrochloric acid and evaporated to complete dryness; moistened with strong hydrochloric acid, again evaporated twice to dryness, so as to agglomerate the silica, the residue treated with dilute acid, and the insoluble silica washed with hot water and ignited.

Insoluble silicates are very finely powdered, intimately mixed with about five times their weight of a dry mixture of sodium and potassium carbonates in equal proportions, and heated to redness in a platinum crucible for half an hour. The cooled mass is treated with water, acidified with hydrochloric acid, and evaporated as above.

(For the separation of silica when the alkalis have to be estimated, *v. Methods of separation*, Group VI.)

Sulphuric acid.

As *barium sulphate* $BaSO_4$, by precipitation with barium chloride. The chief difficulty arises from the tendency of the barium sulphate to separate in a finely divided condition and to carry down impurities, especially in presence of nitrates and potassium salts. These sources of error are avoided by taking care that the solution is somewhat dilute, is free from nitrates, and contains a moderate but not excessive quantity of free hydrochloric acid. The solution and the barium chloride solution should both be heated to boiling, and mixed *gradually, with continual agitation*. The liquid may be filtered as soon as it has become clear, and the precipitate is washed with hot water and heated to dull redness. If too little hydrochloric acid is present, the precipitate is liable to be impure; if a very large excess of the acid is present, precipitation is not quite complete (compare Allen and Johnston, J. Amer. Chem. Soc. 1910, 32, 588).

Sulphurous acid.

Indirectly as barium sulphate after oxidation by bromine water, excess of bromine being expelled by boiling.

Thiosulphuric acid.

Indirectly as barium sulphate after oxidation by bromine water, excess of bromine being expelled by boiling.

Water is usually estimated by difference. If a direct determination is required, the method to be adopted will depend upon circumstances. In many cases it is sufficient to heat the substance on a watch-glass, or in a crucible in a drying oven, at a definite temperature, until the weight is constant. During weighing the dried substance must be carefully protected from the air. Attention must, however, be paid to the possibility of the volatilisation of substances other than water. Many hydrated haloid salts, for example, lose part of their acid. In such cases the substance is previously mixed with a known weight of perfectly dry lead monoxide. Ammonia, ammonium salts, and volatile organic matter may also be given off. If the drying is conducted in a glass tube, the vapours may be led into standard acid and the ammonia determined by titration: the total loss, *minus* the ammonia, gives the amount of water. Some substances increase in weight in consequence of oxidation. Frequently it is desirable to collect the evolved water and weigh it directly. The substance is introduced into a glass tube (plain, or with a bulb in the middle) drawn out and bent at right angles at one end, which passes directly, without any intervening indiarubber tube, through the cork of a U-tube containing either calcium chloride or pumice moistened with strong sulphuric acid (*v.* ORGANIC ANALYSIS).

In certain cases the water may frequently be estimated with considerable accuracy by boiling the substance with paraffin oil and measuring the expelled water in a graduated tube (*cf.* Huntly and Coste, J. Soc. Chem. Ind. 1913, 32, 62; Campbell, *ibid.* 1913, 32, 67; Skertchley, *ibid.* 70; St. von Haydin, Analyst, 1913, 177; Michel, Analyst, 1913, 207).

All fluosilicates, even topaz, evolve silicon fluoride on ignition, and water is estimated by mixing the mineral with lead oxide in a hard glass tube, heating the mixture in a current of dry air and passing the gases over a layer of lead oxide contained in the same tube. The water is collected and weighed in calcium chloride tubes

Methods of Separation.

A. *The Estimation of the Metals in their Ores and Alloys.*

In this section the metals are arranged in the order in which they occur in the qualitative groups. Both gravimetric and volumetric methods are included in this description, the latter being indicated wherever possible, owing to the greater rapidity with which the analysis can be executed.

Group I.

Silver is separated from all other metals by treating its ores and alloys with moderately strong nitric acid, evaporating off excess of solvent, diluting with water, and adding to the filtered solution either hydrochloric acid or sodium chloride. To remove any lead or thallous chloride which may be present, the precipitate is extracted repeatedly with warm water; it should, however, be remembered that silver chloride is not absolutely insoluble in hot water. Silver is conveniently estimated volumetrically in the above dilute nitric acid solution, after boiling off nitrous fumes, by adding ferric indicator and titrating with standard ammonium thiocyanate in accordance with Volhard's method (*see Volumetric section*). The presence of other metals having colourless salts does not interfere with this process; nickel, cobalt, and copper must not be present to any large extent, and mercury should be absent because of the insolubility of mercuric thiocyanate. When more than 60 p.c. of copper is present, the silver is precipitated with excess of alkali thiocyanate. The well-washed silver thiocyanate is decomposed by strong nitric acid, the sulphuric acid produced precipitated by barium nitrate, and the Volhard titration effected without filtering off the barium sulphate (*v.* Ber. 1905, 38, 566).

The silver in argentiferous galena is estimated by fusing the sulphide with crude potassium hydrogen tartrate (argol), and sodium carbonate in an iron crucible, and by heating the lead-silver button thus obtained in a porous bone-ash crucible ('cupel') until the lead is removed as oxide, partly by volatilisation and partly by absorption into the cupel. The residual silver is detached from the cold cupel and weighed.

Gold quartz is assayed for silver by heating the mineral with lead oxide, and a reducing flux, when the lead produced extracts both the gold and silver. This alloy is cupelled, and the silver-gold button is 'parted' by heating with strong nitric acid diluted with three parts of water; the residual gold is collected, ignited, and weighed. The silver is precipitated by hydrochloric acid from the nitric acid solution. When more than 30 p.c. of gold is present in the button before parting, this metal will retain silver. In order to prevent this retention, a known weight of silver is added to the fused button. (For further details of the separations of gold, silver, and lead in the dry way, see Assaying.)

Thallium, in the more stable thallous condition to which thallic salts are readily reduced, is separated from the metals of Group II. by precipitating the latter with hydrogen sulphide in acid solution. Alkali hydroxides separate it from all metals, giving insoluble hydroxides, and ammonium sulphide, which precipitates thallous sulphide, separates this metal from the alkalis and alkaline earths. Gravimetrically, thallium can be weighed as acid sulphate $TlHSO_4$, stable at 240°, and as sulphate Tl_2SO_4, stable at low red heat; it can be precipitated and weighed as iodide TlI, platinichloride Tl_2PtCl_6, and chromate Tl_2CrO_4. Volumetrically, it can be estimated by the oxidation of thallous salts by permanganate or by titrating with thiosulphate the iodine set free in accordance with the following reaction: $TlCl_3 + 3KI = TlI + 3KCl + I_2$ (Chem. Soc. Proc. 1908, 24, 75).

Group II.

Mercury in its ores is generally estimated by distillation with quicklime in a current of coal gas or carbon dioxide. The decomposition of the mercury compounds is facilitated by mixing copper strips with the quicklime, and the presence of this reducing agent is essential in the case of mercuric iodide. The mercury which distils over is collected under water, washed, dried, and weighed. Ores containing only small amounts of mercury are decomposed by heating with iron filings in a porcelain crucible, *a*, having a silver lid, *f*, which is cooled by a water-jacket, *b*, laid upon it. The mercury condenses on the under surface of the silver plate, *f*, which is weighed before and after the experiment (*v.* Holloway, Analyst 1906, 31, 66).

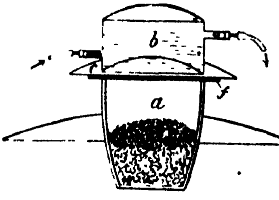


Fig. 8.

Mercury is separated from all other metals in the wet way by dissolving the ore or alloy in nitric acid or aqua regia, diluting considerably, precipitating the sulphides of Group II. by hydrogen sulphide, removing the arsenic-tin sub-group by means of yellow ammonium sulphide (*not* sodium sulphide or hydroxide), treating the residual sulphides with dilute nitric acid (sp.gr. 1·2–1·3), and dissolving the final residue in aqua regia and filtering if necessary from sulphur and lead sulphate. The mercury can be reprecipitated by almost neutralising the acid solution, adding in succession ammonium sulphide, caustic soda and ammonium nitrate. The caustic soda redissolves the sulphide initially formed as the soluble double sulphide $Hg(SNa)_2$, and from this the ammonium nitrate reprecipitates mercuric sulphide in a form suitable for collection. The precipitate is washed successively with water, alcohol, and carbon disulphide, dried at 110°, and weighed as HgS. (For other methods of separating mercury, see Jannasch, Zeitsch. anorg. Chem. 1896, 12, 132, and 359; and Stähler, Chem. Zeit. 1907, 31, 615.)

Lead in its ores and alloys is usually separated from other metals by dissolving the substance in hydrochloric or nitric acid, or if necessary in a mixture of the two acids and evaporating down the solution with sulphuric acid until white fumes are evolved. The mixture is then cooled diluted with water, and the lead sulphate quickly collected. If the amount of lead is small, alcohol must be added to complete the precipitation. The lead sulphate thus obtained is freed from silica, stannic oxide, and other impurities by dissolving it in an excess of ammonium or sodium acetate.

When separated as lead sulphate, the lead can be estimated volumetrically by boiling the precipitate with ammonium carbonate and then dissolving the lead carbonate in acetic acid. The lead is thus converted into lead acetate which is titrated with standard ferrocyanide using as indicator drops of uranium acetate on a porcelain plate. The lead may also be reprecipitated as oxalate from the acetate solution by alkali oxalate, the washed lead oxalate being then suspended in dilute sulphuric acid, and titrated with standard permanganate. From the solution of the sulphate in sodium acetate the lead can be precipitated as chromate by potassium dichromate. The chromate is dissolved in dilute nitric acid, and reduced with methyl or ethyl alcohol. The solution, rendered ammoniacal, is treated with oxalic acid, when lead is precipitated and titrated as above with standard permanganate (*v.* Chem. News, 1896, 73, 18; J. Amer. Chem. Soc. 1896, 18, 737; Zeitsch. anal. Chem. 1902, 41, 653). Lead may be separated from copper by electrolysing a solution of the metals in dilute nitric acid with a weak current (0·5–1·5 amperes and 1·4 volts), when the lead is precipitated as dioxide on the anode (a platinum dish with unpolished inner surface).

Bismuth is separated from all other metals but those of Group II. by the precipitation of its sulphide by hydrogen sulphide in acid solution. The insolubility of the sulphide in ammonium sulphide separates this metal from arsenic, antimony, and tin. The further separation of bismuth from mercury, copper, and cadmium presents no particular difficulty, and is effected by taking advantage of the solubility of bismuth sulphide in nitric acid (sp.gr. 1·25), and the precipitation of bismuth oxychloride on diluting considerably an acid solution of bismuth chloride. The problem of separating bismuth from lead is, however, much more troublesome, and the following appear to be most trustworthy methods: (i.) the separation of the bismuth as basic nitrate and the solution of lead nitrate in dilute ammonium nitrate (J. pr. Chem. 1858, 74, 345); (ii.) the distillation of the mixed sulphides in a current of bromine, when bismuth bromide is volatilised, leaving behind lead bromide (Jannasch, Praktischer Leitfaden der Gewichtsanalyse, 1st ed. 155); (iii.) the precipitation of bismuth as the basic formate; a repetition of this operation gives a precipitate free from lead, which is dissolved in dilute nitric acid, the solution almost neutralised with sodium carbonate, and the bismuth then finally precipitated and weighed as phosphate $BiPO_4$ (Stähler, Chem. Zeit. 1907, 31, 615). The lead in the filtrate from the formate separation is precipitated as sulphide, converted into sulphate, and weighed as such. This method of separation gives accurate results (Little and Cahen, Analyst, 1910, 35, 301).

Copper is separated from the metals of Groups III., IV., V., and VI., by precipitation as sulphide by hydrogen sulphide in acid solution. In alloys and ores it is generally separated from antimony and tin by rendering these insoluble by the action of moderately strong nitric acid. If, however, the sulphides of these metals and arsenic are present, they are extracted from the precipitate with alkali sulphides (not ammonium sulphide). The insoluble residue, containing the sulphides of copper, bismuth, lead, mercury, and cadmium, is treated with nitric acid (*v. Mercury* and *Bismuth*). Copper is readily separated from bismuth by means of ammonium carbonate, which precipitates basic bismuth carbonate, leaving copper in solution. The separation from cadmium may be effected by one of the following methods:—(1) Hydrogen sulphide is passed into a boiling solution of the sulphates of copper and cadmium in dilute sulphuric acid (1 : 4). The precipitated copper sulphide, which contains some cadmium, is redissolved in nitric acid, and, after expelling excess of the solvent, the precipitation is repeated. (2) The copper is precipitated as cuprous thiocyanate, leaving cadmium in solution. (3) The copper is converted into potassium cuprocyanide $K_3Cu(CN)_4$, with a considerable excess of potassium cyanide, and the cadmium precipitated with hydrogen sulphide or ammonium sulphide (compare also Browning, Amer. J. Sci. 1893, [3] 46, 280).

The following volumetric processes for copper are employed in the technical analysis of the ores of this metal. (i.) The mineral is dissolved in hydrochloric and nitric acids, and the solution boiled down with sulphuric acid to expel the volatile acids. The copper is precipitated from the boiling solution by introducing a sheet of aluminium and redissolving in nitric acid with the addition of bromine to destroy nitrous fumes. The solution is neutralised with ammonia, acidified with acetic acid, and treated with excess of potassium iodide, when the liberated iodine is titrated with standard thiosulphate (Low, J. Amer. Chem. Soc. 1902, 24, 1082). (ii.) A solution of potassium cyanide is standardised against pure copper foil by dissolving the latter in nitric acid, adding bromine, boiling to expel nitrous fumes and excess of bromine, adding ammonia till strongly alkaline, and titrating with the cyanide solution until the blue tint disappears. The copper ore is treated as in (i.), the copper being precipitated by aluminium, redissolved in nitric acid, and the resulting solution titrated in manner just described (*v.* Brearley, Chem. News, 1897 76, 189). (For other methods of separating and estimating copper, see also Zeitsch. anorg. Chem. 1896, ii. 268; Chem. Soc. Abstr. 1901, ii. 197; J. Amer. Chem. Soc. 1905, 27, 1224; Zeitsch. anal. Chem. 1907, 46, 128; J. Amer. Chem. Soc. 1908, 30, 760; Chem. Zeit. 1908, 33, 263; Amer. J. Sci. 1909, (iv.) 27, 448.)

(For electrolytic estimation of copper, *v.* ELECTRO-CHEMICAL ANALYSIS.)

Cadmium is separated from the other metals of Group II. by the methods indicated under *copper*, *lead*, &c. In the presence of zinc, Fox recommends precipitation in a solution containing trichloroacetic acid (Chem. Soc. Trans. 1907, 91, 964). Electrolytically, cadmium is deposited from a cyanide solution (0·7–1·2 amperes and 4·8–5 volts); the use of a rotating cathode accelerates the rate of deposition (compare

Flora, Amer. J. Sci. 1906, 70, 268 and 392; and Avery and Dales, J. Amer. Chem. Soc. 1897, 19, 379).

Tin, antimony, and *arsenic* are separated from the remaining metals of Group II. by digesting the group precipitate at 80° with concentrated yellow ammonium sulphide, when the sulphides of these three metals dissolve, leaving the other sulphides insoluble. Copper sulphide is appreciably soluble in this solvent, and in the presence of copper it is preferable to use sodium or potassium sulphide, but in the presence of mercury these reagents are inadmissible, owing to formation of the soluble double sulphide $Hg(SK)_2$. In the presence of much lead a small amount of tin is retained in the insoluble residue. Arsenic rarely occurs in alloys, and in these substances antimony and tin are separated from other metals as insoluble oxy-acids (metantimonic and metastannic acids) by the use of nitric acid as solvent.

Arsenic is separated from antimony and tin by distilling the hydrochloric acid solution of the three elements with ferrous chloride; the arsenic is volatilised as arsenious chloride; this compound is collected in cold water and the arsenic precipitated as trisulphide (Fischer, Zeitsch. anal. Chem. 1881, 21, 266). Various modifications of this method have been introduced; the distillation is carried on in a current of hydrogen chloride and hydrogen sulphide, the latter serving as the reducing agent instead of ferrous chloride; the volatilised arsenious chloride is converted in the cooled receiver into the trisulphide (Piloty and Stock, Ber. 1897, 30, 1649). (For other modifications, *see* Gooch and Danner, Amer. J. Sci. 1891, [3] 42, 308; Andrews, J. Amer. Chem. Soc. 1895, 17, 869; Rohmer, Ber. 1901, 34, 33; Morgan, Chem. Soc. Trans. 1904, 85, 1001.)

The arsenic may also be separated from tin and antimony by dissolving the three sulphides in ammoniacal hydrogen peroxide, neutralising the solution with mineral acid, acidifying with tartaric acid, and precipitating the arsenic as magnesium ammonium arsenate by the addition of ammonia and magnesia mixture (*see Qualitative analysis*).

The following method of separating arsenic and antimony in their ores, leads to volumetric processes for the determination of these elements (Low, J. Amer. Chem. Soc. 1906, 28, 1715). The mineral is decomposed by heating with strong sulphuric acid (20 parts) containing potassium hydrogen sulphate (1·4 parts), and 1 part of tartaric acid. The cooled product is taken up with 350 c.c. of hot water, 10 c.c. of strong hydrochloric acid, and 3 grams of tartaric acid, and the solution saturated with hydrogen sulphide. The mixed sulphides are dissolved in aqueous potassium sulphide, and the filtrate evaporated down with 10 c.c. of strong sulphuric acid and 3 grams of potassium hydrogen sulphate until the sulphur and the greater part of the free aid are expelled. The cooled melt is dissolved in 50 c.c. of strong hydrochloric acid and 25 c.c. of water, and arsenious sulphide precipitated by hydrogen sulphide. The antimony remaining in the filtrate is precipitated as sulphide by diluting the solution and passing in more hydrogen sulphide. The antimonious sulphide is again dissolved in potassium sulphide, the solution evaporated nearly to dryness with strong sulphuric acid and potassium hydrogen sulphate, the melt dissolved in dilute hydrochloric acid and titrated with standard permanganate.

The arsenious sulphide is dissolved in warm ammonium sulphide, and the solution heated strongly with strong sulphuric acid and potassium hydrogen sulphate until all the sulphur and nearly all the acid are expelled. The residue is boiled with water to expel sulphur dioxide, neutralised, and titrated with standard iodine solution in the presence of sodium bicarbonate.

Arsenic may also be estimated in minerals (which do not contain phosphates) by fusing the powdered ore with sodium carbonate and nitre or sodium peroxide, extracting the fused mass with water and precipitating silver arsenate from the neutralised solution. This precipitate is redissolved in nitric acid, and the amount of silver in it determined by standard thiocyanate; whence the quantity of arsenic present can be readily calculated. (For other processes for the estimation of arsenic in technically important materials, *v.* Clark, Chem. Soc. Trans. 1892, 61, 424; Friedheim, Zeitsch. anal. Chem. 1905, 44, 665; Heath, Zeitsch. anorg. Chem. 1908, 59, 87; Gooch and Phelps, Amer. J. Sci. 1906, (iv.) 22, 488; McGowan and Floris, J. Soc. Chem. Ind. 1905, 24, 265; Sanger and Black, *ibid.* 26, 1115; Collins, Analyst, 1912, 37, 229.) (For the detection and estimation of minute quantities of arsenic, *v.* ARSENIC.)

Separation of tin and antimony. In the absence of any large amount of lead or other metal giving a sulphide insoluble in ammonium sulphide, tin and antimony can be separated from these metals by means of this reagent, but if lead is present in considerable amount the tin is never completely extracted, a portion always remaining in the insoluble residue. In this case it is preferable to separate out the tin and antimony by oxidising them to their insoluble hydrated oxides by means of nitric acid. These oxides when fused with caustic soda in a silver crucible yield sodium stannate and antimonate; the latter of these salts is practically insoluble in dilute alcohol (1 vol. alcohol, 2 vols. water), whilst the former is readily dissolved. A repetition of this process with the insoluble antimonate leads to a complete separation.

When present as sulphides, these metals are conveniently dealt with by Henz's modification of Clark's method. The sulphides are dissolved in excess of aqueous caustic potash containing potassium tartrate; the solution is gradually heated to boiling with excess of 30 p.c. hydrogen peroxide. When the oxidation of the sulphides is complete, excess of oxalic acid is added (15 grams for 1 gram of mixed metal), the liquid boiled to destroy excess of hydrogen peroxide, and hydrogen sulphide passed for some time through the hot solution. The precipitated antimony sulphide is dealt with as described under gravimetric estimations. The filtrate is treated with sulphuric acid, concentrated to a small bulk (150 c.c.), and electrolysed at 60° with a current of 0·2–0·3 ampere, and 2·3 volts, using a rotating anode, when the deposition of the tin is complete in about one hour (Henz. Zeitsch. anorg. Chem. 1903, 37, 1; and Cahen and Morgan, Analyst, 1909, 34, 3).

In Clark's original process the filtrate from the antimony sulphide, which contains stannic tin, is mixed with yellow ammonium sulphide in excess and acidified with acetic acid. After some time the stannic sulphide is collected, washed with a solution of ammonium nitrate, and converted into stannic oxide by ignition. In accurate work the antimony sulphide is redissolved, and the oxalic acid separation repeated in order to obtain the last traces of tin (compare Carnot, Compt. rend, 1886, 103, 258). (For descriptions of other methods of estimating tin and antimony in their ores and alloys, see J. Soc. Chem. Ind. 1892, 11, 662; G. W. Thompson, J. Soc. Chem. Ind. 1896, 15, 179; T. Brown, jun., J. Amer. Chem. Soc. 1899, 21, 780; Argenot, Zeitsch. angew. Chem. 1904, 17, 1274; Lévy, Analyst, 1905, 30, 361; Panajotow, Ber. 1909, 42, 1296.)

The following process, due to Pearce, gives a rapid volumetric method for estimating tin in its ores. The mineral is fused in a nickel crucible with about 20 parts of sodium hydroxide with the addition of a little powdered charcoal; the fused mass is dissolved (excepting silica) in hydrochloric acid, and the solution reduced by the addition of iron rods or sheet nickel. The stannous chloride thus produced is titrated with standard iodine solution in presence of sufficient hydrochloric acid (1 : 4) to prevent the oxidation of any arsenic or antimony which may be present.

Gold and *platinum* are separated chiefly in the analytical subgroup containing arsenic, antimony, and tin. Fusion of the sulphides with sodium carbonate and nitre, followed by extraction with water, removes the arsenic. The residue, treated with zinc and hydrochloric acid, reduces tin and antimony to the metallic state; the former is dissolved by boiling hydrochloric acid, and the latter by nitric and tartaric acids, whilst gold and platinum are left. Treatment of the mixed metals with chlorine water removes gold, and dilute *aqua regia* then dissolves platinum, palladium, and rhodium. From this solution platinum is precipitated by ammonium chloride and alcohol, and from the filtrate, after neutralisation with sodium carbonate, palladium is precipitated as cyanide by mercuric cyanide.

For separation of palladium from gold, platinum, rhodium, and iridium by means of dimethylglyoxime, *see* Wunder and Thüringer, (Zeitsch. anal. Chem. 1913, 52, 660; Analyst, 1913, 524).

The residue from the *aqua regia* treatment is roasted in the air; osmium volatilises as the tetroxide, ruthenium sublimes as the dioxide, whilst iridium is left (*v.* Leidié, Compt. rend. 1900, 131, 888; and PLATINUM METALS).

Molybdenum is precipitated as sulphide preferably from a sulphuric acid solution by treatment with hydrogen sulphide under pressure. From the sulphides of the copper-lead subgroup, it is separated by digestion with sodium sulphide under pressure, when the molybdenum passes into solution and is reprecipitated as sulphide by dilute sulphuric acid. Molybdenum sulphide is separated from the sulphides of antimony and tin by dissolving the latter in hydrochloric acid. The sulphides of arsenic and molybdenum are dissolved in hydrochloric acid and potassium chlorate, the arsenic precipitated from the filtrate after adding ammonia and magnesia mixture as magnesium ammonium arsenate. The final filtrate is acidified, and the molybdenum reprecipitated as sulphide. Molybdenum is separated from phosphorus in a similar manner. From tungsten it is best separated by heating the mixed trioxides or their alkali salts at 250°–270° in a current of hydrogen chloride, when the molybdenum is completely volatilised as the additive compound $MoO_3,2HCl$, while the tungsten remains in the non-volatile residue (Debray, Compt. rend. 1858, 46, 1101: and Péchard, *ibid.* 1892, 114, 173).

Selenium and *tellurium* fall into the analytical sub-group containing arsenic, and after this element has been removed as magnesium ammonium arsenate (*v. Molybdenum*); the selenium and tellurium are precipitated by reducing agents such as sulphur dioxide, hydrazine, &c. (i.) Sulphur, selenium, and tellurium are separated by fusion with potassium cyanide in a stream of hydrogen. On dissolving the mass in water and passing air through the solution, the potassium telluride present is decomposed, and tellurium is precipitated. When the filtrate is acidified, the potassium selenocyanate (KCNSe) is decomposed, yielding selenium. (ii.) The mixed dioxides of selenium and tellurium are dissolved in aqueous caustic potash; the solution, faintly acidified with hydrochloric acid, is diluted to at least 200 c.c. with boiling water, rendered just ammoniacal and reacidified with acetic acid. After 30 minutes the tellurium dioxide is collected, washed with cold water, and gently ignited (Browning and Flint, Zeitsch. anorg. Chem. 1909, 64, 104).

Gold from all other metals: reduction of an acid solution by oxalic acid or sulphurous acid.

Selenium from the metals: reduction with sulphurous acid in hydrochloric acid solution.

GROUP III.—The metals of Group III*a.* are separated from those of the succeeding groups by precipitation with ammonia in presence of ammonium chloride; the metals of Group III*b.* are separated from those of the succeeding groups by means of ammonium sulphide (*v. General methods of estimation*).

Iron, aluminium, chromium, uranium, glucinum, and cerium, from zinc, manganese, nickel, cobalt. The solution, which must contain iron and uranium as ferric and uranic salts, is nearly neutralised, mixed with excess of finely divided and recently precipitated barium carbonate, and allowed to remain in a closed vessel at the ordinary temperature for some hours with occasional agitation. In presence of nickel and cobalt, ammonium chloride should be added to prevent precipitation of traces of these metals. Filter and wash with cold water. The precipitate may contain ferric, chromic, aluminium, glucinum, ceric and uranic hydroxides, mixed with barium carbonate; the filtrate contains the other metals, together with some barium. In both cases the barium can be removed by means of sulphuric acid, but as the barium sulphate carries down small amounts of the other metals, it is preferable to separate the metals of Groups III. and IV. by a double precipitation with ammonium sulphide (Treadwell).

Iron and aluminium from zinc, manganese, nickel, cobalt, uranium, and metals of the suc-

ceeding groups. The solution, which must contain iron as a ferric salt, is nearly neutralised by sodium or ammonium carbonate. In presence of iron the liquid becomes deep red, but no precipitate must be formed. Sodium, or, better, ammonium acetate, is added in sufficient but not excessive quantity, and the liquid is boiled until the precipitate becomes granular and settles rapidly. Prolonged boiling makes the precipitate slimy. The liquid is filtered whilst hot, and the precipitate is washed with hot water; if the liquid is allowed to cool the precipitate is partially redissolved. The precipitate is converted into ferric and aluminium oxides by ignition; the other metals are in the filtrate. It is advisable, and in presence of nickel essential, to redissolve the precipitate and repeat the process. This method is not available for the separation of chromium.

The same result can be obtained with ammonium formate or succinate.

Aluminium and chromium from iron, zinc, manganese, nickel, and cobalt. Mix the solution with a moderate quantity of pure normal potassium tartrate, then with pure caustic potash or soda until the precipitate redissolves, add ammonium sulphide in slight excess and allow to stand. Wash the precipitate with water containing ammonium sulphide. Aluminium and chromium are in the filtrate, the other metals in the precipitate. If iron and chromium are absent, it is sufficient to add the alkaline tartrate, excess of ammonia, ammonium chloride and ammonium sulphide.

Separation of iron and aluminium. The following methods have also been employed for this important separation. (i.) Potassium hydroxide dissolves aluminium hydroxide, but not ferric hydroxide; the former is reprecipitated from the filtrate by boiling with ammonium chloride or adding successively nitric acid and ammonia; the iron precipitate is dissolved in acid and reprecipitated by ammonia. (ii.) The two metals are precipitated with ammonia and the weight of the combined oxides determined. The mixture is then digested with strong hydrochloric acid (10 concentrated solution : 1 water) until all the iron has dissolved; the presence of free chlorine or hydriodic acid assists the solution of the ferric oxide. If alumina predominates, it may be necessary to fuse the mixed oxides with potassium pyrosulphate. The solution is saturated with hydrogen sulphide to reduce the iron to the ferrous condition; the excess of this sulphide is expelled by carbon dioxide, and the liquid titrated with standard permanganate. The proportion of aluminium is determined by difference. (iii.) Iron and aluminium may also be separated by treating the mixed chlorides with strong hydrochloric acid and ether (equal vols.); the aluminium chloride is precipitated, collected, washed with ethereal hydrochloric acid and ignited with mercuric oxide (Gooch and Havens, Amer. J. Sci. 1896, 2, 416). (iv.) The separation of small quantities of aluminium from excess of iron has been successfully effected by the use of phenylhydrazine. The iron is first reduced to the ferrous condition by adding hydrochloric acid and ammonium bisulphite, and the solution almost neutralised with ammonia, a slight excess of phenylhydrazine is then added, and after one hour the aluminium hydroxide is collected and washed with a solution of phenylhydrazine sulphite. In this way aluminium can be separated from iron, manganese, calcium, and magnesium (Hess and Campbell, J. Amer. Chem. Soc. 1899, 21, 776).

Separation of iron, aluminium, and phosphoric acid. When the total amount of these substances is small, the precipitate obtained by ammonia is ignited and weighed ($A = Fe_2O_3 + Al_2O_3 + P_2O_5$). The precipitate is then fused with sodium carbonate and silica, and the mass extracted with water containing a little ammonium carbonate. The residue containing iron and aluminium is evaporated down with sulphuric acid to dissolve the iron; the solution is reduced with hydrogen sulphide as in the preceding separation, and titrated with permanganate solution. The solution, which contains all the phosphoric acid, is evaporated down with hydrochloric acid to remove silica; the residue taken up with water, and the phosphoric acid precipitated from the filtrate as magnesium ammonium phosphate. From the weight of magnesium pyrophosphate obtained the amount of P_2O_5 is determined, and the Al_2O_3 is obtained by difference. If the total amount of these three substances is large, the original solution may be divided into three aliquot portions, in one of which the phosphoric acid is precipitated as ammonium phosphomolybdate, in the second part the iron is determined volumetrically, and from the third the total precipitate (Fe_2O_3, Al_2O_3, P_2O_5) is obtained (compare Cooksey, Analyst, 1908, 33, 437).

Chromium is readily separated from many metals, *e.g.* aluminium, by conversion into chromate, which is not precipitated by alkalis. This can be done in one of the following ways. (*a*) Make the solution alkaline with caustic potash or soda, saturate with chlorine, and then heat to expel excess of gas, and decompose hypochlorites by heating with ammonia. (*b*) Ammonium persulphate is added to a solution containing chromium, iron, and aluminium. On boiling, the chromium is oxidised to chromate, the acid set free during oxidation being sufficient to keep the iron and aluminium in solution (G. v. Knorre, Zeitsch. anorg. Chem. 1903, 16, 1097). (For the estimation of chromium in chromite and chrome steel, *see Volumetric section.*)

Aluminium from chromium. After chromium has been converted into chromic acid, the aluminium may be precipitated as hydroxide or as phosphate (*v. Determination of metals*). The filtrate is acidified, heated to boiling, and sodium thiosulphate added until the chromium is completely reduced; it can then be estimated as phosphate in the same way as aluminium; or caustic alkali is added to the solution of the metals until the precipitate at first formed redissolves. Bromine-water is added until the green colour of the solution is changed to the yellow of a chromate solution. The liquid is heated to boiling, and more bromine-water added drop by drop to precipitate the alumina in a non-gelatinous form.

Uranium is separated from the other metals of this group by the solubility of its hydroxide, sulphide, and acid uranates, in ammonium carbonate.

Uranium from Iron and Aluminium. An acid solution containing ammonium salts is mixed with excess of ammonium carbonate and ammonium sulphide in a closed flask. The precipitate contains ferrous sulphide and aluminium hydroxide; the uranium remains dissolved as the double carbonate $UO_2 \cdot CO_3,2(NH_4)_2CO_3$. The filtrate is concentrated considerably, acidified with hydrochloric acid, boiled, and the uranium precipitated as ammonium diuranate with ammonia. The precipitate is ignited and weighed as U_3O_8. Or this oxide is heated with dilute sulphuric acid (1 : 6) at 170 in an inert atmosphere (carbon dioxide): the solution which contains uranyl sulphate (2 mols.) and uranous sulphate (1 mol.), is titrated with standard permanganate solution.

$$1 \text{ c.c. } \frac{N}{10} KMnO_4 = 0 \cdot 03593 U.$$

Uranium ores are treated in the following way. The mineral (0·5–1·0 gram) is dissolved in nitric acid or *aqua regia*, silica removed by evaporation, the soluble residue extracted with hydrochloric acid, and the metals of the copper group precipitated by hydrogen sulphide. The filtrate is oxidised with potassium chlorate, and treated successively with ammonium phosphate, ammonia (till nearly neutral), and sodium carbonate in excess. The mixture is boiled and sufficient ammonium chloride added to decompose excess of sodium carbonate. The precipitate, which contains the iron, vanadium, &c., is washed with aqueous ammonium carbonate. This salt is removed from the filtrate by boiling alone and with nitric acid. The solution is almost neutralised with ammonia, and to the boiling liquid are added successively microcosmic salt, sodium thiosulphate, acetic acid, and finally ammonium acetate. The precipitate, uranyl ammonium phosphate, is collected, ignited, moistened with nitric acid, again ignited and weighed as $(UO_2)_2P_2O_7$.

Uranium is separated from thorium (and iron) by means of hydroxylamine hydrochloride, which in ammoniacal solution precipitates thorium and ferric hydroxides, leaving the uranium in solution (Jannasch and Schilling, Chem. Zeit. 1905, 29, 248).

Cerium is separated *from other metals* by saturating the solution with sodium sulphate, this salt being added in fine powder. A crystalline double sulphate of cerium and sodium separates, and is washed with a saturated solution of sodium sulphate.

Glucinum is precipitated with aluminium in Group III., and separated from aluminium and the other metals of the group by one of the following methods: (i.) A saturated solution of sodium hydrogen carbonate dissolves out glucinum hydroxide from a precipitate containing aluminium and ferric hydroxides, leaving the latter unaffected (Parsons and Barnes, J. Amer. Chem. Soc. 1906, 28, 1589). (ii.) Aluminium and glucinum chlorides are separated by saturating their solutions with hydrogen chloride in the presence of ether; the former is precipitated, the latter remaining dissolved (Amer. J. Sci. [4] 11, 416). (iii.) The acetates may be separated by the use of hot glacial acetic acid, from which solvent basic glucinum acetate $GlO_4(CO_2 \cdot CH_3)_3$ $[GlO_4(CH_3CO_2)_3]$ separates on cooling (Parsons and Robinson, *cf.* also Glassmann, Ber. 1906, 39, 3366; and J. Amer. Chem. Soc. 1895, 17, 688; Wunder and Wegner, Zeitsch. anal. Chem. 1912, 51, 470). This acetate is soluble in chloroform and may be distilled unchanged. Quantitative results may be obtained by volatilising the salt from the basic acetates of iron and aluminium (Kling and Gelin, Bull. Soc. chim. 1914, 15, 205; Analyst, 1914, 232).

Barium carbonate decomposes glucinum chloride, thus separating this metal from those of Group III*b*.

Vanadium is separated from the majority of metallic elements by fusion with sodium carbonate and potassium nitrate; the vanadium dissolves in water as sodium vanadate. Chromium and manganese would also be found in the aqueous extract, but from these metals vanadium is separated by the addition of ammonium sulphide in excess, when chromium and manganese are precipitated respectively as hydroxide and sulphide leaving vanadium in solution as a thiovanadate (cf. Zeitsch. anorg. Chem. 5, 381; Compt. rend. 1904, 138, 810; and Hillebrand, Amer. J. Sci. [4] 6, 209). From arsenic, vanadium may be separated either by reducing with sulphur dioxide and precipitating arsenious sulphide with hydrogen sulphide or by heating the mixed sulphides in hydrogen chloride at 150°, when the arsenic is volatilised (Field and Smith, J. Amer. Chem. Soc. 1896, 18, 1051).

Vanadium is separated from phosphoric acid by reducing vanadic acid to a hypovanadic salt with sulphur dioxide, and precipitating the phosphorus as phosphomolybdate.

Vanadium and molybdenum are separated by the action of hydrogen sulphide on vanadic and molybdic acids under pressure, molybdenum sulphide being precipitated, or ammonium metavanadate may be precipitated by the action of excess of ammonium chloride (Gibbs, Amer. Chem. J. 1883, 5, 371); the latter method serves to separate vanadium from tungsten.

(For methods of estimating vanadium in iron and steel, *see* Brearley and Ibbotson, The Analysis of Steel Works Materials; and Blair, The Chemical Analysis of Iron.)

Tungsten is separated from the majority of other elements by fusion with alkali carbonate and extraction of the alkali tungstate with water. This extract, when acidified with nitric acid and evaporated to dryness, yields tungstic acid as a residue insoluble in water. From arsenic and phosphoric acids tungstic acid is separated by the addition of magnesia mixture, which precipitates the arsenic and phosphorus, leaving the tungstate in solution (Gooch, Amer. Chem. J. 1871, 1, 412; and Gibbs, *ibid.* 1885, 7, 337).

The tungsten in wolframite may be estimated by fusing the finely powdered ore (0·5 gram) with 6 parts of fusion mixture in a platinum crucible for half an hour. The fused mass is extracted with boiling water when alkali tungstate passes into solution together with silicate and stannate. The insoluble residue contains iron, manganese, calcium, and magnesium with small amounts of columbic and tantalic acids. The filtrate is evaporated to dryness with excess of nitric acid, and the residue, after heating at 120°, is extracted with dilute ammonium nitrate solution; the residue, which consists of tungstic oxide with silica and stannic oxide, is weighed and then treated with hydrofluoric acid and weighed again. This second residue consists of tungstic oxide and stannic oxide, and the latter is volatilised by heating repeatedly with ammonium chloride until the weight of the final residue (WO_3) is constant.

To remove tin the mixed oxides may be ignited with zinc powder, and the residue, after extraction with hydrochloric acid, is tungsten trioxide (Angenot, Zeitsch. angew. Chem. 19, 140).

(For other separations of tungsten from its usual associates, *see* J. Amer. Chem. Soc. 1900, 22, 772; Zeitsch. anorg. Chem. 1905, 45, 396; Zeitsch. anal. Chem. 1908, 47, 37; Bull. Soc. chim. 1908, 13, 892; Wunder and Schapira, Ann. Chim. anal. 1913, 18, 257; Marbaker, J. Amer. Chem. Soc. 1915, 37, 86.)

Columbium and *tantalum* are extracted from columbite or tantalite by fusing the mineral with potassium hydrogen sulphate and extracting the fused mass with hot water and hydrochloric acid. The residue is treated with ammonium sulphide to remove tin, tungsten, and again extracted with hot hydrochloric acid. The final residue is then dissolved in hydrofluoric acid, the filtered solution is treated with potassium carbonate: potassium tantalofluoride separates in acicular crystals and the mother liquor furnishes potassium columbium oxyfluoride, crystallising in plates (compare Weiss and Landecker, Zeitsch. anorg. Chem. 1909, 64, 65; and Chesneau, Compt. rend. 1909, 149, 1132).

Titanium. In addition to the process given under the estimation of titanium, this element may be separated from iron by the following methods: (i.) By adding ammonium sulphide to an alkaline tartrate solution of the two elements, when ferrous sulphide is precipitated (Gooch, Amer. Chem. J. 1885, 7, 283). (ii.) By precipitating titanic acid with phenylhydrazine (J. Amer. Chem. Soc. 1895, 25, 421). Titanium is separated from aluminium by boiling with an alkali acetate and dilute acetic acid, when basic titanium acetate is precipitated.

Titanium and *zirconium* are separated by the following methods: (i.) A solution of the elements in dilute sulphuric and acetic acids is boiled for some time, when titanic acid is precipitated (J. pr. Chem. 1869, 108, 75; Zeitsch. anal. Chem. 9, 388). (ii.) The acid solution is boiled with zinc till the titanium is reduced to titanous salt, the zirconium is then precipitated by the addition of potassium sulphate (Compt. rend. 1863, 57, 298). (iii.) A neutral solution of the nitrates is added drop by drop to a boiling concentrated solution of ammonium salicylate ($1 : 5H_2O$), the solution boiled for one hour, concentrated, and the precipitated zirconium salicylate collected and washed with ammonium salicylate solution. Titanium salicylate is soluble in hot water and remains in the filtrate (Dittrich and Freund, Zeitsch. anorg. Chem. 1907, 56, 337, 348).

Cerium is precipitated in the aluminium group (III.*a*), and, together with the other metals of the rare earths, is separated from iron and aluminium by means of oxalic acid or ammonium oxalate. From lanthanum, praseodymium, and neodymium it may be separated by suspending the hydroxides in aqueous caustic potash and passing in chlorine until the liquid is no longer alkaline. The cerium remains precipitated as the yellow hydrated dioxide, whilst the other hydroxides are dissolved (Mosander). Various methods have been proposed similarly based on the oxidation of cerous compounds to the ceric condition (*v.* Ann. Chem. Pharm. 131, 359; Monatsh. 1884, 5, 508; Ber. 35, 672).

Thorium, together with the rare earths, is separated from the other elements by oxalic acid. The further separation is effected by the following methods:—

(i.) Monazite sand is heated with concentrated sulphuric acid at 180°–200° for 2 to 3 hours, and the product taken up with water, and the rare earths precipitated by the addition of oxalic acid. The precipitated oxalates, after washing till free from phosphoric acid, are ignited, and the resulting oxides dissolved in hydrochloric acid. The excess of acid is expelled by evaporation at 100°, the residue dissolved in water and treated with sodium thiosulphate. After 12 hours the solution is boiled for 10 minutes and filtered. The precipitate contains thorium, but contaminated with cerium; it is therefore redissolved and the precipitation repeated until the filtrate gives no precipitate on boiling with ammonia. At this stage the precipitate is ignited, fused with sodium hydrogen sulphate, the product dissolved in water, and the thorium finally precipitated with oxalic acid, the precipitate being ignited and weighed as ThO_2 (Fresenius and Hintz, Zeitsch. anal. Chem. 35, 543).

(ii.) The mixed oxalates obtained as before from the monazite sand are decomposed, and the metals converted into nitrates by repeated evaporation with nitric acid. The neutral solution of the nitrates is diluted with aqueous ammonium nitrate (10 p.c.) warmed to 80°, and the thorium precipitated as peroxide by the addition of pure hydrogen peroxide solution. The precipitate, which contains a trace of cerium peroxide, is filtered, washed with aqueous ammonium nitrate, ignited and weighed as ThO_2 (Benz, Zeitsch. angew. Chem. 1902, 15, 297; compare Chem. Zeit. 1908, 32, 509).

(iii.) Precipitation by organic acids. (*a*) Fumaric acid precipitates thorium fumarate in 40 p.c. alcohol, leaving the other rare earths in solution (Metzger, J. Amer. Chem. Soc. 1902, 24, 901). (β) *m*-Nitrobenzoic acid in aqueous solution precipitates its thorium salt, the separation being complete in the presence of aniline. Under these conditions, cerium, praseodymium, neodymium, and lanthanum remain in solution (Kolb and Akele, Zeitsch. angew. Chem. 1905, 18, 92).

(iv.) Boiling with potassium azide in neutral solution leads to the precipitation of thorium hydroxide, the salts of the other rare earth metals being unaffected (Dennis, J. Amer. Chem. Soc. 1896, 18, 947). Fusion with potassium hydrogen fluoride separates thorium and cerium from zirconium, for on extraction with water containing a little hydrogen fluoride, potassium zirconofluoride dissolves, leaving behind the fluorides of thorium and cerium (Chem. News, 1897, 75, 230).

Manganese and *iron* are separated in their alloys (ferromanganese, &c.) by dissolving the alloy in hydrochloric acid with a little nitric acid. After boiling off nitrous fumes, the solution is filtered and diluted with boiling water to 600 c.c. Ammonia is added till a faint turbidity remains, excess of neutral ammonium acetate is then quickly added, and the solution boiled. The basic ferric acetate thus precipitated contains some manganese; it is therefore redissolved and the separation repeated. The united filtrates are treated with excess of bromine followed by strong ammonia also in excess; the liquid is vigorously agitated during the addition of these reagents, and then heated slowly to boiling. The precipitate is collected, washed with boiling water, ignited and weighed as Mn_3O_4 (compare Riggs, Amer. J. Sci. 43, 135; Gooch, Zeitsch. anorg. Chem. 1898, 17, 268; Brearley and Ibbotson, Chem. News, 1902, 82, 209; Zeitsch. anal. Chem. 1904, 43, 382; Jannasch and Rühl, J. pr. Chem. 1905, 72, 1; Moore and Miller, J. Amer. Chem. Soc. 1908, 30, 593).

Nickel from cobalt. The solution, which should contain but little free acid, is mixed with excess of pure potassium cyanide free from cyanate (the ordinary cyanide is fused with charcoal, dissolved in water, filtered, and evaporated in a silver dish), heated to boiling, and mixed with a solution of mercuric oxide in mercuric cyanide. The precipitate, when washed, dried, and ignited, leaves a residue of nickel oxide NiO, which is weighed. Cobalt is usually determined by difference; but if direct estimation is required, the filtrate from the nickel is evaporated to dryness, heated for some time with strong sulphuric acid, and the cobalt estimated in the solution.

Nickel can be separated from cobalt and all the other metals of Groups III. and IV. by precipitation in ammoniacal or dilute acetic acid solution with dimethylglyoxime (*see Estimation of nickel*). If ferric salts are present, they should be reduced to the ferrous condition, or tartaric acid is added before rendering the solution alkaline; the organic acid prevents the co-precipitation of iron, chromium, and aluminium (Brunck, Zeitsch. angew. Chem. 1907, 20, 1845).

Cobalt from nickel. (i.) In acetic acid solution, nitroso-β-naphthol precipitates the cobalt as cobaltic nitroso-β-naphthoxide (Ilinski and Knorre, Ber. 18, 699). (ii.) Cobaltic hydroxide is precipitated from a neutral solution of the two metals by barium carbonate and bromine water (Taylor, Proc. Manchester Phil. Soc. 1902, 46, (ii.) 1). (iii.) Small quantities of cobalt can be detected and estimated in the presence of nickel by adding to a neutral solution concentrated aqueous ammonium thiocyanate. On shaking with amyl alcohol and ether, these organic solvents extract the double salt $(NH_4)_2Co(CNS)_4$ (blue solution), leaving the nickel in the aqueous solution (Ber. 1901, 34, 2050 and 3913). Zinc is also removed with the cobalt.

Cobalt is precipitated as double nitrite on adding potassium nitrite to an acetic acid solution of the two metals; the nickel is left in solution (Fischer, Pogg. Ann. 72, 477; and Funk, Zeitsch. anal. Chem. 1907, 46, 1).

The solution is treated with ammonium chloride, ammonia, and hydrogen peroxide, and warmed, when $[Co(NH_3)_5Cl]Cl_2$ is formed. On neutralising by means of acid, cooling, and adding excess of ammonium molybdate, the cobalt is precipitated as $Co_2O_3,10NH_3,6MoO_3$. This is washed with water and dried at 110° (Carnot, Bull. Soc. chim. 1917 [iv.] 21, 211).

Separation of zinc, manganese, nickel, and cobalt. The slightly acid solution of the four metals is treated with sodium carbonate till a permanent precipitate is formed, which is redissolved by a few drops of hydrochloric acid; then for every 100 c.c. of liquid 15 drops of the same acid are added, followed by 10 c.c. of 20 p.c. ammonium thiocyanate; the solution heated to 70° is then saturated with hydrogen sulphide; the zinc in the precipitate is determined either as sulphide or oxide. Manganese is separated from nickel and cobalt by passing hydrogen sulphide into a solution of their salts in acetic acid containing excess of ammonium acetate, when nickel and cobalt are precipitated as sulphides; the filtrate may, however, still contain small amounts of these metals. The solution is concentrated, treated with ammonium sulphide, and then with acetic acid. A further precipitate of nickel and cobalt sulphides is thus obtained (*v.* Treadwell and Kramers, Zeitsch. anorg. Chem. 1901, 26, 184; compare J. Soc. Chem. Ind. 1905, 24, 228; Bull. Soc. Chim. 1908, (iv.) 3, 114).

Zinc from nickel and cobalt. Add excess of pure potassium cyanide and precipitate the zinc with sodium sulphide.

GROUP IV.—The metals of this group are separated from those of the following group by precipitation with ammonium carbonate (*v. General methods of estimation*). The liquid is first made alkaline with ammonia and afterwards heated to boiling to ensure complete precipitation.

Barium from calcium and strontium. The dilute neutral or feebly acid solution is mixed with excess of freshly prepared hydrofluosilicic acid and one-third its volume of 95 p.c. alcohol allowed to stand twelve hours, collected on a weighed filter, washed with a mixture of equal parts of water and alcohol, and dried at 100°. Calcium and strontium are not precipitated.

Barium from strontium. Ammonium bichromate and ammonium acetate are added alternately to a solution of barium and strontium salts containing ammonium acetate. After three hours the precipitate, $BaCrO_4$, is washed with ammonium acetate solution, dried at 180°, and weighed (Kahan, Analyst, 1908, 33, 12; *v.* Zeitsch. anal. Chem. 1905, 44, 742; J. Amer. Chem. Soc. 1908, 30, 1827).

Barium and strontium from calcium. The solution is mixed with a concentrated solution of ammonium sulphate, using 50 parts of the latter salt for one part of the mixed salts, heated to boiling with addition of a small quantity of ammonia, and the precipitate washed with water containing ammonium sulphate. The filtrate contains the calcium, which can be precipitated by ammonium oxalate.

Calcium from strontium. Convert the metals into nitrates, evaporate to dryness, and extract with a mixture of equal volumes of alcohol and ether, which dissolves calcium nitrate but not strontium nitrate.

Calcium from strontium and barium. The nitrates are dried at 140° and extracted with amyl alcohol, which dissolves out the calcium salt, leaving the other two undissolved (Browning, Amer. J. Sci. 43, 50, 314).

Calcium from magnesium. The calcium is precipitated by ammonium oxalate (*v. Determination of metals*), adding sufficient of this salt to convert both metals into oxalates, since calcium oxalate is appreciably soluble in a solution of magnesium chloride. In very accurate separations the precipitate should be filtered off, redissolved in hydrochloric acid, and reprecipitated by adding excess of ammonia and a small quantity of ammonium oxalate (*cf.* Richards, Zeitsch. anorg. Chem. 1901, 28, 71; Zeitsch. angew. Chem. 1908, 21, 592; J. Amer. Chem. Soc. 1909, 31, 917).

GROUP V.—*Magnesium from alkalis.* The magnesium is precipitated with ammonium phosphate in the usual way, the filtrate evaporated to dryness, heated to expel ammonium salts, the residue evaporated two or three times with strong nitric acid to remove hydrochloric acid, and the phosphoric acid removed by stannic oxide (*v. Phosphoric acid from metals*; *v.* Gibbs, Amer. J. Sci. [3] 5, 114; Neubauer, Zeitsch. angew. Chem. 1896, 9, 439; Gooch, Zeitsch. anorg. Chem. 1899, 20, 121).

In solutions free from ammonium salts, the magnesium can be precipitated as magnesium hydroxide by the addition of aqueous barium hydroxide. The excess of barium is removed by ammonium carbonate and the alkalis are determined in the filtrate. Magnesium chloride is also separated from the alkali chlorides by ignition with mercuric oxide, when mercuric chloride and the excess of oxide volatilise, leaving magnesia, from which the soluble alkali chlorides are readily separated.

Alkalis from magnesium. (*a*) The solution is made distinctly alkaline with pure milk of lime (calcium hydroxide suspended in water) and boiled for some time, care being taken that it remains alkaline. The liquid is filtered, made alkaline with ammonia, and the calcium precipitated by adding ammonium carbonate and a small quantity of ammonium oxalate. The filtrate is acidified with hydrochloric acid and evaporated in a weighed platinum dish, heated to expel ammonium salts, and the alkaline chlorides weighed. They should dissolve completely in water and should give no precipitate when mixed with ammonium carbonate and allowed to stand for some time. If any calcium is present, it must be removed by repeating the treatment with ammonium carbonate and oxalate.

(*b*) The solution, which must contain only potassium, sodium, and magnesium, is mixed with excess of oxalic acid, evaporated to dryness, and the oxalic acid expelled by heating carefully over a lamp until white fumes cease to come off. The residue is treated with water, when potassium and sodium dissolve as carbonates, whilst magnesium oxide remains undissolved.

Alkalis from silicates. (*a*) The finely powdered silicate (1 gram) is mixed intimately with an equal weight of ammonium chloride and eight parts of dense granular calcium carbonate, and heated to redness for half an hour. The product is boiled with water in a platinum or silver dish for two hours, care being taken to make up the loss by evaporation, the liquid is filtered and the residue well washed with hot water. The filtrate, which contains calcium and the alkalis, is treated in the manner just described. In this method of decomposition, which is due to J. Lawrence Smith, the silicate is decomposed by the calcium oxide, which is dissolved by the fused calcium chloride formed by the action of the ammonium chloride on the calcium carbonate.

(*b*) The silicate is treated in a platinum dish with excess of sulphuric and hydrofluoric acids, and the mixture evaporated on the water-bath until the mineral is entirely decomposed. The temperature is then raised to drive off the greater part of the sulphuric acid, and the cooled residue extracted with water. The sulphates are converted into chlorides by barium chloride, the metals of Groups III. and IV. precipitated by ammonia and ammonium carbonate, the magnesium removed by barium hydroxide, and the excess of this reagent eliminated by ammonia and ammonium carbonate. The alkali chlorides remaining in the final filtrate are estimated as indicated in the following section. Certain native silicates of the andalusite group are not decomposed completely by this treatment with hydrofluoric acid; these minerals may, however, be broken up by ignition with ammonium fluoride.

(*c*) The alkali and other metals contained in a refractory silicate may be separated by heating the mineral with lead carbonate. The product is extracted with nitric acid; the lead removed as chloride and sulphide, and the metals in solution dealt with in the customary manner (Jannasch, Zeitsch. anorg. Chem. 1895, 8, 364).

(*d*) Silicates of different types are decomposed by fusion with boric anhydride followed by extraction with methyl alcoholic hydrogen chloride and evaporation to remove the boric acid as volatile methyl borate (Ber. 1895, 28, 2822; Zeitsch. anorg. Chem. 1896, 12, 208).

Potassium from sodium. The metals are converted into chlorides, which are evaporated to dryness and weighed together after drying at 150°. The salts are dissolved in water, mixed with platinic chloride in sufficient quantity to convert both into platinichlorides, and evaporated nearly but not quite to dryness. The residue is then treated with alcohol, which dissolves the sodium but not the potassium salt (*v. Potassium*). If the mixture is evaporated to complete dryness and heated so that the sodium platinichloride becomes anhydrous, it dissolves with difficulty in alcohol. Under some conditions reversion takes place and sodium chloride separates in white crystals insoluble in alcohol. In this case the alcohol is very carefully evaporated and the residue again treated with platinic chloride.

In order to separate small quantities of potassium from large quantities of sodium, advantage may be taken of the fact that potassium chloride is more soluble than sodium chloride in strong hydrochloric acid (Zeitsch. analyt. Chem. 1880, 156). The dry mixed chlorides are thoroughly moistened with concentrated hydrochloric acid: 2 c.c. of the acid is then added, and the salt thoroughly crushed and stirred with a glass rod. After standing for a few minutes the acid is poured off into a small dish. Ten repetitions of this treatment, using 2 c.c. of acid each time, will suffice to remove all potassium, whilst the greater part of the sodium chloride is not dissolved. The acid solution is evaporated to dryness and the potassium determined as platinichloride (Chem. Soc. Trans. 39, 506). By adopting this plan much less platinic chloride is required, and the separation is much more accurate.

Lithium from sodium and potassium When a lithia-containing silicate (*e.g.* lepidolite) is broken up by one of the preceding processes the precipitable metals of Groups I.–IV. are first removed and the alkali metals converted into chlorides. The combined chlorides are dried and weighed; potassium is estimated in one portion, and in a second portion the lithium is estimated by extracting the chlorides with amyl alcohol, or better, *iso*butyl alcohol, or with ether-alcohol saturated with hydrogen chloride. Anhydrous lithium chloride is soluble in these media, whereas sodium and potassium chlorides are practically insoluble therein (*cf.* Winkler, Zeitsch. anal. Chem. 1913, 52, 628; Analyst, 1913, 581; Palkin, J. Amer. Chem. Soc. 1916, 38, 2326; Analyst, 1917, 54). Lithium chloride has also been separated from the chlorides of the other alkali metals and barium by dissolving it in boiling pyridine, in which the others are insoluble (Kahlenberg and Krauskopf, J. Amer. Chem. Soc. 1908, 30, 1104; Skinner and Collins, J. Soc. Chem. Ind. 1913, 32, 214). (For the separation of lithium as phosphate and fluoride, *see* Ann. Chim. Phys. 98, 193; Frdl. 29, 332, and Analyst, 16, 209.)

Rubidium and *cæsium* are separated from each other and from potassium by taking advantage of the difference in the solubility of their platinichlorides. Rubidium hydrogen tartrate is more than nine times less soluble than the cæsium salt. Cæsium carbonate alone of the alkali carbonates is soluble in alcohol. Cæsium gives rise to a series of sparingly soluble perhalides and yields double chlorides with lead and antimony chlorides (*v.* Wells, Amer. J. Sci. 43, [3] 17; and Amer. Chem. J. 1901, 26, 265). The metals may also be separated by taking advantage of the different solubilities of their respective alums, particularly of their iron alums (Browning and Spencer, Amer. J. Sci. 1916, 42, 279).

Ammonium salts can be removed from a solution in two ways: (1) By evaporating to dryness and carefully heating over a lamp until all fumes cease to come off. (2) By concentrating the solution and heating for some time with excess of strong nitric acid. When evolution of oxides of nitrogen ceases, the liquid is evaporated to complete dryness and the nitrates converted into chlorides by repeated treatment with hydrochloric acid if necessary.

B. *The Estimation of Acid Radicals.*

Bromine from chlorine. (*a*) The two elements are precipitated by excess of silver nitrate and weighed together. The filter ash is removed, the precipitate cautiously heated to fusion, and a portion poured into a weighed porcelain boat. The boat is again weighed, heated to fusion in a current of dry chlorine in a glass tube until all bromine is expelled, and the silver chloride formed is weighed. It is advisable to heat in chlorine for a further period of ten minutes and weigh again. The loss of weight multiplied by 4·223 gives the amount of silver bromide in the weight of precipitate treated with chlorine, from which the quantity in the whole precipitate is readily calculated (*v. Indirect methods of determination*).

This method gives accurate results if the proportion of bromine is not too small. When a small quantity of bromine is mixed with a large quantity of chlorine, the former may be concentrated by taking advantage of the fact that if a limited quantity of silver nitrate is added, the precipitate will contain all the bromine, but only a portion of the chlorine. In one portion of the substance the two elements are determined together by complete precipitation. Another portion in somewhat dilute solution is mixed with a quantity of silver nitrate insufficient for complete precipitation, and allowed to stand in the cold for some time with repeated agitation. The precipitate is collected, washed, and weighed, and the proportion of bromine determined in the manner already described. The quantity of silver nitrate which should be used depends upon the relative proportions of chlorine and bromine. If one part of bromine is present for every 1000 parts of chlorine, one-fifth or one-sixth of the silver necessary for complete precipitation should be used; if one part to 10,000, only one-tenth; if one part to 100,000, only one-sixtieth (Fehling).

(*b*) The solution of the two halides heated at 70°–80° is treated with ammonium persulphate, and the liberated bromine volatilised in a current of air, collected in sulphurous acid, and estimated as silver bromide (Engel, Compt. rend. 1894, 118, 1263).

Iodine is separated from chlorine in exactly the same way as bromine from chlorine. The loss of weight on treating with chlorine, multiplied by 2·569, gives the weight of silver iodide in the portion of precipitate taken.

Iodine from chlorine or bromine. The solution is slightly acidified with hydrochloric acid, mixed with palladious chloride until precipitation is complete, and allowed to stand in a warm place for twenty-four or forty-eight hours. The precipitate of palladious iodide PdI_2 is collected on a weighed filter, washed with warm water, and dried at 100°, or is reduced by heating in hydrogen and the metal weighed.

Iodine can also be liberated by nitrous acid and estimated volumetrically (*v. Volumetric methods*).

Bromine, chlorine, and iodine from one another. (*a*) The three elements are precipitated and weighed together in one part of the solution. In another part the iodine is separated as palladious iodide by palladious chloride, or better, nitrate; the excess of palladium is removed by hydrogen sulphide and excess of the latter by ferric sulphate; and the chlorine and bromine in the filtrate are precipitated completely or fractionally and the bromine determined in the manner previously described. The chlorine is estimated by difference.

(*b*) A direct method of estimating the three halogens in a mixture of their soluble salts has been investigated by Jannasch and his collaborators. The process in its present stage of development gives a sharp separation of chlorine and iodine, but the results for bromine are rather low. The mixture dissolved in 25 c.c. of water is heated to boiling with acetic acid and hydrogen peroxide, and the liberated iodine expelled by a current of carbon dioxide. The bromine is then liberated by adding excess of hydrogen peroxide and moderately strong sulphuric acid (5 : 3). The iodine is collected in an ammoniacal solution of hydrazine sulphate and the bromine in alkaline hydrazine sulphate. After acidifying with nitric acid, the iodine and bromine are precipitated as silver salts, and the chlorine left in the distilling flask is similarly precipitated (Ber. 1906, 39, 196, 3655; J. pr. Chem. 1908, 78, 29; Zeitsch. anorg. Chem. 1, 144 and 245). (For other processes for separating the halogens, *see Volumetric section*; and Monatsh. 13, 1; Chem. Soc. Trans. 1893, 63, 1051; Compt. rend. 1898, 126, 187; Ber. 1899, 32, 3615.)

Several indirect methods of estimating these three elements in a mixture have been proposed. They are based on the methods given, together with the fact that the radicals may be precipitated exactly by a standard solution of silver nitrate and the precipitate weighed, the proportion of silver and halides in the precipitate being thus determined (*v.* Fresenius, Quantitative Analysis, sect. 5).

Indirect Methods of Determination. This estimation of two or three halogens in a mixture furnishes a good example of indirect methods of analysis, which are adopted in those cases where the separation of two or more constituents is either impossible or inconvenient. The calculation of the relative proportions of these constituents becomes possible when one can obtain as many independent relationships as there are radicals to be determined. The estimation of chlorine and bromine (*a*) is a case in point. The loss of weight due to the replacement of Br.(79·92) by Cl(35·46) is proportional to the amount of bromine present. Let w = loss of weight. Now

$$\frac{Cl}{Br} = \frac{35{\cdot}46}{79{\cdot}92} \text{ and hence } Br - \frac{35{\cdot}46}{79{\cdot}92}Br = w;$$

or Br = 1·797 w: *i.e.* the loss of weight multiplied by 1·797 gives the quantity of bromine present.

Similarly, the halogens in a mixture of soluble chloride, bromide, and iodide can be calculated from the following data: (i.) the amount of iodine present, set free by nitrous acid or hydrogen peroxide and acetic acid; (ii.) the total weight of mixed silver halides obtained from a known amount of mixture; (iii.) the silver required for the complete precipitation of the three halogens; this is obtained volumetrically. The indirect method can also be applied to the estimation of sodium and potassium contained in the mixed chlorides from a silicate analysis (*v. supra*). The data required are: (i.) the weight A of mixed chlorides; (ii.) the weight B of chlorine therein contained, this amount being determined either gravimetrically or volumetrically. Let x and y be the amounts of potassium and sodium respectively, then these quantities are readily calculated from the following equations, where Cl, K, and Na represent the atomic weights of these elements.

$$x + y = A - B$$

$$\frac{Cl}{K}x + \frac{Cl}{Na}y = B$$

These indirect methods give useful results only when the atomic or molecular weights of the two radicals differ considerably, and when the quantities present are approximately equal. Moreover, the results are affected to a considerable extent by comparatively small experimental errors.

Cyanide from chloride. Silver nitrate is added in excess to an approximately 2 p.c. solution of soluble cyanide and chloride. An excess of normal nitric acid is now added, and the mixture containing the freshly precipitated silver salts is distilled, when hydrocyanic acid is expelled quantitatively and estimated in the distillate by precipitation as silver cyanide with acidified silver nitrate, drying this precipitate at 110°, and weighing in a Gooch crucible or on a tared filter paper (Plimmer, Chem. Soc. Trans. 1904, 85, 12; compare also Richards and Singer, Amer. Chem. J. 1902, 27, 205).

Phosphoric acid from metals. (*a*) The nitric acid solution, as free as possible from hydrochloric acid, and free from silicic and arsenic acids, is mixed with excess of a solution of ammonium molybdate in nitric acid, heated gently for a few minutes, and filtered after standing for a short time. The precipitate is washed with dilute nitric acid, dissolved in ammonia, and the phosphoric acid precipitated by magnesia mixture. This method is more especially applicable when the quantity of phosphoric acid is relatively small. To prepare ammonium molybdate solution, 25 grams of the salt is dissolved in 100 c.c. of dilute ammonia, and the solution poured gradually with constant and vigorous agitation into 500 c.c. of a mixture of 3 vols. strong nitric acid and 1 vol. water. The liquid is heated at 50° for some time and the clear solution drawn off.

(*b*) By stannic oxide. The nitric acid solution is concentrated, mixed with fuming nitric acid boiling at 86°, heated gently, and granulated tin added gradually in quantity not less than four times the amount of phosphoric acid present. The stannic oxide produced forms an insoluble compound with the phosphoric acid. This is filtered off, washed with hot water, dissolved in caustic potash, the solution saturated with hydrogen sulphide, acidified with acetic acid, and the stannic sulphide removed. The filtrate is concentrated, any stannic sulphide which separates subsequently is removed, and the phosphoric acid is estimated in the usual way. The original filtrate from the stannic oxide contains the metals previously combined with the phosphoric acid.

(*c*) The nearly neutral solution is mixed with silver nitrate and digested for some time with excess of silver carbonate. The phosphoric acid separates as silver phosphate, the metals remain in solution with the excess of silver nitrate. The silver is removed by hydrochloric acid.

(*d*) When the phosphoric acid is combined with metals which form phosphates insoluble in water but soluble in acetic acid, the solution is nearly neutralised, mixed with sodium or ammonium acetate, and a slight excess of ferric chloride containing a known weight of iron added. The liquid is heated to boiling, the mixture of ferric phosphate and basic acetate washed with hot water, dried, and heated in a platinum crucible until the weight is constant. The weight of the precipitate *minus* the known weight of the ferric oxide gives the phosphoric anhydride P_2O_5. The precipitate may be moistened with nitric acid before the final ignition.

Phosphoric acid in silicates. In the analysis of silicates (*v. supra*) the phosphoric acid is found together with iron and aluminium in the precipitate produced by ammonia in the filtrate from the silica. This mixture is analysed in accordance with the method indicated under the separations of metals (Group III.).

Phosphorus and silicon in iron and steel. The iron or steel borings are dissolved in nitric acid ($1HNO_3$ sp.gr. 1·4 : $1H_2O$); the solution evaporated to dryness, and the residue ignited carefully until all the ferric nitrate is converted into ferric oxide. The ignited residue is dissolved in concentrated hydrochloric acid heated nearly to boiling, when the ferric oxide and phosphate pass into solution, leaving insoluble silica. The solution is evaporated to dryness, moistened with strong hydrochloric acid, and taken up with water; the silica is collected, ignited, and weighed, its purity being tested by treatment with hydrofluoric and sulphuric acids. The phosphoric acid in the filtrate is estimated by either of the following methods.

(*a*) The ferric solution, diluted and almost neutralised with ammonia, is reduced with sulphurous acid or sodium sulphite. Hydrochloric acid is added and the excess of sulphur dioxide expelled by boiling. A small portion of the ferrous iron is now reoxidised with a few drops of bromine water. Ammonia is added carefully till a brown precipitate is formed which becomes green on stirring. Acetic acid is added till the precipitate either dissolves or becomes whiter, and the solution then heated to boiling. The precipitate, which contains all the phosphorus as ferric phosphate mixed with basic ferric acetate, is dissolved in hydrochloric acid, the solution evaporated nearly to dryness, excess of citric acid added, and then magnesia mixture and ammonia. The magnesium ammonium phosphate is redissolved in hydrochloric acid and reprecipitated in the presence of citric acid to remove a small amount of iron, and ignited and weighed as $Mg_2P_2O_7$.

(*b*) The filtrate from the silica is evaporated to dryness, the residue dissolved in dilute nitric acid, ammonium nitrate added, and the solution heating to boiling. A boiling solution of ammonium molybdate is then added to phosphate solution, when ammonium phosphomolybdate is precipitated quantitatively. This precipitate is redissolved in ammonia to which ammonium nitrate and ammonium molybdate are added, and reprecipitated by adding hot nitric acid to the boiling solution. The compound is now pure, and is collected, washed with water containing ammonium nitrate and nitric acid, and either dried at 160°–180° or gently ignited. In the former case it is weighed as $(NH_4)_3PO_4,12MoO_3$ (containing 3·782 p.c. P_2O_5) or in the latter as $P_2O_5,24MoO_3$ (containing 3·946 p.c. P_2O_5) (*v.* Ber. 1878, 11, 1640; Zeitsch. anorg. Chem. 1893, 32, 144; Amer. Chem. J. 34, 204; Analyst, 1909, 34, 392; Chem. Zeit. 21, 442).

Separation of phosphoric and titanic acids (*v.* J. Soc. Chem. Ind. 1895, 14, 443). Estimation of phosphorus in phosphor-bronze (*v.* J. Amer. Chem. Soc. 1897, 19, 396) in phosphor-tin (J. Soc. Chem. Ind. 1908, 27, 427).

Silicic acid from titanic acid. The silica and titanium dioxide are weighed together, the mixture fused with a somewhat large quantity of potassium hydrogen sulphate, and the cooled mass extracted with water. Silica is left undissolved, titanic oxide dissolves, and can be precipitated from the filtrate by ebullition (*v. Titanium*).

Sulphides. If the sulphides are decomposable by hydrochloric acid, the hydrogen sulphide is absorbed in hydrochloric acid containing bromine (*v. Determination of metals*). Insoluble sulphides are decomposed by gently heating with *aqua regia* or with hydrochloric acid and bromine, and the sulphuric acid estimated in the solution. The latter method gives the total sulphur.

Sulphur in coal and coke. The finely powdered material (1 gram) is mixed intimately with 1 gram of calcined magnesia and 0·5 gram of sodium carbonate, and ignited to dull redness in an open platinum crucible for 1 hour, the mixture being stirred every five minutes with a platinum wire. The mixture is then heated strongly for 10 minutes with 1 gram of ammonium nitrate. The residue is extracted with water and the sulphate determined in the usual way (Eschka). The sulphur may also be determined by heating the coal with sodium or potassium carbonate (4 parts) alone, and extracting the residue with hydrochloric acid and a few drops of bromine (Nakamura). (*Compare* also Zeitsch. angew Chem. 1905, 18, 1560; Chem. Zeit. 1908, 32, 349; J. Russ. Chem. Soc. 1902, 34, 457.)

Sulphur in pyrites. The pyrites is oxidised either by fusion with sodium peroxide and sodium carbonate or by oxidation with nitric acid and bromine. These processes convert the sulphur to sulphate, which is estimated in the usual way (*v.* J. pr. Chem. 1892, [2] 45, 103; Zeitsch. anorg. Chem. 6, 303; *l.c.* 1896, 12, 129; J. Soc. Chem. Ind. 1905, 24, 7; Chem. News, 1906, 93, 213).

A convenient method of determining sulphur in pyrites consists in oxidation with bromine in carbon tetrachloride solution, followed by treatment with nitric acid, and precipitation of the sulphuric acid as barium sulphate after removal of silica and reduction of ferric salts (J. Soc. Chem. Ind. 1912, 919). Bartsch (Chem. Zeit. 1919, 43, 33) finds that the sulphur in pyrites yields hydrogen sulphide when treated with hydrobromic acid in contact with mercury and bases on this observation a rapid method for the valuation of pyrites. For details of the process and the apparatus employed, *see* Analyst, 1919, 148.

Sulphuric acid from all other acids except hydrofluosilicic by precipitation with barium chloride in presence of hydrochloric acid.

Sulphuric acid from hydrofluosilicic acid. The solution is mixed with excess of potassium chloride and an equal volume of strong alcohol, filtered through a weighed filter, and the precipitate of potassium silicofluoride (K_2SiF_6), washed with a mixture of equal volumes of alcohol and water, and dried at 100°. The sulphuric acid in the filtrate is estimated in the usual way after evaporation of the alcohol.

Titanic acid from silicic acid (*v. Silicic acid from titanic acid*).

Boric acid. The borates of the alkali and alkaline earth metals, when heated with pure methyl alcohol (free from acetone) and acetic acid, evolve all the boron present in the form of methyl borate (b.p. 65°). This liquid, when added to moist lime, is completely hydrolysed and the boric acid set free combines with the calcium oxide forming calcium borate. The decomposition is effected in a small retort fitted with a tap funnel for introducing further quantities of methyl alcohol. The retort is connected with a water condenser and a conical flask containing a weighed amount of quicklime. This lime is carefully slaked before the distillation, and the methyl borate dropping into the conical flask is decomposed and the boric acid taken up by the lime. The contents of the receiver are rinsed into a platinum dish, and the methyl alcohol evaporated at as low a temperature as possible. The residue is cautiously ignited to destroy calcium acetate, and the increase in weight of the lime represents the amount of boric anhydride B_2O_3 obtained from the borate. Instead of lime, aqueous ammonium carbonate may be used in the receiver, and the liquid poured on to slaked lime (from a known weight of quicklime) contained in a platinum dish (Zeitsch. anal. Chem. 1887, 26, 18, 364).

VOLUMETRIC METHODS.

In volumetric analysis the proportion of a substance is ascertained, not by separation and weighing, but by determining the exact volume of a reagent solution of known concentration required to produce some particular reaction, such as neutralisation, oxidation, or precipitation. The termination of the reaction is indicated by some end-reaction, which is usually a production, destruction, or change of colour, the formation of a permanent precipitate or the cessation of the formation of a precipitate. In determining the strength of caustic soda, for example, it is coloured yellow with methyl orange, and a dilute solution of sulphuric acid of known strength is added gradually until the yellow colour of the methyl orange just changes to red, thus indicating the point of neutralisation. The volume of acid required is noted; the weight of sulphuric acid which it contains, and hence the weight of soda which it will neutralise, is known, and thus the proportion of soda in the substance is determined.

In order that a reaction may serve as the basis of a volumetric process, it must be rapid, simple, and definite, and not complicated by secondary reactions. It should remain constant through considerable variations in conditions, and should not, for example, be materially affected by the degree of concentration of the solution. A final reaction should be rapid, perfectly decisive, and should only require a slight excess of the reagent for its production. In many cases a third substance is employed to indicate the completion of the reaction, and is termed an *indicator*. It is an *internal indicator* if it is added to the bulk of the liquid, an *external indicator* if drops of the liquid are removed and brought in contact with it.

The execution of volumetric processes involves the possession of accurately graduated instruments of three kinds, viz. flasks, pipettes, and burettes. The flasks should be fitted with well-ground stoppers, and should have somewhat long necks, the graduation being not higher than the middle of the neck, in order that there may be sufficient empty space for efficient agitation. Flasks holding respectively 1000 c.c., 500 c.c., 250 c.c., and 100 c.c., are used. Each flask should have two graduation marks, viz. the *containing mark*, indicating the point to which the flask must be filled in order that it may then contain the particular volume of liquid, and the *delivery mark* or point to which the flask must be filled in order that it may deliver the given volume of liquid when emptied by draining. A pipette is usually a cylindrical bulb terminating at each end in a tube, the lower of which is drawn out to a jet, whilst the end of the upper tube is slightly contracted so that it may be readily closed by the forefinger and the flow of liquid regulated or stopped altogether. Usually a pipette has only a *delivery* mark, but occasionally they are graduated throughout their whole length, and then take the form of a somewhat wide tube contracted to a jet at the bottom and terminating in a narrower tube at the top. Pipettes of 100 c.c., 50 c.c., 25 c.c., 10 c.c., and 5 c.c. capacity are most generally useful. A burette is a long tube of uniform bore, 12 to 15 mm. in diameter, graduated in cubic centimetres and tenths or fifths. A convenient capacity is 50 c.c. It is open at the top and contracted at the lower end, to which a glass jet is attached by means of a piece of narrow indiarubber tubing. This tubing is nipped by a spring pinchcock, which is opened by the pressure of the fingers, the flow of liquid being thus regulated. A better plan is to insert in the indiarubber tubing a short piece of glass rod the diameter of which is just sufficient to prevent the flow of liquid when the tubing remains circular. If, however, the tubing is squeezed out laterally by the pressure of the thumb and fore-finger (Fig. 9), a channel is made through which the liquid can pass, and by increasing or reducing the pressure, the flow of liquid can be regulated to a nicety. Certain reagents act upon indiarubber, and for these a burette with a glass stopcock should be used. This form is, in fact, the most convenient for all purposes. The stopcock may be prevented from sticking by a little vaseline or paraffin, and from slipping out by a small indiarubber ring passed over the tap and round the burette tube. Sometimes the tube carrying the stopcock is not in the same line with the burette, but is bent twice at right angles, so that the burette jet, although still vertical, is one or two inches in advance of the burette itself. This form is useful when titrating hot liquids, since the risk of heating the burette and its contents is reduced. An alternative method is to have the top of an ordinary burette funnel-shaped, which admits of the burette being slung in a stand by the funnel without other support, so that it can be tilted from the vertical when titrating hot solutions.

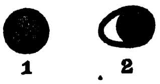

FIG. 9.

When a burette is in use, it is important that it should be supported in a vertical position. This can be done by means of a clamp attached to a stand similar to a retort stand. A useful and easily constructed burette stand is described in J. Amer. Chem. Soc. 1905, 27, 1442.

When several different solutions are being used continually, it is convenient to have the series of burettes attached to a revolving stand, so that each may be brought round to the front when required. Short test-tubes inverted over the tops of burettes serve to keep out dust.

Standard solutions should be kept in well-stoppered bottles in a cool place protected from bright light. When many determinations of the same kind have to be made, it is convenient to keep the reservoir of standard solution attached to the burette to facilitate the filling of the latter. A glass T-piece is introduced between the graduated part of the burette and the stopcock or pinchcock, and is attached by means of an indiarubber tube to a tubulus at the bottom of the bottle which contains the standard solution and stands on a shelf above the burette. If this bottle has no tubulus, a glass tube bent twice at right angles, with one limb reaching to the bottom of the bottle and the other connected with the burette, is fitted into the neck of the bottle by means of a cork, and is kept always full, so that it acts as a siphon. There must, of course, be an entrance for air as the liquid flows from the bottle. The flow of liquid into the burette is regulated by a pinchcock on the indiarubber tube. If the standard solution acts upon indiarubber, all these connections must be constructed of glass tubing. Burettes may now be obtained fitted with Greiner and Friedrich's three-way taps (compare Fig. 12); these are readily connected to reservoirs and filled from the bottom. Filling the burette from the bottom avoids the formation of air-bubbles, but it can also be filled from the top if the tube from the stock bottle is bent slightly so that the liquid flows down the side of the burette. A convenient form of apparatus for this method, which is the only one available with an ordinary tap burette without a side-tube attachment, is described in Chem. News, 1906, 93, 71. When the standard solution alters if exposed to air, the surface of the liquid may be covered with a layer of rectified paraffin of moderately high boiling-point, or the neck of the bottle may be provided with a cork carrying a tube containing caustic potash, or alkaline pyrogallate, through which all air entering the bottle has to pass. A still better plan is to fill the upper part of the stock bottle with carbon dioxide, or, if the nature of the solution permits, with coal gas, and connect it by means of a cork and tube with a self-acting carbon dioxide apparatus or the ordinary gas supply. When solution is withdrawn, carbon dioxide or coal gas enters. The burette should be kept permanently attached to the reservoir as just described, and the top end of the burette also put into communication with the inert gas supply.

Graduation of the instruments.—Accurate calibration of the measuring vessels is of course necessary if correct results are to be obtained, and it is never advisable to trust the makers' graduations. All the instruments should be checked before being taken into use. Although it is sufficient for most purposes if the relative volumes of the vessels are correct, they should nevertheless be graduated in true cubic centimetres. With gas-volumetric apparatus this procedure is essential. If the calibration is performed at a temperature of 18°–20°, variations from the true volume resulting from the expansion of the glass are so small for the intervals of temperature through which the laboratory is likely to vary, that they may be neglected.

The vessels are checked by ascertaining the weight of distilled water at a known temperature which they will contain or deliver as the case may be. A large beaker of distilled water is placed in the balance room, and left for some hours till its temperature has become constant. The vessels to be calibrated are thoroughly cleansed by successive treatments with concentrated caustic potash, distilled water, and a warm solution of chromic acid in concentrated sulphuric acid, and then rinsed well with distilled water. The flasks are then dried. A narrow strip of paper is attached vertically to the neck of the litre flask near the mark, the flask placed on one pan of a large balance capable of responding to 0·05 gram, and counterpoised. Weights corresponding with the weight of water which at the temperature of the supply in use will occupy 1000 c.c., are then placed in the pan; the flask is filled nearly to the mark with water, and water is gradually added until flask and weights are in equilibrium. Any water adhering to the inside of the neck of the flask above the mark must be removed by means of filter paper. If the mark on the neck of the flask is thus found to be in error, a pencil mark is made on the strip of paper at the point corresponding with the lower edge of the meniscus, the glass above and below is evenly coated with a thin film of wax, and a horizontal ring is scratched through by means of a needle precisely on a level with the pencil mark. The ring is covered with a small piece of filter paper, which is moistened with hydrofluoric acid, care being taken to remove air-bubbles. After a few minutes the acid is washed off and the wax removed, when a new mark will be found etched into the glass.

In calibrating volumes by determining weights of water, it is necessary to reduce the weight to vacuum standard, and then divide the result by the density of the water in order to obtain accurately the volume in true cubic centimetres. This calculation can be avoided by making use of the following table:—

t°	0°	1°	2°	3°	4°	5°	
x	1·19	1·13	1·09	1·07	1·06	1·07	
t°	6°	7°	8°	9°	10°	11°	
x	1·09	1·13	1·18	1·25	1·33	1·43	
t°	12°	13°	14°	15°	16°	17°	
x	1·53	1·65	1·78	1·93	2·09	2·25	
t°	18°	19°	20°	21°	22°	23°	
x	2·43	2·62	2·82	3·03	3·26	3·49	
t°	24°	25°	26°	27°	28°	29°	30°
x	3·73	3·98	4·24	4·52	4·80	5·08	5·38

x is the quantity to be subtracted from 1000 to obtain the apparent weight (in air, when brass weights are employed) of 1000 c.c. of water at the temperature t. For example, at 18° the apparent weight of 1000 c.c. is $1000 - 2{\cdot}43 = 997{\cdot}57$ grams.

The litre flask having been graduated to contain, it should now be graduated to deliver. The full flask is carefully emptied and allowed to drain for a definite time—say thirty seconds—again counterpoised with the water adhering to the inside, and again filled with a further 1000 c.c. of water in the manner previously described. The other flasks are graduated in the same way, subtracting only $\frac{1}{2}x$ from 500 grams in the case of the 500 c.c. flask, $\frac{1}{4}x$ from 250 grams for the 250 c.c. flask and so on.

The quantity of liquid which a pipette will deliver depends to some extent on the manner in which it is emptied. A small quantity of liquid always remains in the jet, and this should not be blown out. The best plan is to allow the pipette to empty itself whilst held vertically, and then to let it drain for twenty seconds with the point of the pipette just touching the side of the receiving vessel; but the method of emptying employed in the calibration must be adhered to in its subsequent use.

To test the accuracy with which a pipette has been graduated, it is filled to the mark with distilled water at an observed temperature, the contents delivered into a light, tared, stoppered flask, and accurately weighed. The operation is repeated several times, and from the mean result the true volume is calculated by using the table previously given; for it is clear that $1 - \frac{x}{1000}$ denotes the apparent weight of 1 c.c. of water at $t°$, or $1 + \frac{x}{1000}$ equals the volume at $t°$ occupied by 1 gram of water weighed in air with brass weights. If the error in graduation is greater than can be allowed, another mark must be made; its position may be found by repeated trials, a strip of paper being pasted along the stem, and the volumes corresponding to various pencil marks being found as above. The new mark is then etched in with hydrofluoric acid.

A convenient method for directly calibrating pipettes is described by Thorpe (Quantitative Analysis). The pipette is suspended from one arm of a balance by means of a clip, so as to hang perpendicularly and pass through a hole in the bottom of the balance case or of a specially constructed table. A suitable clip (Fig. 10) consists of a stout brass wire frame carrying two clips of sheet brass closed by sliding collars. The upper end of the pipette is passed through the lower clip and connected by caoutchouc tubing with a glass stopcock fixed in the upper clip. The other end of the stopcock is provided with a piece of caoutchouc tubing, to which a piece of thermometer tube or a piece of wider glass tube can be attached. The wider glass tube, which serves as a mouthpiece, is first attached to the stopcock, and the pipette is filled with water to a short distance above the mark, and then emptied by the method to be adopted in its subsequent use. It is then counterpoised on the balance with the adhering water inside, the wide tube being replaced by the thermometer tube, and the requisite weights placed on the other pan. The pipette is again filled to a short distance above the mark; the thermometer tube, which is drawn out at one end, is attached again, and the stopcock is opened. Water drops very slowly from the end of the pipette, and it can be arrested the moment the balance is in equilibrium. The level of the water is marked on a piece of paper gummed to the pipette, and a new ring etched with hydrofluoric acid.

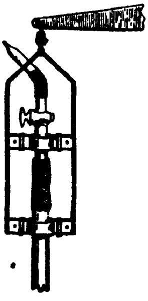

FIG. 10.

The burette is most simply calibrated by the method due to Ostwald with the help of a small pipette of about 2 c.c. capacity, attached to the burette as indicated in Fig. 11. The burette and pipette are filled with water to the zero mark and the mark a respectively, taking care to leave no air bubbles in the tubes. The clip I (or the tap of the burette) is opened and water allowed to run from the burette into the pipette till the level b is reached. The burette reading is then noted, and the pipette emptied to mark a. These operations of filling the pipette, taking a burette reading, and then emptying the pipette, are repeated to the full extent of the burette readings. Suppose, for example, that after twenty-four fillings the burette reading is 49·49 c.c. The burette is now refilled, and exactly this amount of distilled water is run out into a tared flask and weighed, using all the precautions that would be observed in an actual titration. From the table already given the true volume of this water is calculated. Suppose this to be 49·44 c.c. Then the volume of the calibrating pipette must be $\frac{49{\cdot}44}{24} = 2{\cdot}060$ c.c. The differences between the successive burette readings and the successive numbers 2·06, 4·12, 6·18 . . . give at once the burette errors at these intervals, due regard being paid to the sign of the difference. In the example quoted, the correction to be applied for 50 c.c. is obviously $-0{\cdot}05$ c.c. (*see* J. Amer. Chem. Soc. 1900, 22, 149; and for a modification of above, J. Amer. Chem. Soc. 1901, 23, 484).

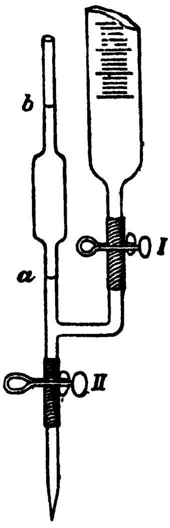

FIG. 11.

A better design for a calibrating pipette is shown in Fig. 12, which also illustrates the Greiner and Friedrich three-way tap (Morse and Blalock, Amer. Chem. J. 1894, 16, 479).

The gas burettes described under *Gas analysis* may be calibrated in much the same way as an ordinary burette, by filling with water or mercury, drawing off aliquot portions and weighing them, the temperature of the liquid being noted and the appropriate correction made for expansion. Any error thus detected must be used as a correction in subsequent readings.

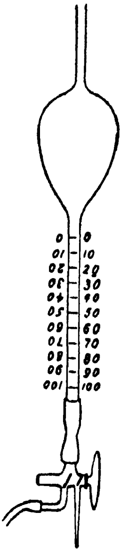

FIG. 12.

Standard solutions. — These form the basis of all volumetric work, and great care should be exercised in their preparation. When a solution is used only for the estimation of one substance, it may be convenient to adjust its strength so that each c.c. is equivalent to some simple and definite quantity of the substance, say 0·01 gram; but for general purposes the so-called *normal solutions* should be employed. A *normal solution* contains in 1000 c.c. the equivalent in grams of the active substance. A solution of one-tenth this strength is termed a *decinormal* solution, and one of a hundredth a *centinormal* solution. Thus a normal solution of sulphuric acid contains 49·04 grams of real acid per litre, a decinormal solution of iodine contains 12·69 grams of iodine per litre, and each litre of a decinormal solution of potassium permanganate contains 0·8 grams of active oxygen.

Standard solutions are usually made up approximately normal or decinormal as the case may be, and afterwards accurately standardised by titration against a weighed amount of some pure compound. If the solution has been purposely made rather too concentrated, it may then be suitably diluted until exactly normal or decinormal. Since accurate adjustment by dilution is difficult to effect, and in a certain cases inadvisable, it is usually better to avoid the process and determine *a factor* by which readings must be multiplied in order to convert them into equivalent readings of a normal or decinormal solution. For example, if 1 c.c. of potassium permanganate solution is found to be capable of oxidising 0·005630 grams of iron, then since the corresponding figure for a decinormal solution is 0·005585, the permanganate is $\frac{5630}{5585}$, or 1·008 times decinormal, and when using it to estimate a substance of equivalent x, each c.s. of permanganate will oxidise $\frac{x}{10000} \times 1{\cdot}008$ grams of substance. When only one or two litres of a standard solution are required, and the pure reagent is at hand, the exact quantity may be weighed out and diluted to the appropriate volume; *e.g.* solutions of silver nitrate and potassium dichromate may be thus prepared.

Measurements.—In measuring out solutions, &c., the vessels must be perfectly dry, which is inconvenient, or must be well drained and then rinsed out with a small quantity of the solution to be measured, which is allowed to run away.

To read correctly the level of the liquid in a burette or pipette requires certain precautions. In the first place, the instrument must be held in a vertical position. Ordinary liquids form a concave surface, or meniscus, and the reading should always be taken from the lowest point of this curve, except in the case of very dark-coloured solutions, when the upper line of the surface must be taken. The meniscus must be properly illuminated, and on a level with the eye, in order to avoid parallax. The best method of avoiding this error is by the use of a burette having the graduation marks carried half-way round the tube. In default of such a burette, use may be made according to Mohr of a piece of card one-half of which is black and the other half white. This is attached to the burette by an indiarubber ring, and is adjusted so that the horizontal edge of the black half, which is lowest, is 2 to 3 mm., *but not more,* below the meniscus. The lower edge of the curve then appears black against the white background. If the card is too low, the reading will be slightly too high. The little clamp and screen designed by Göckel are based on the same principle. Some burettes are provided at the back with a dark vertical line on a milk glass background. When the eye is on a level with the bottom of the meniscus, the dark line appears to be drawn out to two fine points which just touch one another. By means of these devices accurate readings can easily be taken even without using a burette float.

In addition to the errors incident to all analytical processes, another error arises in volumetric analysis, owing to variations in the concentrations of the solutions due to changes of temperature. In the case of $N/10$-solutions this affects the results to the extent of 0·1 p.c. for each 5° variation in temperature. With concentrated solutions, especially those of the acids and alkalis, the error is greater. The coefficients of expansion of certain standard solutions have been determined by A. Schulze (Zeitsch. anal. Chem. 21, 167).

Errors due to changes of temperature may be eliminated by weighing the solutions instead of measuring them. The liquid is contained in a light glass bottle, with a long jet-like neck, and a tubulus at the shoulder which can be closed by the finger, and the flow of liquid thus regulated. The bottle is weighed, the solution poured gradually from it until the reaction is complete, and the bottle again weighed. The difference between the two weighings gives the quantity of solution used. Convenient weight burettes are described in Chem. News, 1877, 35, 98; J. Amer. Chem. Soc. 1908, 30, 31.

Volumetric methods may be broadly classified as I. Methods of Saturation; II. Methods of Oxidation and Reduction; III. Methods of Precipitation; and examples of the two latter types of processes are indicated below. (For methods of saturation, *v.* ACIDIMETRY AND ALKALIMETRY.)

In the following section the methods for preparing and standardising the more commonly employed solutions are first described, followed by details of the various volumetric estimations for which these solutions may be conveniently employed, alphabetically arranged under the names of the elements that are determined.

PREPARATION OF STANDARD SOLUTIONS.

Potassium permanganate.

Employed as an oxidising agent, usually in dilute sulphuric acid solution, when the permanganate decomposes according to the equation:

$$2KMnO_4+3H_2SO_4 \\ =K_2SO_4+2MnSO_4+3H_2O+5O.$$

The oxidation of ferrous sulphate, for example, is represented in the following manner:—

$$2KMnO_4+10FeSO_4+8H_2SO_4 \\ = K_2SO_4+2MnSO_4+5Fe_2(SO_4)_3+8H_2O$$

and of oxalic acid thus:

$$2KMnO_4+5H_2C_2O_4+3H_2SO_4 \\ = K_2SO_4+2MnSO_4+8H_2O+10CO_2.$$

In order to facilitate calculation, these oxidations are conveniently expressed as a transference of oxygen from one oxide to another, *e.g.*:

$$10FeO+Mn_2O_7 = 5Fe_2O_3+2MnO.$$

The utility of permanganate solution depends upon the facts that such oxidation processes are usually quite easy to effect, the end-point being readily indicated by the solution acquiring a faint permanent pink tinge, due to the presence of a slight excess of permanganate, which thus acts as its own indicator. Oxidation usually proceeds rapidly at the ordinary temperature, but solutions of oxalic acid must be heated to 60°–80°. It is most essential that a considerable excess of sulphuric acid should be present (about 5 c.c. of concentrated acid per 100 c.c. of solution), since otherwise the solution becomes turbid owing to the separation of manganese dioxide, and the determination is spoilt. The presence of hydrochloric acid in the solution should be avoided, if possible, since it reacts with the permanganate under certain circumstances, particularly in the presence of iron salts. The error that thus arises can be reduced to a negligible amount by adding manganese sulphate to the solution, and titrating very slowly. The addition of colloidal silicic acid, added in the form of a solution of sodium silicate, containing about 0·1 gram SiO_2 per 1 c.c., entirely prevents the oxidation of the hydrochloric acid in presence of manganous sulphate.

Preparation and titration of the solution.—A decinormal solution containing 3·16 grams of the salt per litre of solution is most convenient for general use; it is most readily prepared by grinding the solid repeatedly with small amounts of distilled water in a mortar and decanting the solution into the stock bottle. After a day or two, the solution is filtered through asbestos, and standardised. If kept away from direct sunlight, reducing gases and dust, it retains its titre for a long time; its spontaneous decomposition is largely augmented by the presence of solid dioxide, which explains the necessity for the filtration through asbestos (Amer. Chem. J. 1896, 18, 401).

The solution is best standardised against electrolytic iron, anhydrous sodium oxalate, or by the iodimetric method of Volhard, using a thiosulphate solution which has been recently titrated against pure iodine. (For the latter method, *see Thiosulphate solution*, and for the first, which requires a somewhat complicated apparatus, consult Treadwell-Hall, vol. 2, 81.)

Titration by sodium oxalate.—This method was proposed by Sörensen, and its accuracy has been fully established by various other chemists (Zeitsch. angew. Chem. 1902, 15, 1244; 1904, 17, 230 and 269; 1905, 18, 1520). The pure oxalate, prepared by Kahlbaum according to Sörensen's directions, should be dried at 100° for a few hours before use.

Three or four portions of the oxalate, each weighing about 0·25–0·30 grams, are dissolved in an excess of dilute sulphuric acid; the solutions are warmed to 60°–80°, and titrated with the permanganate solution until a faint, permanent pink colouration is obtained. From the relation $2Na_2C_2O_4 = O_2$, the value of the permanganate solution is calculated for each titration, and the mean of the concordant results adopted as the true value (*cf* McBride, J. Amer. Chem. Soc. 1912, 34, 393).

Many other methods for standardising permanganate have been proposed, *e.g.* titration against crystalline oxalic acid $H_2C_2O_4,2H_2O$, ammonium oxalate $(NH_4)_2C_2O_4,H_2O$, ferrous sulphate $FeSO_4,7H_2O$, Mohr's salt $FeSO_4.(NH_4)_2SO_4,6H_2O$, &c., which although at times convenient, are less accurate than the methods given. Standardisation against iron wire is not to be recommended, since the small quantities of oxidisable impurities present consume more permanganate than would be required by their own weight of iron, and the error is augmented by making allowance for the actual iron content of the wire (Zeitsch. anal. Chem. 1903, 42, 359; Zeitsch. angew. Chem. 1901, 14, 1233; also Treadwell-Hall, *l.c.*).

It is usual to express the concentration of a permanganate solution in terms of the amount of iron it can oxidise; thus 1 c.c. of *N*/10-$KMnO_4$ = 0·005585 gram Fe.

Potassium dichromate.

A solution of this reagent may replace permanganate in the titration of ferrous salts, with the advantage that it can be used in the presence of either hydrochloric or sulphuric acid. An excess of free acid is essential, the oxidation of ferrous chloride, for example, proceeding according to the equation:

$$K_2Cr_2O_7+6FeCl_2+14HCl \\ = 2KCl+2CrCl_3+6FeCl_3+7H_2O$$

which is essentially:

$$2CrO_3+6FeO = Cr_2O_3+3Fe_2O_3.$$

A decinormal solution obtained by dissolving $\frac{K_2Cr_2O_7}{60} = 4·903$ grams of the pure dry recrystallised salt in distilled water and diluting the solution to 1 litre, requires no further standardisation. A stock solution of approximate strength may be standardised against several weighed amounts (1·0–1·4 grams) of pure ferrous ammonium sulphate by a similar procedure to that described under the standardisation of permanganate by sodium oxalate. The titrations, however, are made in cold solution, and the dilute sulphuric acid used should be gently boiled for half an hour to expel dissolved air, and cooled rapidly just before use. Since the green colour of the chromic salt prevents the excess of dichromate from being seen, an external indicator is necessary. Drops of a *dilute* solution of potassium ferricyanide, free from ferrocyanide, are placed on a white plate, and from time to time the end of a glass rod, previously dipped in the titrating flask, is brought into contact with a drop of the ferricyanide. As long as any ferrous salt remains a blue precipitate is produced; the approach of the end is indicated by the decrease in intensity of the blue colouration, and when very near the end about thirty seconds should be allowed for the colour to develop. The end-point is reached when the blue colour ceases to appear. The ferricyanide solution should be prepared only when required by dissolving in water a crystal of the salt which has been rinsed to remove superficial ferrocyanide: the yellow colour of the drops on the white plate should be barely visible; if the ferricyanide is too concentrated, the blue colouration changes through various shades of green into a brown tint.

Iodine, Sodium thiosulphate, and Sodium arsenite.

Decinormal solutions of these reagents are frequently used in conjunction with one another. The reaction between iodine and sodium thiosulphate is essentially:

$$2Na_2S_2O_3+I_2 = Na_2S_4O_6+2NaI$$

although under certain circumstances oxidation to sulphate proceeds to a small extent, even at the ordinary temperature (Pickering). When using decinormal solutions the end-point is readily indicated by the appearance or disappearance of the yellow colour of the iodine, provided the solution undergoing titration is not unduly diluted and is otherwise colourless. The production of a blue colour when free iodine and starch solution are brought together is, however, much more sensitive, and is the method usually employed in ascertaining the end-point.

Preparation of starch solution.—About 1 gram of powdered starch is rubbed into a paste with a little cold water, and slowly added to 200 c.c. of boiling water, the boiling is continued for two or three minutes, the solution cooled, and after some hours the clear liquid is decanted. The solution will only keep for one or two days, unless sterilised, when it is conveniently preserved in small bottles, completely filled and closed by soft rubber stoppers; it will then keep indefinitely. Starch paste prepared from Gastine's formula (5 grams starch, 0·01 gram mercuric iodide, and 1 litre water) retains its sensitiveness for a long time. Addition of 1 c.c. of oil of cassia to a litre of starch liquor is also recommended as a preservative.

Sensitiveness of the iodine-starch reaction.—This depends upon several circumstances. It is necessary to work with cold solutions, preferably neutral or slightly acid; the presence of mineral acid in high concentration greatly impairs the sensitiveness of the reaction, since it hydrolyses the starch. It is essential that a soluble iodide should be present (usually this is potassium iodide) in moderate amount; the best concentration of potassium iodide to employ is about *N*/150, since the sensitiveness of the reaction then reaches a maximum (*see* Zeitsch. anal. Chem. 1902, 41, 485; Amer. J. Sci. 1900, [iv.] 10, 151; J. Amer. Chem. Soc. 1909, 31, 1038).

Good starch solution first yields a pink colouration with iodine, which more iodine develops into the blue colour; starch which produces green tints should be rejected (J. Amer. Chem. Soc. 1908, 30, 31). It frequently happens in titrating arsenious and antimonious oxides with iodine that various tints of red make their appearance instead of the usual blue colouration. This is due to impurity in the starch: in such a case one or two grams of potassium iodide are added, the end-point being ascertained from the development of the yellow colour of the iodine, and then confirmed by the starch (Amer. J. Sci. 1902, [4] 13, 379).

Sinnatt (Analyst, 1910, 35, 309) has shown that 1 c.c. of a dilute aqueous solution of methylene blue (0·05 gram per litre) may be used in place of starch as an indicator in iodimetric titrations (*see* also Analyst, 1912, 37, 252).

For the *iodine solution* 25 grams of potassium iodide are dissolved in a little water, 12·7 grams of commercial iodine added, and the mixture shaken till the iodine has dissolved; the solution is then filtered through asbestos and diluted to 1 litre. It should be kept in the dark, and protected from dust. For the *thiosulphate solution* the crystalline salt $Na_2S_2O_3,5H_2O$ is dissolved in distilled water, using 25 grams per litre, and the solution kept away from direct sunlight for two weeks before it is standardised. It then retains its titre for months. For the *sodium arsenite*, 4·948 grams of resublimed arsenious oxide are dissolved in a little warm sodium hydroxide free from iron, the solution rinsed into a litre flask, and made just acid to phenolphthaleïn with dilute sulphuric acid. A filtered solution of 20 grams of sodium bicarbonate in 500 c.c. of water is added, and if the mixture reacts alkaline to the phenolphthaleïn, sulphuric acid added till the pink colour disappears. This solution, when diluted to 1 litre and thoroughly mixed, is strictly decinormal, and keeps indefinitely. A measured quantity of the *N*/10-arsenite solution is delivered into an Erlenmeyer flask, and the iodine solution run in from the burette until present in slight excess, starch paste being added nearly at the finish of the titration (*see* remarks on starch above). The reaction

$$As_2O_3+2I_2+2H_2O \rightleftharpoons As_2O_5+4HI$$

proceeds to completion in the sense of the upper arrow in neutral solution, a condition secured by the presence of the bicarbonate, which neutralises the hydriodic acid produced. Since the solution should be saturated with carbon dioxide, it is advisable to stopper the flask except when actually introducing the iodine (J. Amer. Chem. Soc. 1908, 30, 31).

The iodine being standardised, the thiosulphate can be directly titrated against it, preferably by running the iodine into a measured volume of thiosulphate.

Many alternative methods have been proposed for standardising iodine and thiosulphate solutions. The latter may be titrated against pure iodine: 0·5 gram of pure iodine and 0·1 gram of potassium iodide are powdered and mixed together in a porcelain dish, and heated on a sand-bath till vapour is copiously evolved; the dish is then covered with a dry watch-glass, and the greater part of the iodine sublimed on to it. The watch-glass is covered with a second accurately fitting glass and the whole weighed, the weight of the glasses having been previously found. The whole is gently placed in a solution of 1 gram of potassium iodide in 10 c.c. of water, and after a few seconds the solution is diluted to 100 c.c. and titrated with the thiosulphate.

The thiosulphate may also be standardised against permanganate, itself verified by reference to sodium oxalate. One or two grams of potassium iodide are dissolved in water, acidified with 5 c.c. of hydrochloric acid (1 : 5) and 25 c.c. of standard permanganate added. The iodine, which is quantitatively liberated:

$$Mn_2O_7 + 10HI = 2MnO + 5H_2O + 5I_2$$

is then titrated with the thiosulphate, after diluting the solution to 100 c.c. By the reverse process of calculation, a permanganate solution may be standardised against a thiosulphate solution that has been verified by either of the preceding methods (*see Standardisation of permanganate; cf.* Annalen, 1897, 198, 333; Zeitsch. angew. Chem. 1904, 17, 815; Ann. Chim. Anal. 1904, 9, 365; Zeitsch. anorg. Chem. 1906, 49, 277).

(For the use of potassium dichromate in this connection, *see Volumetric estimation of chromium*: Zeitsch. anorg. Chem. 1899, 19, 427; 1906, 49, 277. *See* also *Copper* under *Volumetric estimations*. For a gravimetric method for standardising iodine solution, consult Amer. J. Sci. 1909, (iv.) 28, 33.)

Titanous chloride.

This reagent, introduced into volumetric analysis by Knecht (J. Soc. Dyers and Colourists, 19, No. 6; Ber. 1907, 40, 3819), is a powerful reducing agent. For example, a hydrochloric acid solution of ferric chloride is quickly and quantitatively reduced in the cold, according to the equation:

$$FeCl_3 + TiCl_3 = FeCl_2 + TiCl_4$$

and the end-point is reached when a drop of the liquid ceases to produce a red colouration with potassium thiocyanate. Chromic acid and cupric salts may be similarly estimated, and also a large number of organic dyes.

Fifty c.c. of the commercial 20 p.c. solution of titanous chloride, which usually contains a little iron, are mixed with an equal volume of concentrated hydrochloric acid, boiled for several minutes, and diluted to 1 litre with air-free water. The solution must be kept protected from the air; a convenient method is figured in Sutton's Volumetric Analysis (9th ed.), p. 224.

The concentration of the solution is fixed by titrating against a known quantity of either ferric salt or potassium dichromate. In the former case 35 grams of pure ferrous ammonium sulphate are dissolved in dilute sulphuric acid and the solution diluted to 1 litre; 25 c.c. are then exactly oxidised with dilute permanganate, and the resulting ferric sulphate titrated with the titanous chloride until a drop of the solution no longer gives a red colour with potassium thiocyanate. Instead of using this 'spot-out' method, 10–20 c.c. of 10 p.c. potassium thiocyanate may be added to the ferric solution. If the standardisation be effected with potassium dichromate, addition of the indicator to the solution itself is inadmissible. Nearly all the titanous chloride necessary, may, however, be added at once, since the colour changes, through orange to green and then violet, afford an indication of the end-point. Drops of solution are removed for testing when the green colour has just disappeared (J. Soc. Chem. Ind. 1908, 27, 673).

Pure ferric alum, the preparation of which is described by De Koninck (Bull. Soc. chim. Belg. 1909, 23, 222), might also be employed for this standardisation.

For a number of estimations it is necessary to employ titanous sulphate instead of the chloride.

Stannous chloride.

This reagent has long been employed as a reducing agent, but the closely allied and more powerfully reducing titanous salts appear to be displacing it. Ferric salts are easily reduced in hot acid solution:

$$2FeCl_3 + SnCl_2 = SnCl_4 + 2FeCl_2.$$

Iodine in cold acid solution oxidises it quantitatively:

$$2SnCl_2 + 2I_2 = SnI_4 + SnCl_4.$$

Ten grams of pure tin in thin pieces are heated with 200 c.c. of concentrated hydrochloric acid in a platinum dish until dissolved: or a glass flask may be used with a piece of platinum foil touching the tin to promote its speedy solution. The solution is diluted to 1 litre, and preserved out of contact with the air.

The solution is best standardised by that process for which it is afterwards to be employed, *e.g.* if required for iron estimations, by titration against a known amount of ferric chloride. The latter may be obtained by dissolving 10·03 grams of bright iron wire (99·7 p.c. iron) in hydrochloric acid, oxidising with potassium chlorate, expelling the excess of chlorine by boiling, and diluting the solution to 1 litre; 25 c.c. are conveniently used for titrating the above solution.

Several methods have been proposed for determining the end-point. The iron solution containing 20–40 c.c. of concentrated hydrochloric acid in a volume of 125 c.c. may be titrated nearly at the boiling-point, 15 c.c. of indicator solution (34 grams $HgCl_2$+0·05 gram Pt as chloride per litre) being added. The end-point is reached when a dark-cloud of finely divided mercury and platinum is produced (Amer. Chem. J. 1893, 15, 360). Or a drop of the solution may be mixed with ammonium molybdate on a white plate; the slightest trace of stannous salt causes a blue colouration. An alternative is to add a slight excess of stannous chloride, and titrate back the cold solution with iodine.

(For the standardisation by means of iodine, *see Volumetric estimation of tin.*)

Silver nitrate, Sodium chloride, and Ammonium thiocyanate.

These precipitation reagents, which are conveniently made of decinormal strength, are of great service for the volumetric estimation of silver, copper, mercury, the halogen acids, cyanides, and thiocyanates.

Silver nitrate is used either in neutral or in nitric acid solution. In the first case potassium chromate is employed as indicator when halogens are being estimated (Mohr's method). Silver chromate is decomposed by solutions of halogen salts forming silver halide and metallic chromate; consequently, silver chromate cannot permanently exist in the solution until all the halogen has been precipitated. The first drop of silver nitrate in excess then produces a permanent precipitate of silver chromate, which gives a faint red tint to the previously pale-yellow liquid. This colour change is more readily observed in monochromatic light (from a powerful sodium flame). One or two drops of a 10 p.c. solution of potassium chromate are added to the solution, which should not be unduly diluted. Silver chromate is soluble in mineral acids or ammonia; hence the necessity for working in neutral solution. An alkaline solution may be acidified with dilute nitric acid, and then neutralised with powdered calcium carbonate. Barium must be absent from the solution, since it precipitates the indicator; it may be removed with sodium sulphate.

In the presence of nitric acid, silver nitrate and ammonium thiocyanate solutions are used in conjunction (Volhard's method, Annalen, 1878, 190, 47). The addition of thiocyanate to a nitric acid solution containing silver causes the precipitation of white silver thiocyanate, and the end-point is indicated by the red colouration produced by the interaction of the first drop of thiocyanate in excess with a ferric salt previously introduced into the solution. The thiocyanate should always be added to the silver solution. The ferric indicator is prepared by adding nitric acid (4 : 1 boiled to expel nitrous acid) to a saturated solution of iron alum until colourless; 5–10 c.c. are used in the titration.

Standard sodium chloride solution is used for the estimation of silver by the very exact method originally due to Gay-Lussac. (For a description of the method, *v.* ASSAYING.)

Decinormal silver nitrate is obtained by dissolving 16·99 grams of the pure dry recrystallised silver nitrate in water and diluting the solution to 1 litre. If it is to be used in conjunction with the thiocyanate, this solution may also be prepared by dissolving 10·788 grams of pure silver in a slight excess of nitric acid, boiling till nitrous acid is expelled, and diluting to 1 litre.

The thiocyanate is prepared approximately decinormal by dissolving the salt in distilled water (8 grams per litre), and is standardised against the silver nitrate solution, 25 c.c. of which are diluted to 100 c.c. and titrated as described above.

VOLUMETRIC ESTIMATIONS.

Aluminium. *Iodimetrically.* The neutral solution is boiled with excess of potassium iodide and potassium iodate for twenty minutes in a stream of hydrogen; the iodine evolved, and collected in potassium iodide, together with that which remains in the distilling flask, is titrated with *N*/10-thiosulphate (Amer. J. Sci. 1905, 20, 181; Zeitsch. anorg. Chem. 1907, 52, 286):

$$Al_2(SO_4)_3+5KI+KIO_3+3H_2O$$
$$=2Al(OH)_3+3K_2SO_4+3I_2.$$

Antimony. ANTIMONIOUS SOLUTIONS. (*a*) *Iodimetrically.* One or two grams of Rochelle salt are added, the solution made alkaline with sodium bicarbonate, and titrated with *N*/10-iodine. I_2 = Sb (*v.* ARSENIC).

(*b*) *By oxidation.* The hot hydrochloric acid solution (above 60°) is titrated with *N*/10-potassium bromate, which has been standardised against a known amount of pure antimony—

$$3SbCl_3+KBrO_3+6HCl=3SbCl_5+KBr+3H_2O.$$

The end-point is indicated by the bleaching of a few drops of methyl orange added to the hot solution (Chem. Zeit. 1903, 27, 749; J. Soc. Chem. Ind. 1906, 25, 1181; Chem. News, 1907, 95, 49).

(*c*) *By oxidation.* The cold solution, freely acidified with hydrochloric acid, is titrated with *N*/10-permanganate (Zeitsch. angew. Chem. 1901, 14, 1179; J. Amer. Chem. Soc. 1907, 29, 66).

ANTIMONIC SOLUTIONS. (*a*) *By reduction* to the tervalent state, and estimation by one of the foregoing processes. Reduction may be accomplished: (i.) by boiling the hydrochloric acid solution with sodium sulphite or sulphurous acid (Zeitsch. angew. Chem. 1888, 155); according to Rohmer, the reduction is not quantitative unless a gram of potassium bromide is added (Ber. 1901, 34, 1565); (ii.) by boiling the sulphuric acid solution (100 c.c. containing 5 c.c. of concentrated acid and 4 grams of Rochelle salt) with 1·0–1·5 grams of potassium iodide till nearly all the iodine is expelled, exactly bleaching the remainder with dilute sulphurous acid, diluting, rapidly cooling, and neutralising. The solution is then titrated in bicarbonate solution with *N*/10-iodine (Amer. J. Sci. 1892, 42, 213).

(*b*) *Iodimetrically.* The cold solution containing 20–25 c.c. of hydrochloric acid in a volume of 100 c.c., is mixed with 0·5–1·0 gram of potassium iodide and the liberated iodine titrated with *N*/10-thiosulphate. I_2 = Sb (Zeitsch. anorg. Chem. 1908, 58, 202; cf. *ibid.* 1903, 37, 337).

Arsenic. ARSENIOUS SOLUTIONS. *Iodimetrically.* The solution, containing sodium bicarbonate in excess, is titrated with *N*/10-iodine as described under the standardisation of iodine solution. The bicarbonate may with advantage be replaced by disodium hydrogen phosphate (J. Amer. Chem. Soc. 1908, 30, 31).

ARSENIC SOLUTIONS. (*a*) *By reduction* with hydriodic acid as described under *Antimony*, and subsequent titration with iodine; no Rochelle salt is necessary (Amer. J. Sci. 1900, 10, 151). Reduction may also be effected by heating the sulphuric acid solution with sulphurous acid in a stoppered bottle for an hour, diluting and boiling down to half the volume to expel excess of sulphurous acid (Zeitsch. anal. Chem. 1883, 22, 378; Chem. News, 1886, 53, 221).

(*b*) *By precipitation.* The neutral or acetic acid solution is precipitated with excess of silver nitrate, and the precipitated silver arsenate collected, washed, dissolved in nitric acid, and the silver titrated with *N*/10-thiocyanate. 3Ag = As.

(*c*) *Iodimetrically* (Zeitsch. anal. Chem. 1906, 45, 596; compare Amer. J. Sci. 1900, 10, 151). (*See* also Zeitsch. anorg. Chem. 1909, 62, 123, for a method suitable for small quantities of arsenic.)

Barium. *Iodimetrically.* Excess of potassium iodate is added to the faintly ammoniacal solution, the precipitated iodate washed with ammonia and then with alcohol, dissolved in hydrochloric acid and potassium iodide, and the iodine titrated with $N/10$-thiosulphate. $6I_2=Ba$ (J. Amer. Chem. Soc. 1909, 31, 43).

Bismuth. (*a*) *Iodimetrically.* The solution, as free as possible from mineral acids, is mixed with excess of $N/2$-potassium chromate, shaken for 10 minutes, diluted to a known volume, and the chromate in an aliquot part of the filtrate from the bismuthyl chromate $Bi_2O_3 \cdot 2CrO_3$ is titrated iodimetrically (Zeitsch. anorg. Chem. 1902, 32, 362; Zeitsch. anal. Chem. 1907, 46, 223).

(*b*) As *bismuth ammonium molybdate* (J. Amer. Chem. Soc. 1903, 25, 907).

Boron. (*a*) *v.* ACIDIMETRY AND ALKALIMETRY.

(*b*) *Iodimetrically.* The reaction

$$5KI+KIO_3+6HBO_2=3I_2+3H_2O+6KBO_2$$

is quantitative in a solution saturated with mannitol (*v.* Amer. J. Sci. 1899, 8, 127).

Bromine *v. Halogens.*

Calcium. *By oxidation.* The oxalate, precipitated from a hot slightly ammoniacal solution (*see Gravimetric methods*), is washed with warm water till free from ammonium oxalate, decomposed with hot dilute sulphuric acid, and the oxalic acid titrated with $N/10$-permanganate. The precipitate may also be dissolved in dilute hydrochloric acid, 0·5 gram of manganese sulphate added, and the solution titrated with permanganate (*v.* Amer. Chem. J. 1905, 33, 500).

Carbon. CARBON DIOXIDE. *v.* ACIDIMETRY and ALKALIMETRY, and *Gas analysis.*

CYANOGEN ACIDS. CYANATES. The cold, dilute solution is exactly neutralised with $N/10$-hydrochloric acid (using methyl orange or congo red as indicator), excess of acid is added, the solution boiled for ten minutes, cooled and titrated back $N/10$-sodium hydroxide. Excess of $N/10$-sodium hydroxide is then added, the solution boiled to expel ammonia, and titrated back with $N/10$-hydrochloric acid. From these data two values for the cyanate can be calculated, which serve to check one another (Chem. News, 1906, 93, 5; compare Zeitsch. angew. Chem. 1901, 24, 585; J. Soc. Chem. Ind. 1904, 23, 244).

$$KCNO+2HCl+H_2O = KCl+NH_4Cl+CO_2.$$

CYANIDES. (*a*) *By precipitation.* (i.) Excess of $N/10$-silver nitrate is added to the neutral cyanide solution, and then a little nitric acid. The excess of silver is titrated with $N/10$-thiocyanate after filtering off the silver cyanide. (ii.) The slightly alkaline solution is titrated with $N/10$-silver nitrate with constant stirring till a permanent turbidity is produced (Liebig, Annalen, 1851, 77, 102). This marks the end of the reaction:

$$2KCN+AgNO_3=KNO_3+KAg(CN)_2.$$

The end-point is best observed by adding 5–10 drops of 20 p.c. potassium iodide as an indicator. A permanent yellow turbidity, due to silver iodide, is produced as soon as the above reaction is completed (Ann. Chim. Phys. 1895, (vii.) 6, 381).

(*b*) See *Ferrocyanides* (*b*).

FERRICYANIDES. (*a*) The salt is reduced to ferrocyanide by boiling with sodium hydroxide and ferrous sulphate and the filtered solution strongly acidified with sulphuric acid and titrated with $N/10$-permanganate (*v. Ferrocyanides*). Reduction may also be effected by boiling with sodium peroxide (Arch. Pharm. 232, 226).

(*b*) *Iodimetrically.* The neutral solution (50 c.c.) is mixed with 3 grams of potassium iodide and 1·5 grams of zinc sulphate, the mixture well shaken, and the iodine titrated with $N/10$-thiosulphate. $2K_3Fe(CN)_6=I_2$ (Zeitsch. anorg. Chem. 1910, 67, 418; compare *ibid.* 67, 322).

FERROCYANIDES. (*a*) *By oxidation.* The solution is strongly acidified with sulphuric acid and titrated with $N/10$-permanganate till the colour changes from yellowish-green to yellowish-red. If any difficulty is experienced in determining the end-point, a drop of the solution may be mixed with dilute ferric chloride. A blue colour will develop whilst any ferrocyanide remains (de Haen, Annalen, 1854, 90, 160; compare Zeitsch. anorg. Chem. 1910, 67, 418).

An excess of permanganate may also be added, the excess being determined iodimetrically. (For details, consult Zeitsch. anorg. Chem. 1910, 67, 322.)

(*b*) *By conversion into hydrocyanic acid.* The ferrocyanide solution is boiled for five minutes with 10 c.c. of N-sodium hydroxide and 15 c.c. of $3N$-magnesium chloride, 100 c.c. of boiling $N/10$-mercuric chloride are then added, and the boiling continued for ten minutes. The mercuric cyanide produced is distilled for thirty minutes with 30 c.c. of $3N$-sulphuric acid, the prussic acid collected in 25 c.c. of N-sodium hydroxide, a little potassium iodide added, and the cyanide titrated with $N/10$-silver nitrate (Feld, Chem. Zentr. 1903, ii. 1398; Analyst, 1908, 33, 261; 1910, 35, 295).

THIOCYANATES. (*a*) *By precipitation.* As in standardising ammonium thiocyanate solution; the thiocyanate must be added to the silver nitrate, and not *vice versâ*, since nitric acid decomposes thiocyanates.

(*b*) *By oxidation.* The thiocyanate is titrated in concentrated hydrochloric acid solution with potassium iodate, in a stoppered bottle, with vigorous shaking. The end-point is reached when 5 c.c. of chloroform previously introduced are no longer coloured by iodine (J. Amer. Chem. Soc. 1908, 30, 760); *e.g.*

$$4CuCNS+7KIO_3+14HCl$$
$$=4CuSO_4+7KCl+7ICl+4HCl+5H_2O.$$

Oxidation in dilute sulphuric acid solution with permanganate is untrustworthy.

Cerium. (*a*) *Iodimetrically.* Ceric oxide is warmed with concentrated hydrochloric acid and potassium iodide in a stoppered bottle till complete solution is effected. The liberated iodine is then titrated with $N/10$-thiosulphate (Bunsen, Annalen, 1858, 105, 49; also Amer. J. Sci. 1899, 8, 451).

$$2CeO_2+8HCl+2KI=2CeCl_3+2KCl+I_2+4H_2O$$

(*b*) *By oxidation.* The washed oxalate is suspended in hot dilute sulphuric acid and titrated with $N/10$-permanganate (*v. Calcium;* Zeitsch. anal. Chem. 1880, 19, 194; Amer. J. Sci. 1899, 8, 457).

(*c*) *By reduction.* The cerium is oxidised with sodium bismuthate in boiling sulphuric acid solution to ceric sulphate and the filtered solution reduced by a slight excess of ferrous sulphate, the excess being titrated with *N*/10-permanganate. Other rare earth metals do not interfere (J. Amer. Chem. Soc. 1909, 31, 523; 1910, 32, 642; compare Compt. rend. 1899, 128, 101; Ber. 1900, 33, 1924; Ber. 1903, 36, 282).

(*d*) *Other methods* (Zeitsch. anorg. Chem. 1907, 54, 104; 1908, 59, 71).

Chlorine *v. Halogens.*

Chromium. The chromium should be in the form of chromate.

(*a*) *Iodimetrically.* The chromate solution is acidified with hydrochloric acid (5 c.c. of concentrated acid per 100 c.c. solution), 1 or 2 grams of potassium iodide added, and the covered solution allowed to stand for 15 to 20 minutes. It is then diluted to 400–500 c.c. and the liberated iodine titrated with *N*/10-thiosulphate. $3I_2=2Cr$. A known dichromate solution can in this way be used to standardise sodium thiosulphate (J. pr. Chem. 1868, 103, 362; Zeitsch. anorg. Chem. 1899, 19, 427; 1906, 49, 277; Zeitsch. angew. Chem. 1900, 1147).

(*b*) *By reduction* (i.) with ferrous ammonium sulphate, of which a slight excess is added to the chromate solution containing sulphuric or hydrochloric acid, the excess of ferrous salt being then titrated with *N*/10-dichromate; (ii.) with titanous chloride (*v. Preparation of standard solutions*; J. Soc. Chem. Ind. 1908, 27, 673); (iii.) with arsenious oxide (Amer. J. Sci. 1896, 1, 35).

Chromium in chrome steel. Three grams of alloy are dissolved in 35 c.c. of concentrated hydrochloric acid, and the excess evaporated; 150 c.c. of strong nitric acid are added, the boiling continued till no more brown fumes are evolved, when all chlorine has been expelled. The chromium is then oxidised by adding 10 grams of potassium chlorate, and the solution boiled down to 40 c.c. to decompose excess of chlorate; 100 c.c. of water are added, and one or two drops of hydrochloric acid, to dissolve separated manganese dioxide. The chromate solution is boiled to expel chlorine, cooled and titrated according to method (*b*) (i.) above. (For other methods, *see* J. Amer. Chem. Soc. 1905, 27, 1550; 1908, 30, 1116; J. Soc. Chem. Ind. 1907, 26, 1010; Chem. News, 1904, 90, 320; 91, 3; also *Manganese* and *Vanadium* (*v. infra*).)

Chromium in chromite. The valuation of this, the only important ore of chromium, is usually effected by a volumetric method; the finely powdered ore is fused with sodium peroxide in a nickel crucible, and the chromate in the aqueous extract estimated as described above, after boiling for ten minutes to decompose excess of peroxide (*v.* J. Soc. Chem. Ind. 1896, 15, 155, 436; Chem. Zeit. 1897, 21, 3; Bull. Soc. Chim. 1909, 5, 1133; Chem. News, 1896, 73, 1).

Cobalt. (*a*) *Iodimetrically.* The solution is mixed with hydrogen peroxide, and then with sodium hydroxide, when the cobalt is precipitated as sesquioxide Co_2O_3, whilst nickel is simply precipitated as green hydroxide. After boiling for a minute, the black ppt. is dissolved in hydrochloric acid and potassium iodide, and the iodine titrated with *N*/10-thiosulphate (Chem. News, 1900, 82, 66, 73; 1903, 88, 184).

(*b*) *By precipitation* with ferrocyanide, as described under *Nickel* (*b*).

Columbium. *By reduction and subsequent oxidation* (*v.* Zeitsch. anorg. Chem. 1909, 62, 383).

Copper. (*a*) *Iodimetrically.* The solution of cupric salt preferably neutral or containing acetic acid, is diluted to 100 c.c., 5 grams of potassium iodide are added, and the liberated iodine titrated with *N*/10-thiosulphate, using starch paste as indicator. If more than 25 c.c. of thiosulphate are required, 2–3 grams more potassium iodide should be added (Amer. J. Sci. 1907, 24, 65; compare J. Amer. Chem. Soc. 1902, 24, 1082; 1905, 27, 1224; see also *Methods of separation*).

$$2CuSO_4+4KI=2K_2SO_4+I_2+Cu_2I_2.$$

(*b*) *By titration with potassium cyanide* (*Steinbeck's process*). The ammoniacal copper solution is titrated with potassium cyanide until colourless (*v.* Chem. News, 1897, 76, 189; *Methods of separation*; and the article Copper).

(*c*) *By precipitation as thiocyanate* and estimation of the precipitate by potassium iodate in hydrochloric acid solution (*v. Thiocyanates*; and J. Amer. Chem. Soc. 1908, 30, 760).

(*d*) *By oxidation.* The oxalate is precipitated in a nitric acid solution by adding excess of ammonium oxalate, washed and titrated with *N*/10-permanganate (Amer. J. Sci. 1909, 27, 448).

(*e*) *By reduction* to cuprous salt. To the sulphuric or hydrochloric acid solution, 10–20 c.c. of 10 p.c. potassium thiocyanate and a little ferrous salt are added, when a deep red colouration is produced, since ferrous salts in acid solution are partly oxidised by cupric salts. The cold solution is titrated with titanous chloride until the red colouration is destroyed (Chem. Soc. Trans. 1906, 89, 1491). Or a slight excess of titanous chloride may be added, and titrated back with standard ferric alum.

Fluorine. *Acidimetrically.* The fluoride is mixed with ten times its weight of finely powdered and ignited quartz, and decomposed by warming with concentrated sulphuric acid; the silicon fluoride evolved passes through a dry U-tube filled with glass beads and immersed in cold water, in order to remove sulphuric acid, and is then absorbed in 50 p.c. alcoholic potassium chloride, which precipitates silicic acid and potassium silicofluoride, leaving hydrochloric acid in the solution:—

$$3SiF_4+2H_2O=2H_2SiF_6+SiO_2$$
$$H_2SiF_6+2KCl=K_2SiF_6+2HCl.$$

The hydrochloric acid is titrated with *N*/5-sodium hydroxide, using lacmoid as indicator. $2HCl=3F_2$. (For full experimental details, which are absolutely essential in order to obtain accurate results, consult Chem. News, 1879, 39, 179; Amer. J. Sci. 1906, 22, 329; or Low's Technical Methods of Ore Analysis.)

Gold. *Iodimetrically.* The auric solution is treated with potassium iodide in more than sufficient quantity to dissolve the aurous iodide first precipitated, and the iodine liberated is estimated with standard thiosulphate (Amer. J. Sci. 1899, 8, 261; compare Zeitsch. anorg. Chem. 1899, 19, 63).

Halogens. This term is restricted in this connection to chlorine, bromine, and iodine, fluorine being treated separately, since its analytical reactions are quite different.

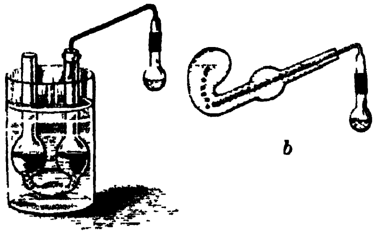

Fig. 13.

Estimation of halogens. *Iodine* is estimated by solution in potassium iodide and titration with $N/10$-thiosulphate, using starch paste as indicator (*v. Preparation of standard solutions*, *Bromine* and *chlorine* are absorbed in potassium iodide solution, setting free an equivalent quantity of iodine, which is titrated with $N/10$-thiosulphate.

A large number of substances, *e.g.* peroxides, chlorates, chromates, &c., may be readily determined indirectly by distillation with concentrated hydrochloric acid, the available oxygen of the compound setting free its equivalent of chlorine, which is absorbed in potassium iodide, and the liberated iodine titrated with $N/10$-thiosulphate. It is very desirable to exclude air in the process of distillation, since it liberates iodine from the hydrogen iodide set free in the receiver, by the hydrogen chloride distilling over during the experiment. The apparatus devised by Bunsen, the originator of this analytical method, is shown in Fig. 13, *b*. The small flask (50 c.c.) and the delivery tube are ground at their junction to fit, and the joint made with caoutchouc tubing; a ground-glass joint is better, a spring holding the two parts tightly together. The mixture is rapidly boiled, the chlorine passing into potassium iodide contained in the retort, the size of which must be suitably chosen to prevent overflowing. A different receiving vessel is shown in Fig. 13, *a*. It is very convenient to perform such distillations in a current of carbon dioxide or other inert gas, and various designs of apparatus for such a purpose are given in Amer. J. Sci. 1898, 6, 168; Chem. News, 1899, 79, 85; Chem. Soc. Trans. 1892, 61, 87; Zeitsch. angew. Chem. 1890, 477.

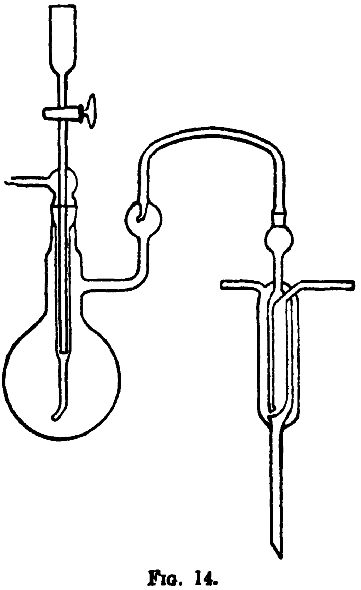

Fig. 14.

The apparatus shown in Fig. 14 (Analyst, 1908, 33, 117) admits of the gradual introduction of a liquid reagent during distillation in carbon dioxide, steam, or any other gas or vapour. Contamination of the reagents with cork or indiarubber derived from stoppers, &c., is avoided by fitting the condenser and the dropping funnel to the distilling flask by ground-glass joints.

Estimation of halogens in halide salts. *By precipitation.* (i.) *Mohr's method.* The neutral solution is titrated with $N/10$-silver nitrate in the presence of a few drops of potassium chromate as indicator (*v. Preparation of standard solutions*. It is advisable to perform a blank experiment under identical conditions, to allow for the silver nitrate necessary to bring out the reddish colouration. (ii.) *Volhard's method.* The nitric acid solution of the halide is precipitated by adding a slight excess of $N/10$-silver nitrate, the excess being then titrated with $N/10$-ammonium thiocyanate. Silver chloride must be filtered off before the latter titration is performed, since it reacts with the thiocyanate (J. Amer. Chem. Soc. 1907, 29, 269; compare Zeitsch. anorg. Chem. 1909, 63, 330); but silver bromide and iodide do not interfere. It is advisable to titrate iodide in a stoppered bottle with vigorous shaking when adding both the silver solution and the thiocyanate, to minimise error due to occlusion. It is more accurate to weigh out a very slight excess of pure silver, dissolve it in nitric acid (carefully expelling nitrous acid, which interferes with the indicator), and add to the halide solution than to measure out $N/10$-silver nitrate. After vigorous shaking, the excess of silver is then titrated with a dilute thiocyanate solution (1 c.c. = 1 milligram Ag).

Iodides. *Iodimetrically.* (i.) A slight excess of potassium iodate is added, and the solution acidified with dilute sulphuric acid. The liberated iodine is extracted with chloroform, carbon disulphide or toluene, and titrated with $N/10$-thiosulphate. A weaker acid than sulphuric acid may be employed, *e.g.* acetic or tartaric acid. Five-sixths of the iodine found was originally present as iodide (Chem. Zeit. 1904, 28, 1191; Amer. J. Sci. 1897, 3, 293; J. pharm. Chim. 1902, 16, 207; J. Amer. Chem. Soc. 1903, 25, 1138). This method is available in the presence of bromide and chloride, if acetic acid be employed. (ii.) The solution, containing the iodide, 2 grams of pure potassium arsenate, and 10 c.c. of concentrated sulphuric acid, is boiled down from a volume of 100 c.c. to

35-40 c.c., when all the iodine is expelled. The arsenious salt in solution is then titrated with $N/10$-iodine (Amer. J. Sci. 1890, 39, 188). $As = I_2$. In the presence of chloride the results are a little low; bromide causes them to be slightly high. (iii.) (*v.* Chem. Soc. Trans. 1885, 47, 471.)

ESTIMATIONS OF HALOGENS IN OXYHALOGEN COMPOUNDS. (*a*) *By reduction* to a halide salt and determination of the latter. *Iodates* are reduced by adding sulphurous acid to the sulphuric acid solution of the iodate till the separated iodine is redissolved; an excess of $N/10$-silver nitrate is added to precipitate the iodide, the mixture boiled with excess of nitric acid, and finally the excess of silver titrated with $N/10$-thiocyanate. *Bromates and chlorates* are reduced by adding an excess of iron filings to the sulphuric acid solution; after an hour, excess of $N/10$-silver nitrate is added, the mixture boiled with nitric acid to oxidise the ferrous salt, and the excess of silver titrated (Amer. Chem. J. 1904, 32, 242).

(*b*) *By reduction* to a halide salt and estimation of the reducing agent used up in the process. With *chlorates and bromates*, the sulphuric acid solution is boiled for ten minutes with excess of standard ferrous sulphate in an atmosphere of carbon dioxide, the solution cooled, manganese sulphate added and the unchanged ferrous salt titrated with $N/10$-$KMnO_4$. $6Fe = ClO_3$ or BrO_3 (Zeitsch. anorg. Chem. 1904, 38, 110). *Bromates* may also be reduced with arsenious oxide (Amer. J. Sci. 1902, 14, 285). *Chlorates* are reduced by adding an excess of $N/10$-titanous sulphate, and after three minutes, titrating back with ferric alum (J. Soc. Chem. Ind. 1908, 27, 434).

(*c*) *Iodimetrically. Chlorates.* (i.) By distillation with concentrated hydrochloric acid. $ClO_3 = 3I_2$ (*Bunsen's method; v. Estimation of halogens;* Chem. Soc. Trans. 1892, 61, 87). (ii.) By reduction with concentrated hydrochloric acid and potassium bromide (Chem. Zeit. 1901, 25, 727), or with potassium iodide and dilute sulphuric acid in presence of vanadyl sulphate (Zeitsch. anal. Chem. 1907, 46, 521). (For other methods, *see* Amer. J. Sci. 1891, 42, 220; J. Amer. Chem. Soc. 1903, 25, 756; Zeitsch. anal. Chem. 1907, 46, 308.)

Hypochlorites. A slight excess of $N/10$-sodium arsenite is added and the excess titrated with $N/10$-iodine, or the hypochlorite is directly titrated with the arsenite till a drop of the solution ceases to colour starch-potassium iodide paper blue. $As = ClO$ (*Penot's method*; compare Chem. Zeit. 1904, 28, 59).

Perchlorates. The concentrated solution is boiled with a large excess of titanous sulphate, the excess oxidised with permanganate, and the chloride produced is titrated as usual (Zeitsch. anorg. Chem. 1909, 62, 108; Chem. Zeit. 1909, 33, 759).

Bromates. The substance is digested at 100° with potassium iodide and concentrated hydrochloric acid in a stoppered bottle, and the liberated iodine titrated with thiosulphate. $BrO_3 = 3I_2$ (compare Zeitsch. anorg. Chem. 1899, 19, 427).

Iodates. These are simply added to a slight excess of potassium iodide solution, acidified with sulphuric or hydrochloric acid, and the liberated iodine titrated. $IO_3 = 3I_2$.

ESTIMATIONS INVOLVING MIXTURES OF THE FOREGOING HALIDE SALTS.

Chloride, Hypochlorite and Chlorate. The solution is titrated with $N/10$-sodium arsenite by Penot's method for the *hypochlorite*; the *chlorate* is then estimated in the solution, after acidifying with sulphuric acid, by reduction with standard ferrous sulphate, and the total chlorine then titrated by Volhard's method (Compt. rend. 1896, 122, 449; cf. J. Amer. Chem. Soc. 1909, 31, 525, 1273).

Chloride, Chlorate and Perchlorate. Chloride is titrated in one portion of the solution by Volhard's method, and in another portion after reducing the chlorate with ferrous sulphate. For *perchlorate* the dry substance, mixed with five times its weight of pure quartz sand and covered with a layer of the same 2 cm. deep, is fused in a platinum crucible for half an hour, cooled, extracted with water, and the total chloride estimated (Compt. rend. 1896, 122, 452).

Chloride and Iodide. The *total halogen* is titrated by a suitable method in one portion of solution, and the *chlorine* in another portion after removing iodine by one of the following methods (Amer. J. Sci. 1890, 39, 293). (i.) To the neutral solution (400 c.c.) is added 10 c.c. sulphuric acid (1 : 1), 2 grams ferric sulphate, and 3 c.c. nitric acid, and the whole boiled till all iodine is expelled; 1 c.c. nitric acid is again added, and the solution again boiled. (ii.) The ferric sulphate and nitric acid of method (i.) are replaced by 2 grams of pure sodium nitrite (or, failing this, by passing into the solution the vapours generated from the slightly impure nitrite and dilute sulphuric acid).

Bromide and Iodide (*v. supra, Iodides*).

Bromide and Chloride. The solution is acidified so as to contain 25 c.c. of concentrated nitric acid in a total volume of 100 c.c., heated to boiling and boiled for one minute, the source of heat removed and air sucked through the solution until it is perfectly colourless (and for one minute longer). The bromine is then completely expelled; the residual *chloride* is titrated by Volhard's method. The *total halogens* are titrated in another portion of solution (J. Soc. Chem. Ind. 1909, 28, 505).

(For a very accurate but more elaborate method, *v.* J. Amer. Chem. Soc. 1907, 29, 275; also Zeitsch. anorg. Chem. 1895, 10, 387; Zeitsch. anal. Chem. 1900, 39, 81.)

Chloride, Bromide, and Iodide. (*a*) The *iodide* is decomposed with potassium iodate and acetic acid, the iodide extracted with chloroform and titrated. The *bromide* is destroyed by boiling with $5N$-nitric acid, any iodate remaining is decomposed with a slight excess of potassium iodide, which excess is readily decomposed by boiling with nitric acid, and the residual *chloride* titrated. The total *halogens* are titrated in another portion of solution (J. Amer. Chem. Soc. 1903, 25, 1138).

(*b*) The *iodide* is destroyed by boiling with ferric sulphate and sulphuric acid, and the amount of ferric salt reduced is determined with $N/10$-dichromate. The *total halogens* are determined by Volhard's method, and, in another portion of solution, the iodide is removed by adding hydrogen peroxide and acetic acid and distilling in steam, the bromine separated as described under *Bromide and Chloride* and the residual *chloride* titrated (J. Soc. Chem. Ind. 1909, 28, 505).

Iron. FERROUS SALTS. *By oxidation.* (a) The cold solution is strongly acidified with dilute sulphuric acid and titrated with $N/10$-permanganate. This simple and accurate method requires modification when hydrochloric acid is present, since it reacts with permanganate. This side-reaction can be practically prevented by adding a moderate quantity of manganese sulphate to the solution and titrating very slowly. A solution is prepared as follows: 67 grams of crystalline manganese sulphate are dissolved in water, 138 c.c. of phosphoric acid (sp.gr. 1·7), and 130 c.c. concentrated sulphuric acid (sp.gr. 1·82) are added, and the mixture diluted to 1 litre. Of this solution, 25 c.c. are added to the ferrous solution to be titrated. The phosphoric acid keeps the ferric solution colourless, and thus facilitates the observation of the end-point (Zeitsch. anal. Chem. 1863, 1, 329; Chem. Zeit. 1889, 13, 323; Amer. Chem. J. 1905, 34, 109; Analyst, 1908, 33, 43, and 1909, 34, 306).

(b) The acid solution is oxidised by $N/10$-dichromate as described under *Preparation of standard solutions.*

FERRIC SALTS. (a) *By reduction* to ferrous salt and titration with permanganate or dichromate. Reduction may be effected in any of the following ways: (i.) The sulphuric acid solution is heated to boiling and hydrogen sulphide passed through it until the solution is completely colourless; the excess of hydrogen sulphide is expelled from the boiling solution by a current of carbon dioxide. (ii.) The nearly neutral solution is boiled with sulphurous acid or ammonium sulphite, excess being removed by continued boiling, preferably in a current of carbon dioxide. (iii.) Eight or ten grams of granulated zinc are added to the warm sulphuric acid solution, and the action allowed to continue until a drop of the solution no longer gives a colouration with potassium thiocyanate. The solution is cooled, filtered through glass wool, and titrated. The use of the zinc-copper couple is preferable (Analyst, 1901, 26, 225; compare Chem. News, 1908, 97, 50). Reduction may be rapidly effected by pouring the liquid through a long column of zinc (The Jones' Reductor (Fig. 15); Chem. News, 1889, 60, 93; Blair's Chemical Analysis of Iron, 6th ed. 94). (iv.) The hydrochloric acid solution is heated nearly to boiling, and stannous chloride (25 p.c. solution) added drop by drop until the solution is colourless; 10 c.c. of saturated mercuric chloride are added to destroy excess of stannous chloride, the solution diluted, manganese sulphate added (*v. supra*), and the ferrous salt titrated with $N/10$-permanganate [best after the addition of about 5 c.c. of water-glass solution of sp.gr. 1·17] (Analyst, 1909, 34, 306). (v.) *Reduction by palladium-hydrogen* in boiling acid solution; this introduces no foreign substance into the solution (Zeitsch. angew. Chem. 1902, 15, 398, 424; Analyst, 1904, 29, 346). (vi.) *Reduction with titanous sulphate* (Amer. J. Sci. 1908, 25, 343).

(b) *By direct titration with a reducing agent.* (i.) *Titanous chloride.* The sulphuric or hydrochloric acid solution of the ferric salt is titrated as described under *Preparation of standard solutions.* (ii.) *Stannous chloride.* The nearly boiling hydrochloric solution is titrated as described under *Preparation of standard solutions*, using either the mercuric chloride indicator (Amer. Chem. J. 1893, 15, 360) or titrating back with iodine.

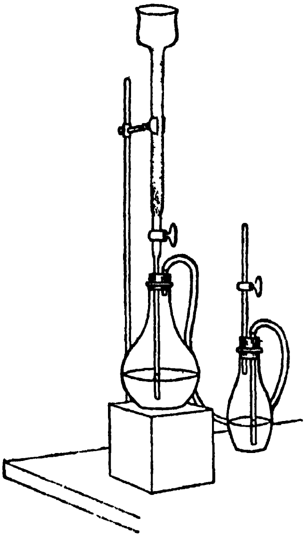

FIG. 15.

FERROUS IRON IN MINERALS AND ROCKS. The only satisfactory method consists in decomposing the coarsely powdered substance with sulphuric and hydrofluoric acids in an atmosphere of carbon dioxide, and titrating the ferrous salt produced (*Cooke's Method*; Amer. J. Sci. 1867, 44, 347; *see* also Amer. J. Sci. 1894, 48, 149). The old method of heating with dilute sulphuric acid in a sealed tube (Mitscherlich) is worthless in the presence of sulphur or sulphides (J. Amer. Chem. Soc. 1900, 22, 625). (For an exhaustive discussion of this problem, *v.* Hillebrand's Analysis of Silicate and Carbonate Rocks.)

Iron and Aluminium. After weighing the ignited sesquioxides, they are brought into solution by fusion with potassium hydrogen sulphate or acid potassium fluoride (followed by evaporation with sulphuric acid), and the *iron* reduced and titrated (Zeitsch. angew. Chem. 1905, 18, 815).

Iron and Titanium. Ferric salts can be reduced with sulphurous acid or hydrogen sulphide without reducing *titanic* salts; or reduction of both may be effected with zinc and sulphuric acid, the *titanous* salt oxidised with a slight excess of bismuth oxide, and the *ferrous* salt titrated in the filtered solution. To estimate both elements present, one of the preceding methods may be combined with the reduction process for titanium, described later, which would give the *total iron and titanium* (*v.* also J. Soc. Chem. Ind. 1909, 28, 189; Analyst, 1910, 35, 198).

Iron and Vanadium. Reduction with sulphur dioxide proceeds with the vanadium as far as to the oxide V_2O_4; reduction with zinc carries it as far as V_2O_2; hence two such reductions and titrations with permanganate furnish data for calculating both iron and vanadium (Amer. J. Sci. 1908, 26, 79).

Lead. *By precipitation* (i.) *As molybdate.* The boiling acetic acid solution is titrated with standard ammonium molybdate (4·75 grams per litre, titrated against pure lead) until a drop of solution gives a brown or yellow colour with a drop of dilute tannic acid solution. The indicator not being very sensitive, a 'blank' experiment should be made and the necessary correction allowed for both in an assay and in standardising the solution. (ii.) *As ferrocyanide.* The cold acetic acid solution is titrated with potassium ferrocyanide (10 grams per litre titrated against pure lead) until a drop of the solution produces a brown colouration with a drop of saturated uranium acetate solution; a 'blank' experiment should also be made (J. Amer. Chem. Soc. 15, 550; Chem. News, 1896, 73, 18). In determining lead in ores, &c., it is usually separated as sulphate and dissolved in ammonium acetate previous to titration. (For a comprehensive review of methods for lead, *v.* Chem. News, 1903, 87, 40; Gaz. chim. ital. 1896, 26, i. 327; *see* also *Methods of separation*; and J. Amer. Chem. Soc. 1903, 25, 632; 1904, 26, 1135.)

Magnesium. (*a*) *Acidimetrically.* The magnesium is precipitated as the double ammonium phosphate, the precipitate washed with dilute ammonia, and then with aqueous alcohol till free from extraneous ammonia, dissolved in a measured excess of *N*/10-hydrochloric acid, and the excess titrated with *N*/10-sodium hydroxide, using methyl orange for indicator:

$$Mg(NH_4)PO_4+2HCl = MgCl_2+H_2(NH_4)PO_4$$

(Chem. Zentr. 1876, 727; for a method which obviates the use of alcohol, *v.* J. Amer. Chem. Soc. 1900, 22, 31; *see* also *Phosphorus*).

(*b*) *Iodimetrically.* The magnesium is precipitated as double ammonium arsenate, dissolved in hydrochloric acid and potassium iodide, and the iodine titrated (J. Amer. Chem. Soc. 1899, 21, 746; Zeitsch. anal. Chem. 1907, 46, 714).

Manganese. (*a*) *By oxidation with permanganate.* (*Volhard's method, modified.*) The neutral chloride or sulphate solution containing 10 grams of zinc sulphate is heated to boiling, 1 gram of freshly ignited zinc oxide added, and the liquid titrated with *N*/10-permanganate, boiling and shaking frequently until the supernatant liquid is red; 1 c.c. pure glacial acetic acid is added, and the titration slowly finished with permanganate in the hot *but not boiling* liquid. The manganese can be accurately calculated from the equation:

$$3MnO+Mn_2O_7 = 5MnO_2$$

(Zeitsch. anal. Chem. 1909, 48, 751; Little and Cahen, Analyst, 1911, 36, 52).

(*b*) *By precipitation as dioxide* and estimation of the available oxygen. Precipitation may be effected in one of the following ways: (i.) By adding bleaching-powder solution and calcium carbonate to a hot, neutral solution of the manganese salt containing ferric and zinc chlorides (Chem. Soc. Trans. 1879, 35, 365; J. Soc. Chem. Ind. 1891, 10, 333). (ii.) By boiling the solution in concentrated nitric acid (quite free from any hydrochloric acid) with potassium (or preferably sodium) chlorate. (iii.) By boiling the dilute sulphuric acid solution with ammonium persulphate (Zeitsch. angew. Chem. 1901, 14, 1149; 1903, 16, 905; Compt. rend. 1902, 135, 965; 1903, 136, 449). The washed precipitate in either case is dissolved in a sulphuric acid solution of standard ferrous sulphate or oxalic acid, and the excess of reagent titrated. The precipitate obtained by method (ii.) is deficient in available oxygen (Amer. J. Sci. 1898, 5, 260), and the standard solution employed in the final titration must therefore be standardised on a known amount of manganese treated in a similar fashion.

(*c*) *By conversion into permanganic acid.* (i.) The cold solution free from hydrochloric acid, and containing one quarter its volume of nitric acid (specific gravity 1·42), is oxidised by shaking with 2–4 grams of sodium bismuthate for three minutes, diluted with half its volume of 3 p.c. nitric acid, the solid residue allowed to settle, and the permanganic acid solution filtered into a slight excess of ferrous sulphate; excess of the latter is then titrated with *N*/10-permanganate (Dingl. poly. J. 269, 224; Chem. Soc. Trans. 1895, 67, 268; Chem. News, 1901, 84, 209, 247; J. Amer. Chem. Soc. 1904, 26, 793). (ii.) The oxidation of small quantities of manganese may be effected by boiling the nitric acid solution with lead peroxide, or by heating with ammonium persulphate in the presence of a little silver nitrate (Chem. News, 1901, 84, 239).

Manganese in Ferromanganese and Steels. The foregoing methods *a*, *b*, and *c* (i.) have all been employed for this purpose; method *c* (i.) is the simplest and probably the most accurate. In method *a* it is necessary to remove iron from the solution; this is conveniently performed by adding a slight excess of zinc oxide to the solution (*v.* references given above; also J. Amer. Chem. Soc. 1902, 24, 243; Ann. Chim. anal. 1906, 11, 124).

Manganese and Chromium occurring together in steels may be estimated by oxidising with ammonium persulphate in sulphuric acid solution in the presence of silver nitrate; one portion of solution is titrated for total permanganate and chromate with ferrous sulphate, and another for permanganate alone by means of arsenious oxide (J. Amer. Chem. Soc. 1905, 27, 1550; *v.* also Chem. News, 1901, 83, 25; 1905, 91, 3; Chem. Zeit. 1905, 29, 987; Chem. Zeit. Rep. 1905, 29, 380).

The foregoing bismuthate method *c* (i.) may be applied in the presence of *molybdenum, tungsten, titanium*, and *vanadium*; also, with certain precautions, in the presence of *chromium* (Chem. News, 1901, 84, 247). (For estimating *manganese* in *tungsten steels*, *v.* also J. Soc. Chem. Ind. 1907, 26, 345.)

Mercury. (*a*) *By precipitation.* Mercuric nitrate is readily titrated with *N*/10-thiocyanate, using ferric nitrate as indicator, provided that nitric acid is present in fairly high concentration (Ber. 1901, 34, 3502; 1902, 35, 2015). Chloride must be absent; if necessary, the mercury is precipitated as oxide with sodium hydroxide, and the washed precipitate dissolved in nitric acid.

(*b*) *Iodimetrically.* The mercuric solution (25–50 c.c.) containing 1 gram of potassium iodide is made alkaline with sodium hydroxide, 2–3 c.c. of 40 p.c. formaldehyde added, and the whole shaken vigorously for two minutes. The solution is acidified with acetic acid, and the reduced mercury is dissolved by adding an excess of *N*/10-iodine. After shaking, the excess of iodine above that required to form mercuric iodide is titrated with *N*/10-thiosulphate (Ber. 1906, 39, 3702; 1907, 40, 3276; Bull. Soc. chim. 1907, [iv.] 1, 1169). Mercurous salts require a preliminary oxidation.

(For other methods, *v.* Compt. rend. 1863, 56, 63; Chem. Soc. Trans. 1892, 61, 364; Arch. Pharm. 241, 444.)

Molybdenum. (*a*) *By reduction and subsequent oxidation.* The sulphuric acid solution is reduced by passing it through a long column of amalgamated zinc to a condition represented by the formula Mo_2O_3; the liquid is caught directly in ferric sulphate solution, which reoxidises the molybdenum salt, and the ferrous sulphate produced is titrated with *N*/10-permanganate (Amer. J. Sci. 1907, 24, 313; compare Ber. 1905, 38, 604; Analyst, 1907, 32, 250).

(*b*) *Iodimetrically.* The solution in concentrated hydrochloric acid is boiled with a slight excess of potassium iodide till the volume is reduced to 25 c.c., when complete reduction to the condition Mo_2O_5 is effected. The solution is cooled, diluted to 125 c.c., 0·5 gram of manganese sulphate added, and then a slight excess of *N*/10-permanganate; *N*/10-arsenious acid is next added, and after the addition of tartaric acid and sodium bicarbonate, the excess is titrated with *N*/10-iodine. The permanganate *plus* iodine and *minus* the arsenious acid measure the Mo_2O_5 present (Amer. J. Sci. 1901, 12, 449; compare *ibid.* 1896, 2, 156; 1898, 6, 168).

Molybdenum in Steels and Alloys (*v.* J. Amer. Chem. Soc. 1904, 26, 675).

Nickel. (*a*) *By double cyanide formation.* A few drops of 10 p.c. potassium iodide are added to the cold, slightly ammoniacal nickel solution, and then a small measured volume of silver nitrate (3 grams of silver per litre). Standard potassium cyanide (25 grams per litre) is then run in with stirring till the precipitate of silver iodide just disappears; more silver nitrate is added till a very faint turbidity is produced, which is then dissolved by the least possible excess of cyanide. The relative values of the silver nitrate and cyanide solutions are determined by a preliminary experiment, and the cyanide standardised against a known amount of pure nickel (or pure silver, and calculated to nickel). The method is rapid and accurate (Chem. News, 1895, 72, 92).

(*b*) *By precipitation.* The hot nickel solution containing ferric chloride and citric acid is made feebly ammoniacal and titrated slowly, stirring constantly, with standard potassium ferrocyanide (20 grams per litre, titrated against pure nickel), until a drop of the solution when acidified with dilute acetic acid develops a green colour in five minutes (J. Amer. Chem. Soc. 1910, 32, 757; Bull. Soc. chim. 1907, 4, 1163).

Nickel in Steel. Method (*b*) can be directly applied; method (*a*) can also be employed without removing iron, molybdenum, or chromium, if a sufficient excess of ammonium citrate or sodium pyrophosphate is added to the solution; or a moderate amount (2–3 grams) of each of these reagents may be added (J. Amer. Chem. Soc. 1907, 29, 1201; 1908, 30, 1116; 1899, 21, 854; Chem. Zeit. 1908, 32, 1223). (For modifications in presence of other metals, *v.* Chem. News, 1898, 78, 177, 190.)

Nitrogen. AMMONIA (*v.* ACIDIMETRY AND ALKALIMETRY).

HYDRAZINE. *Iodimetrically.* A moderate excess of sodium bicarbonate or sodium acetate is added to the solution of a hydrazine salt, which is then titrated with *N*/10-iodine. $N_2H_4=2I$ (J. pr. Chem. 1902, 66, 332; 1903, 67, 140; *v.* also Gazz. chim. ital. 1899, 29, 265).

HYDROXYLAMINE. (*a*) *By oxidation.* The solution of a hydroxylamine salt is slowly added to excess of boiling and well-stirred Barreswil's (Fehling's) solution, the precipitated cuprous oxide washed, dissolved in acid ferric alum, and the ferrous salt titrated with permanganate. $NH_2OH=Cu_2$ (Chem. Soc. Trans. 1903, 83, 1394; compare Ber. 1877, 10, 1940).

(*b*) *By reduction.* An excess of titanium sesquisulphate is added to the acid solution, and the ammonium salt produced is estimated by distillation with sodium hydroxide (Ber. 1909, 42, 2695).

NITRATES. (*a*) *By reduction.* The solution is made strongly alkaline with sodium hydroxide, 5 c.c. of alcohol and 2·5–3 grams of powdered Devarda's alloy added, and the flask connected with a distilling apparatus, the receiver of which contains excess of *N*/2-hydrochloric acid. After standing for half an hour, the liquid is steam-distilled for an equal length of time, when all the nitrate has been converted into ammonia and driven over into the acid; the excess of the latter is then titrated (Zeitsch. anal. Chem. 1894, 33, 113; Analyst, 1910, 35, 307; *v.* also the *Gravimetric section*).

(*b*) *Iodimetrically* (*v.* Zeitsch. angew. Chem. 1890, 3, 477; Chem. Soc. Trans. 1891, 59, 530; Amer. J. Sci. 1892, 44, 117).

NITRITES. (*a*) *By oxidation.* The nitrite solution is slowly added to a measured quantity of *N*/10-permanganate, which is acidified with sulphuric acid, diluted to 400 c.c., and warmed to 40°, until the colour is just discharged. $2HNO_2 = O_2$. Otherwise, the cold dilute nitrite solution is slowly titrated with *N*/10-permanganate to a red colouration; a few drops of sulphuric acid are then added, followed by an excess of permanganate. The liquid is then strongly acidified with sulphuric acid, heated nearly to boiling, and the excess of permanganate titrated with *N*/10-oxalic acid (Amer. Chem. J. 1883, 5, 388).

(*b*) *Iodimetrically.* Several methods have been based on the reaction.

$$2HI+2HNO_2 = I_2+2NO+2H_2O.$$

It is necessary to perform the experiment in an atmosphere free from oxygen; the iodine may be determined by thiosulphate or arsenite. (For details, *v.* Pharm. J. 19, 741; Chem. News, 1904, 90, 114; *cf.* *Organic analysis,* Aromatic amines.)

Colorimetrically. Nitrous acid may be estimated by the formation of a yellow colour due to the production of paranitrosodimethylaniline, by adding a solution of dimethylaniline hydrochloride to an acidulated solution of the nitrous acid, and comparing the intensity of the colour produced with a standard solution of sodium nitrite with the same reagents. (For details, *see* Miller, Analyst, 1912, 37, 345.)

Osmium. *Iodimetrically* (*v.* Chem. Zentr. 1898, ii. 65).

Oxygen. PEROXIDES. (*a*) *Iodimetrically.* Such peroxides as those of manganese and lead may be estimated by distillation with concentrated hydrochloric acid, and collecting the chlorine evolved in potassium iodide (*Bunsen's method*). Finely divided peroxides of manganese react quantitatively with cold dilute hydrochloric acid and potassium iodide (Chem. Soc. Trans. 1880, 37, 128), a method of estimation that is available with the peroxides of the alkali and alkali earth metals, which do not give satisfactory results by the distillation method (Arch. Pharm. 1902, 240, 437). Hydrogen peroxide may be determined in this manner (Analyst, 1888, 13, 62).

(*b*) *By reduction.* Hydrogen peroxide, or peroxides of the alkali and alkaline-earth metals, may be dissolved in cold dilute acid and titrated with *N*/10-permanganate, which loses as much oxygen as is lost by the peroxide (*v.* also *Gas-Volumetric methods*).

(For critical reviews of methods, &c., *v.* Arch. Pharm. 228, 432; Amer. Chem. J. 1906, 36, 117; Zeitsch. angew. Chem. 1901, 14, 828; 1908, 21, 589; Chem. Zeit. 1906, 30, 1275; 1907, 31, 1257; Zeitsch. anal. Chem. 1908, 47, 465.)

Phosphorus. PHOSPHORIC ACID (ORTHO-). (*a*) (*v.* ACIDIMETRY AND ALKALIMETRY).

(*b*) *Acidimetrically, with previous precipitation.* (i.) The precipitated magnesium ammonium phosphate (*v. Gravimetric section*) is washed and titrated as described under *Magnesium* (Zeitsch. anal. Chem. 1898, 37, 217; Zeitsch. angew. Chem. 1905, 18, 655; compare Zeitsch. anal. Chem. 34, 33). (ii.) The precipitate of ammonium phosphomolybdate (*v. Gravimetric section*) after washing is dissolved in a slight excess of standard potassium hydroxide free from carbonate, and the excess titrated with standard nitric acid using phenolphthaleïn as indicator. One molecular proportion of P_2O_5 present as $(NH_4)_3PO_4,12MoO_3$, requires 23 molecules of K_2O in pure aqueous caustic potash. $P_2O_5{=}23K_2O$ (J. Amer. Chem. Soc. 1895, 17, 950; 1897, 19, 703; J. Soc. Chem. Ind. 1904, 23, 1186).

(*c*) *By precipitation.* To the solution, feebly acid with acetic acid, 10 c.c. of 10 p.c. ammonium acetate are added and standard uranium acetate solution (35 grams per litre) run in from a burette until a drop of the solution gives a brown colouration with potassium ferrocyanide upon a white tile. The solution is heated to boiling, when the latter reaction will no longer take place, and more uranium acetate added until the brown colouration is obtained once more, *e.g.*:

$$KH_2PO_4+UO_2(C_2H_3O_2)_2+NH_4{\cdot}C_2H_3O_2$$
$$= KC_2H_3O_2+2HC_2H_3O_2+UO_2NH_4PO_4$$

In analysing alkali phosphates, the uranium solution is standardised against pure potassium dihydrogen phosphate, while a solution of calcium phosphate in acetic acid, standardised gravimetrically by the method of Woy (Chem. Zeit. 1897, 21, 442), must be used if the uranium acetate is to be used for estimating phosphates of the alkaline earths (J. Soc. Chem. Ind. 1892, 11, 328). It is essential that titrations should be made under conditions closely approximating those which obtained when the uranium solution was standardised.

PHOSPHORUS IN IRON AND STEEL. This is usually separated as ammonium phosphomolybdate; it may then be titrated according to *b* (ii.) above, or the precipitate is washed with dilute ammonium sulphate, dissolved in ammonia, the solution strongly acidified with sulphuric acid, reduced with zinc, and the Mo_2O_3 solution collected directly in ferric alum, the ferrous salt being then titrated as described under *Molybdenum* (Amer. J. Sci. 1907, 24, 313; compare Blair's Analysis of Iron).

Potassium. *By oxidation.* The acetic acid solution, free from ammonium salts, is evaporated on the water-bath till pasty with sodium cobaltinitrite solution in rather large excess, cooled and stirred with 50–100 c.c. of cold water. The dipotassium sodium cobaltinitrite is collected, on asbestos, washed with cold water, and then immefsed in an excess of nearly boiling permanganate solution. After 5 minutes the solution is acidified with sulphuric acid, excess of *N*/10-oxalic acid added, and the clear solution titrated with permanganate. The permanganate is best standardised against a pure potassium salt. The oxidation of 2 molecular porportions of $K_2NaCo(NO_2)_6$ by permanganate requires 11 atomic proportions of oxygen or 4K = 22H (Amer. J. Sci 1907, 24, 433; compare Chem. Soc. Trans. 1900, 77, 1076). (For another method, *v.* Chem. Zeit. 1895, 19, 301.)

Selenium. SELENIOUS ACID. *By oxidation.* To the cold solution containing 5 p.c. by volume of concentrated sulphuric acid is added an excess of *N*/10-permanganate; a moderate excess of *N*/10-oxalic acid is then added, and the titration finished at 50°–60° with permanganate. $2SeO_2 = O_2$ (Amer. J. Sci. 1895, 50, 51).

(For an entirely different method, *v.* Amer. Chem. J. 1896, 18, 703; Amer. J. Sci. 1899, 7, 287.)

SELENIC ACID. *Iodimetrically.* (i.) The acid is boiled with hydrochloric acid (25 c.c. concentrated acid in a total volume of 75 c.c.) for 10 minutes in a Bunsen distilling apparatus or one of its various modifications, and the chlorine evolved is collected in potassium iodide (*v. supra, Volumetric estimation of halogens*, p. 209) $SeO_3 = Cl_2$ (Amer. J. Sci. 1895, 50, 400). (ii.) The solution (60 c.c.) containing 20 c.c. of sulphuric acid (1 : 1) and 1 gram of potassium bromide is distilled and the liberated bromine collected in potassium iodide. $SeO_3 = Br_2$ (Amer. J. Sci. 1895, 50, 402).

SELENIUM IN EITHER STATE OF OXIDATION. *Iodimetrically.* This is effected by a Bunsen distillation, the solution (60 c.c.) containing 5 c.c. of concentrated hydrochloric acid and 1–3 grams of potassium iodide. The selenium compound is reduced to the element itself, and an equivalent of iodine is distilled into potassium iodide and titrated. $SeO_2 = 2I_2$ and $SeO_3{=}3I_2$ (Amer. J. Sci. 1895, 50, 249; for a simpler method *v.* Amer. J. Sci. 1896, 1, 31).

Silver. *By precipitation.* (i.) The nitric acid solution is titrated with standard sodium chloride until no further precipitation is observed. (For details of this very exact method, *v.* the article on ASSAYING.) A number of devices have been described for rapidly filtering a portion of the liquid in order to test it for further precipitation (Chem. Soc. Trans. 1908, 93, 1037; Gazz. chim. ital. 1909, 39, ii. 240). A modified method consists in adding a slight deficit of sodium chloride, filtering and titrating the remaining silver with dilute ammonium thiocyanate (J. Amer. Chem. Soc. 1897, 19, 814; *v.* also Chem. Soc. Trans. 1900, 77, 232; Zeitsch. angew. Chem. 1904, 17, 647). (ii.) Titration may be effected with *N*/10-thiocyanate as described under *Preparation of standard solutions.*

Sodium (*v.* Chem. Soc. Trans. 1898, 73, 167).

Sulphur, Acids of. HYDROGEN SULPHIDE. *Iodimetrically.* The gas or a measured volume of solution is absorbed in an excess of *N*/10-iodine, the excess being afterwards titrated with *N*/10-thiosulphate. $H_2S = I_2$. Direct titration with iodine leads to low results (Zeitsch. anal. Chem. 1906, 45, 541).

HYDROSULPHUROUS ACID. *By oxidation.* The sodium salt, used in indigo-dyeing, can be estimated by dissolving it in air-free water in an atmosphere of carbon dioxide, adding a drop of ferrous sulphate, and running in standard potassium ferricyanide solution until a blue colour appears, air being rigidly excluded (Zeitsch. angew. Chem. 1905, 18, 168):

$$Na_2S_2O_4+2K_3Fe(CN)_6=2SO_2+2K_3NaFe(CN)_6.$$

If necessary, a little acetic acid is added to ensure that the liquid shall be acid.

SULPHUROUS ACID. *Iodimetrically.* An aqueous solution of sulphur dioxide is estimated by running it into an excess of standard iodine solution with constant stirring, and not *vice versâ*, since that method causes a separation of sulphur due to the side-reaction:

$$SO_2+4HI=S+2H_2O+2I_2$$

(Annalen, 1887, 242, 94). Sulphites may be accurately determined by adding the powdered salt to excess of *N*/10-iodine, and after the decomposition is complete, titrating back with *N*/10-thiosulphate (J. Soc. Chem. Ind. 1884, 3, 197; 1885, 4, 303)

$$SO_2+I_2+2H_2O = H_2SO_4+2HI.$$

SULPHURIC ACID. (*a*) *Iodimetrically.* The feebly acid boiling dilute sulphate solution is precipitated with an excess of a solution of barium chromate in hydrochloric acid (3–4 grams $BaCrO_4$, 30 c.c. conc. HCl, diluted to 1 litre). Barium sulphate is thus precipitated, and an equivalent of chromic acid liberated. The boiling solution is neutralised with powdered chalk to remove excess of barium chromate, and the chromic acid in the cold filtrate titrated iodimetrically. $CrO_3=SO_3$ (Amer. Chem. J. 1889, 11, 567; Chem. Zeit. 1898, 22, 357).

(*b*) *By precipitation.* (i.) The boiling sulphate solution, slightly acid with hydrochloric acid, is titrated with standard barium chloride until no more precipitate is produced. $Ba=SO_4$ (Chem. News, 1889, 59, 41). A device for readily observing the end-point is described in Chem. Soc. Trans. 1907, 91, 1370. (ii.) Method (i.) may be modified by adding an excess of barium chloride, and determining the excess by adding sodium acetate, acetic acid, and ammonium dichromate, and titrating an aliquot part of the filtrate with *N*/20-ferrous sulphate (Chem. Soc. Trans. 1909, 95, 2198). (iii.) The sulphate is precipitated from dilute solution with excess of benzidine hydrochloride solution as benzidine sulphate, and the precipitate titrated with *N*/10-sodium hydroxide, using methyl orange as indicator (*v.* Zeitsch. angew. Chem. 1907, 20, 9, for details, corrections, &c.).

THIOSULPHURIC ACID. *Iodimetrically.* Thiosulphates are titrated with iodine as in standardising thiosulphate solution (*v. supra*, p. 205); sparingly soluble salts are suspended in water and titrated, shaking vigorously in a stoppered bottle all the time.

PERSULPHURIC ACID. (*a*) *By oxidation.* The solution is acidified with sulphuric acid, a considerable excess of standard ferrous sulphate is added, and then 100 c.c. of hot distilled water (70°–80°). Excess of ferrous salt is then quickly titrated with *N*/10-permanganate. $H_2S_2O_8=2FeO$ (Chem. Soc. Abst. 1900, ii. 45).

(For other methods, *v.* Chem. Zentr. 1900, 435; Amer. J. Sci. 1901, 12, 367; Gazz. chim. ital. 1902, 32, ii. 383; Bull. Soc. chim. 1903, 30, 930.)

Tellurium. TELLUROUS COMPOUNDS. (*a*) *By oxidation.* The solution is rendered alkaline with sodium hydroxide, an excess of *N*/10-permanganate is added, and the excess estimated by acidifying with sulphuric acid, adding *N*/10-oxalic acid in excess, and finishing the titration with permanganate. $2TeO_2=O_2$ (Chem. Soc. Trans. 1891, 59, 238; Amer. J. Sci. 1899, 8, 122).

(*b*) *By precipitation* as tetraiodide in moderately concentrated sulphuric acid solution (Amer. J. Sci. 1896, 2, 271).

(*c*) *Iodimetrically* (*v.* Amer. Chem. J. 1898, 20, 278).

TELLURIC COMPOUNDS. *Iodimetrically.* The tellurate is distilled with concentrated hydrochloric acid in Bunsen's apparatus, the chlorine absorbed in potassium iodide and the iodine set free is titrated with *N*/10-thiosulphate. Telluric anhydride must be previously dissolved in concentrated potassium (not sodium) hydroxide, since it is scarcely attacked by hydrochloric acid. The reduction, which proceeds to tellurous acid, may be also effected by distilling with potassium bromide and dilute sulphuric acid (Zeitsch. anorg. Chem. 1894, 7, 132).

Thallium. *Iodimetrically.* The dilute solution of thallic salt is mixed with excess of potassium iodide, and the iodine liberated is titrated with *N*/10-thiosulphate. $Tl = I_2$ (Compt. rend. 1902, 134, 655).

Tin. STANNOUS SALTS. *Iodimetrically.* The cold hydrochloric acid solution of the stannous salt is titrated with *N*/10-iodine. $Sn = I_2$ (J. Amer. Chem. Soc. 1897, 19, 809). Free exposure of the solution to air must be avoided, since stannous salts readily undergo oxidation; it is preferable to work in an atmosphere of carbon dioxide.

STANNIC SALTS must be reduced before titration with iodine; this may be accomplished by heating the hydrochloric acid solution with iron, or sheet nickel, or with finely powdered antimony (Chem. News, 1901, 84, 167).

Titanium. *By reduction and subsequent oxidation.* It is difficult to obtain accurate results with quantities of titanium dioxide exceeding 0·15 gram. The warm, dilute sulphuric acid solution of titanic salt is reduced to the tervalent condition by means of zinc, aluminium-magnesium alloy, or zinc-aluminium alloy (Zn, 90 p.c. Al 10 p.c., cast in sticks), cooled and rapidly filtered into ferric sulphate solution; the equivalent quantity of ferrous sulphate produced is titrated with $N/10$-permanganate. Ti = Fe (Chem. Zeit. 1907, 31, 399; Amer. J. Sci. 1908, 25, 130; Analyst, 1910, 35, 198; compare J. Amer. Chem. Soc. 1895, 17, 878).

Titanium and Iron (*v. Iron*).

Tungsten. *By reduction and subsequent oxidation.* The solution is reduced by zinc and hydrochloric acid to a condition corresponding to the oxide WO_2, filtered and titrated with a standard ferric solution. The end-point is perceived by the disappearance of the intense blue colour of the intermediate compound corresponding to W_2O_5, the reaction

$$Fe_2O_3+WO_2 = WO_3+2FeO$$

being quantitative (Chem. Soc. Proc. 1909, 25, 227).

Uranium. (*a*) *By reduction and subsequent oxidation.* The solution, containing 20 c.c. of concentrated sulphuric acid in a volume of 125 c.c., is poured upon 100 grams of pure zinc (in sticks 2 cm. long), heated nearly to boiling for 15 minutes, filtered into a large porcelain dish, and the zinc washed with cold dilute sulphuric acid (1 : 10 by volume) till the total volume of solution is 300 c.c. The solution of uranous sulphate, which should be sea-green in colour, is then titrated with $N/10$-permanganate. The solution can also be reduced by passage through a long column of amalgamated zinc; in either case the reduction proceeds a little too far, but oxidation to the uranous state is accomplished during the filtration and washing. High results are obtained by carrying out the experiment in an atmosphere of carbon dioxide.

$$5U(SO_4)_2 = 2KMnO_4 = 10FeSO_4, \text{ or } U = 2Fe$$

(J. Amer. Chem. Soc., 1909, 31, 367; compare *ibid.* 1901, 23, 685; 1906, 28, 1541; Amer. J. Sci. 1903, 16, 229).

(*b*) *Iodimetrically* (*v.* Ber. 1904, 37, 189).

Uranium and Vanadium (*v.* J. Amer. Chem. Soc. 1906, 28, 1443).

Vanadium. (*a*) *By reduction and subsequent oxidation.* (i.) The vanadic solution containing sulphuric acid is boiled with sulphur dioxide until the colour is a pure blue, and the excess of sulphur dioxide then expelled with carbon dioxide; the solution, containing vanadium salt corresponding to the oxide V_2O_4, is then titrated hot with $N/10$-permanganate. (ii.) The sulphuric acid solution is passed through a long column of amalgamated zinc, and the reduced solution collected and titrated as described under *Molybdenum*. In this case reduction proceeds as far as the oxide V_2O_3 (Amer. J. Sci. 1908, 25, 332; compare *ibid.* 1903, 15, 389). (iii.) The solution is evaporated nearly to dryness three times with concentrated hydrochloric acid, when vanadyl chloride $VOCl_2$ is formed; hydrochloric acid is removed by evaporation with sulphuric acid, the solution diluted and titrated with $N/10$-permanganate (Ber. 1903, 36, 3164).

(*b*) *By reduction.* The vanadate solution, hot or cold, and containing hydrochloric or sulphuric acid, is titrated with standard (2 p.c.) stannous chloride (titrated against iodine) until a drop of the solution gives a blue colouration with ammonium molybdate. Reduction proceeds as far as the tetroxide V_2O_4 (Bull. Soc. chim. 1908, 3, 626).

(*c*) *Iodimetrically.* (i.) About 0·3–0·5 gram of vanadate is distilled with 1·5–2·0 grams of potassium bromide and 30 c.c. of concentrated hydrochloric acid, the liberated bromine absorbed in potassium iodide, and the iodine titrated with $N/10$-thiosulphate; $V_2O_5 = Br_2$, the reduction proceeding to the tetroxide (Chem. Zentr. 1890, i. 977; for other iodimetric methods, *v.* Amer. J. Sci. 1896, 2, 185, 355; 1902, 14, 369).

Vanadium and Chromium (*v.* Bull. Soc. chim. 1904, 31, 962).

Vanadium and Uranium (*v.* J. Amer. Chem. Soc. 1906, 28, 1443).

Vanadium and Iron (*v. Iron;* and J. Amer. Chem. Soc. 1908, 30, 1229, 1233).

Zinc. (*a*) *By precipitation.* The chloride solution, containing 3 c.c. of concentrated hydrochloric acid in a volume of 250 c.c., is heated nearly to boiling, and titrated with standard potassium ferrocyanide solution (21·5 grams per litre, titrated against pure zinc) until one or two drops of the solution produce a brown colouration with uranium nitrate (J. Amer. Chem. Soc. 1900, 22, 198; 1904, 26, 4; 1908, 30, 225; Zeitsch. anal. Chem. 1906, 44, 174). The uranium nitrate indicator may be replaced by ammonium molybdate (Chem. Zeit. 1905, 29, 951). It has been recommended to add excess of ferrocyanide, and titrate back with standard zinc chloride (Zeitsch. anal. Chem. 1896, 35, 460).

(For the application of this method to ores and alloys, *v.* J. Amer. Chem. Soc. 1907, 29, 265; Chem. Zeit. 1905, 29, 951; J. Soc. Chem. Ind. 1905, 24, 228, 1278.)

(*c*) *Iodimetrically.* As for *Magnesium, v. supra*, p. 212; and J. Amer. Chem. Soc. 1900, 22, 353.

Colorimetric Methods.

These methods are especially valuable for the estimation of very small quantities of substances, and are capable of giving very accurate results. The depth of tint produced by some characteristic colour reagent in a given volume of the solution is compared with the tint produced by the same reagent in an equal volume of a solution containing a known quantity of the substance to be determined. The tint in the comparison tube can be varied by varying the proportion of the substance which it contains, and when the tints are equal the quantities of the substance in each tube are also equal. The quantity in one tube is known, and hence that in the other is determined. It is important that the comparison be made under comparable conditions with respect to degree of acidity or alkalinity, proportion of the reagent, and the like. It is also important that the depth of tint should not be materially affected by the presence of other saline substances in the solution under examination.

The following substances may be determined by these methods:—

Lead, with hydrogen sulphide.

Copper, with hydrogen sulphide or potassium ferrocyanide (Carnelley, Chem. News, 32, 308).

Iron, with potassium ferrocyanide (Carnelley, Chem. News, 30, 257).

Iron, with potassium thiocyanate (Thomson, Chem. Soc. Trans. 1885, 493).

Vanadium, with hydrogen peroxide.

Titanium, with hydrogen peroxide (Weller, Ber. 1882, 15, 2593).

Ammonia, by Nessler's solution (*v.* WATER).

Iodine, in solution in carbon disulphide, or with starch.

Nitrates, by phenolsulphonic acid test (*v.* WATER).

Nitrites, by (i.) *m*-phenylenediamine; (ii.) sulphanilic acid and α-naphthylamine (*v.* WATER).

The principle may likewise be applied to the comparison of colouring matters, provided that the solutions are sufficiently diluted (*v.* COLORIMETER).

ULTIMATE ANALYSIS OF CARBON COMPOUNDS.

The majority of carbon compounds contain carbon, hydrogen, and oxygen, or carbon, hydrogen, oxygen, and nitrogen; a smaller number contain one or more of the halogens, or sulphur. There are a still smaller number of organic derivatives of phosphorus, arsenic, antimony, silicon, and other metalloidal and metallic elements, and the metals also occur in the salts of organic acids.

Qualitative Examination.

Carbon is converted into carbon dioxide when the substance is heated with cupric oxide.

Hydrogen. The substance is heated to a temperature below that at which decomposition begins, until all water existing as such is expelled, and is then heated with finely divided and recently ignited cupric oxide; the hydrogen is evolved as water.

Nitrogen. Many carbon compounds containing nitrogen evolve this element in the form of ammonia when heated with caustic soda or soda-lime, but this test is not applicable to nitro-, nitroso-, azo-, and diazo- derivatives.

Many nitro-, nitroso-, and diazo- derivatives evolve oxides of nitrogen, with or without explosion, when heated.

Nitrogen in all classes of carbon compounds, with the exception of the diazo- compounds, may be detected by heating the substance with metallic sodium or potassium, together with some sodium carbonate if the substance is explosive. The nitrogen is converted into alkali cyanide, and the cooled mass is extracted with water and the cyanogen detected by the Prussian-blue test, which consists in adding ferrous sulphate to the alkaline solution after filtration, warming gently and then acidifying. Nitrogenous carbon compounds containing sulphur yield, when heated with sodium, a thiocyanate, and the Prussian-blue test cannot be used. A large excess of potassium is recommended in this case, when it is stated that sulphur does not interfere (Täuber, Ber. 1899, 32, 3150). A mixture of potassium carbonate (138 parts) and magnesium powder (72 parts) has been recommended for general use in detecting nitrogen even in the case of diazo- derivatives and stable pyrrole compounds (*v.* Ber. 1902, 35, 2523; Gazz. chim. ital. 1904, 34, [2] 359). This mixture is, however, found to take up nitrogen from the atmosphere (Ellis, Chem. News, 1910, 102, 187).

Halogens are detected by heating the substance with pure lime or pure soda-lime, extracting with water, slightly acidifying with nitric acid, and testing with silver nitrate. Highly nitrogenous compounds, when heated with lime, are apt to yield calcium cyanide; hence the supposed precipitate of silver halide should always be tested for cyanide (*v. Separation of cyanide and chloride*), unless nitrogen is known to be absent. With soda-lime no cyanide is formed. The substance may also be heated with sodium or potassium as in testing for nitrogen; iodine and bromine are detected by acidifying, adding chlorine water, and shaking up with chloroform, which becomes purple or brown. The supposed silver chloride should, however, always be tested for cyanide.

Sulphur and phosphorus in non-volatile substances are detected by fusing with caustic soda or potash mixed with about one-fifth its weight of potassium nitrate, or by heating with sodium peroxide diluted with sodium carbonate; in either case the product is tested for sulphuric or phosphoric acid. Volatile or non-volatile substances may be oxidised by heating in a sealed tube at 150°–300°, according to circumstances, with fuming nitric acid of sp.gr. 1·5. Sulphur and phosphorus are oxidised to sulphuric and phosphoric acid respectively.

Sulphur is also detected by heating the substance with sodium, extracting with water, and adding sodium nitroprusside, when a brilliant violet colouration indicates the presence of alkaline sulphide.

Arsenic and antimony are detected by fusing the substance with equal weights of sodium carbonate and sodium peroxide, extracting with water, acidifying, and passing in hydrogen sulphide. Other appropriate tests for these two elements may be applied.

Quantitative Determinations.

Carbon and hydrogen in absence of nitrogen, halogens, &c.

The simplest and most convenient method for general purposes is to burn the compound in a glass tube in a current of oxygen, assisted by cupric oxide; the carbon is converted into carbon dioxide, which is absorbed by caustic potash; the hydrogen is converted into water, which is absorbed by calcium chloride or concentrated sulphuric acid.

Erlenmeyer's modification of Von Babo's furnace is frequently employed. The heat is supplied by a row of 20–25 Bunsen burners, each of which is provided with a tap and a perforated collar for regulating the supply of air. The flames strike the under side of a semicircular fireclay or sheet-iron trough or gutter in which the combustion tube rests on a layer of magnesia or asbestos. Inclined at an angle over this gutter on either side is a row of fireclay tiles by which the flame is reverberated upon the upper part of the glass tube, which is thus heated all round. Each tile can be pulled back and rested against an iron rail which runs down each side of the furnace, and thus any part of the tube can be readily examined, and moreover the tiles can be made to assist in regulating the temperature.

In Hofmann's furnace the tube is heated by two double rows of perforated cylindrical fireclay burners placed over ordinary fish-tail burners. The tube rests upon the top of a central row of much shorter burners. The burners are inclosed by flat vertical tiles, and flat tiles are laid horizontally on the top.

In the Glaser furnace the heat is provided by a row of Bunsen burners. The tube is supported by a series of semicircular perforated iron plates, placed close together. The flames strike the bottom of these plates, and then pass through the perforations and strike against the fireclay covers, by which they are reverberated on the tube, so that the latter is heated from the top and sides as well as from the bottom. The tube is usually wrapped round with wire gauze. This furnace will give higher temperatures than the Erlenmeyer furnace, but consumes more gas.

A more modern type of combustion furnace which gives very high temperatures with a small consumption of gas has been introduced by Fletcher. The furnace itself consists of six separate hollow fireclay blocks 6 inches in length and of the same height, which are placed end to end, so as to give a total length of 3 feet. The combustion tube is supported on a fireclay trough placed along the top of the row of furnace blocks which are each pierced along one side with five holes leading to a hollow space immediately below the trough. The main gas-supply pipe is a brass tube of square section which is raised about 1½ inch above the stone bench by terminal brass supports; it carries thirty burners projecting at right angles from it in a slanting direction, so that their nozzles reach upwards to the perforations in the furnace blocks, the centres of these holes being about 3½ inches above the bench. Each furnace block is therefore heated by five burners, and reverberation is ensured by small semicircular fireclay arches, three of which fit loosely on each of the furnace blocks. Owing to their oblique position, the burners are readily kept clean, the brass heating arrangement is quite separate from the earthenware furnace, and the taps and lower parts of the burners are protected from the heat of the furnace by a brass shield running along the whole length of the main gas pipe. The furnace can be built up in shorter lengths by using fewer of the furnace blocks, of which two are represented in Fig. 16.

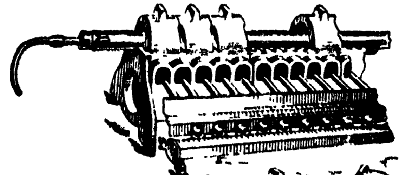

FIG. 16.

To avoid the necessity for using an indiarubber stopper between the combustion tube and the water-absorption apparatus, Marek suggests a mercury joint made by drawing out the combustion tube to a conical end, and fixing round this a knee tube by means of asbestos and fused silver chloride. The knee joint, which is loosely filled with silver ribbon, fits into a bell-shaped tube dipping under mercury (J. pr. Chem. 1907, [2] 76, 180).

The combustion tube should consist of infusible potash or Bohemian glass 1·5–2 mm. thick, with an internal diameter of 12–15 mm. It should be of such a length that it projects about 2 cm. from each end of the gutter or trough. Pieces of copper wire gauze about 2 cm. broad, heated in a flame to remove grease, are rolled up into plugs which fit moderately tightly in the tube, and one of these plugs is pushed into the tube to a distance of about 25 cm. from one end. The tube is then filled with freshly ignited granular cupric oxide to within 5 or 6 cm. of the other end, and a second plug is inserted. The granules of cupric oxide should be fairly regular in size, and 1·5–2 mm. cube. Another plug about 10 cm. long is made by rolling a piece of copper gauze round a stout copper wire 12 cm. long, and bending the projecting end of the latter into a loop by means of which it can be withdrawn from the tube. This plug is placed in the other end of the tube behind the boat. The end of the tube nearest to the copper oxide is fitted with a dry caoutchouc stopper perforated to receive the tube of the absorption apparatus; the other end is closed by a similar stopper, which carries a piece of tubing of very narrow bore, which is connected with the apparatus for drying the oxygen.

The substance to be analysed is contained in a platinum or porcelain boat about 70 mm. long and 8 mm. deep, of such diameter that it slides easily in the combustion tube. It may conveniently be inclosed in a small well-corked tube while being weighed.

The water is absorbed by granulated anhydrous calcium chloride, which is treated with a current of dry carbon dioxide, and then with a current of dry air to convert any calcium oxide present into carbonate, and thus prevent the absorption of carbonic dioxide.

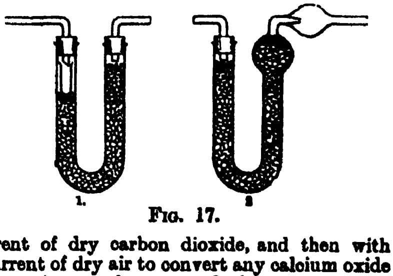

FIG. 17.

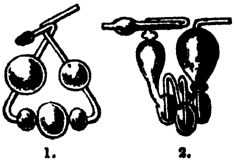
The calcium chloride is contained in a U-tube provided with a small side bulb for condensing the water, the tube from this bulb fitting directly into the cork in the combustion tube, whilst the other limb of the U-tube is closed by a caoutchouc cork carrying a narrow tube bent at a right angle and connected with the potash bulbs (Figs. 18

and 19). In the absence of the side bulb, each limb of the tube is closed by a caoutchouc cork carrying a narrow tube bent at a right angle, one of these tubes fitting directly into the cork of the combustion tube, and the other being connected with the potash bulbs. A small test-tube, 2–3 cm. long, placed in the upper part of the first limb of the U-tube, collects the greater part of the water, and thus protects the calcium chloride (No. 1, Fig. 17). (For other forms of calcium chloride tubes, v. Chem. Soc. Proc. 1906, 22, 87; Chem. Zeit. 1907, 31, 342.)

A U-tube containing pumice moistened with strong sulphuric acid may also be used to collect the water, but bulbs filled with the acid must not be used, since it dissolves an appreciable quantity of carbon dioxide.

The carbon dioxide is absorbed in a strong solution of potassium hydroxide made by dissolving this substance in an equal quantity of water. The solution is contained in 'potash bulbs,' of which there are many forms. Geissler's form is the most convenient, since it will stand on its own base (No. 2, Fig. 18). Liebig's original form (No. 1) is still used, but the more recent form devised by Bender (Fig. 19) secures efficient absorption, and is convenient for weighing, as it stands either on its own base or on an aluminium foot.



1. 2.

Fig. 18.

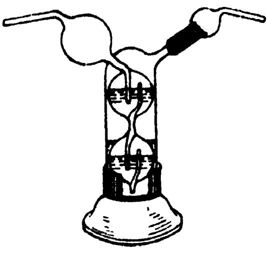


Fig. 19.

The Geissler or Liebig bulbs must contain such a quantity of caustic potash solution that it washes up to a certain extent in the last bulb, but yet is not sufficient to fill the large first bulb in case a vacuum is produced by rapid absorption of the gas. In addition to the potash bulbs, a U-tube filled with granulated soda-lime, with a layer of calcium chloride 2 cm. deep in the upper part of each limb, is used to absorb the last traces of the gas and any small quantity of moisture that may be given off from the caustic potash solution. Two such soda-lime tubes may be used in place of potash bulbs. (For other forms of carbon dioxide absorption tubes, v. Chem. Zeit. 1905, 29, 569; 1907, 31, 342; 1908, 32, 77; Amer. Chem. J. 1906, 35, 309; Ann. Chim. anal. 1907, 12, 318; Chem. Soc. Proc. 1908, 24, 182.)

The tube containing the soda-lime is connected with a U-tube filled with calcium chloride, to protect the absorption apparatus from moisture; this is especially needful when the air is drawn through the apparatus by means of an aspirator.

The oxygen or air used in the combustion is freed from carbon dioxide by passing through a strong solution of caustic potash. If compressed oxygen is employed, it is advisable to pass it first through a short length of heated combustion tube containing cupric oxide, in order to burn out any carbonaceous impurity. The air or oxygen is then dried by passing through dry calcium chloride or through pumice moistened with concentrated sulphuric acid, the same desiccating agent must be used to dry the gas as is employed to collect the water produced during the combustion.

The oxygen is dried by passing it through two long U-tubes containing calcium chloride. Instead of the U-tubes we may use a tall cylinder with the lower half filled with soda-lime and the upper with calcium chloride.

The oxygen required for combustions in the open tube may be prepared from potassium chlorate and manganese dioxide and stored over water in gasholders of moderate capacity. The gas may also be generated as required by the following method, which furnishes the gas under sufficient pressure for use in combustions. A solution of 25 grams of potassium permanganate in 500 c.c. of water, and 50 c.c. of sulphuric acid is introduced drop by drop into a litre flask containing 500 c.c. of hydrogen peroxide (10 vols.). The gas contains chlorine and ozone, which are removed during its passage through the purifiers (Bull. Soc. Chim. 1907, [4] 1, 501).

The operation.—The tube is placed in the furnace and connected at one end with the drying apparatus and at the other with the calcium chloride guard tube, but not with the absorption apparatus. It is gradually heated to redness, a current of dry oxygen is passed through for half an hour to remove all moisture and organic matter, and the tube is allowed to cool. When a combustion tube is being used for the first time or after a long interval, it is advisable to carry out a blank experiment by putting on the absorption apparatus and heating the tube for some time in a stream of dry oxygen. If the tube is ready for the analysis, the weight of the absorption tube and apparatus should be constant. The solid or non-volatile liquid substance is now weighed into the platinum boat, which is introduced into the tube by removing the long copper plug at the back, and the latter is then replaced. The front end of the tube is then connected with the absorption apparatus, and the other end is connected with the drying tubes and the oxygen reservoir. The burners under the front part of the tube are now lighted and the temperature gradually raised until the tube is at a dull-red heat to within 12 cm. of the boat. The tube in contact with the stopper at the front end should be so hot that it can only just be touched by the finger, and this temperature should be maintained throughout the operation by regulating the first two burners, in order to prevent condensation of moisture without decomposing the stopper. If any water should condense, it may be volatilised by bringing one of the hot tiles close over the tube. The last two or three burners under the long copper plug at the back are now lighted and the temperature gradually raised to dull redness, whilst at the same time the copper oxide is heated to within 5–6 cm. of the boat, and a current of oxygen is passed through the tube at the rate of a bubble every two seconds. One of the burners under the boat is then lighted and the boat very gradually heated, combustion being regulated so that the bubbles passing into the potash bulbs can easily be counted. When the substance is completely carbonised, the temperature of the boat is raised and the current of oxygen increased to a bubble per second. Towards the close of the operation the boat is heated to redness and a somewhat more rapid current of gas is passed. It is not necessary to heat the tube above redness, and a higher temperature produces distortion. When combustion is complete, the current of oxygen is continued for a short time to drive out all carbon dioxide and reoxidise any reduced copper. When the oxygen bubbles through the potash bulbs at the same rate as through the drying apparatus, the oxygen reservoir is disconnected and a current of air is drawn through the whole apparatus to expel the oxygen. At the same time the tube is gradually cooled and is ready for a second operation. If the tube is carefully heated and cooled, it may be used for a very large number of analyses. The absorption apparatus is disconnected and weighed. All the weighings should be made without the plugs of caoutchouc tubing and glass rod which are used to protect the contents of the tubes and bulbs from the air. When several analyses are being made of substances which burn only with difficulty, the entire heating may with advantage be carried out in a current of oxygen, and some saving of time is effected by weighing the absorption apparatus filled with oxygen.

Volatile liquids are inclosed in a small thin cylindrical glass bulb 3 cm. long, with a capillary neck, readily made by drawing out a piece of wider tubing. The bulb is weighed, heated, and the capillary tube immersed beneath the liquid. As the tube cools a small quantity of the liquid enters. This is heated to boiling, and when the air is expelled the end of the tube is again placed in the liquid, and when the vapour condenses the bulb is completely filled. If the liquid is very volatile, the capillary end may be sealed before weighing the tube, but usually this is not necessary. The bulb is placed in the boat with the capillary end open and directed towards the copper oxide. Combustion is conducted as already described, but much greater care is required, especially if the liquid is very volatile. The front part of the copper oxide must be quite red-hot before the liquid begins to volatilise, and it is advisable that the bulb be empty before the copper oxide near the boat is heated. With an iron gutter sufficient heat is conducted to vapourise volatile liquids, but in other cases a very low flame may be used, or one of the hot tiles may be held over the boat. In all cases it is difficult to prevent diffusion of vapour into the back of the tube and even into the drying apparatus. The long copper plug at the back increases the speed of the current by decreasing the diameter of the passage, and the narrow diameter of the entrance tube assists in a similar manner, but in all cases of the analysis of a volatile substance a slow current of air should be passed almost from the beginning. Later, oxygen should be passed, but not too soon, otherwise an explosive mixture may be formed. The open tube, in fact, does not yield such satisfactory results with volatile liquids as with other substances, and in such cases combustion should be made by the following method.

Liebig's original method as modified by Bunsen. Granular cupric oxide and some of the finely divided oxide are heated strongly, and while still hot are placed in flasks with long necks which are then tightly corked. The combustion tube is drawn out at one end in the manner shown in the figure, and sealed at the point *a*.

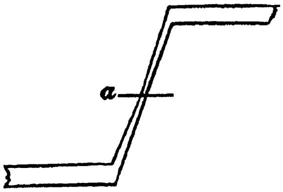

FIG. 20.

A layer of granular cupric oxide about 10 cm. long is first introduced by placing the combustion tube in the neck of the flask (Fig. 21) containing it, and then 2–3 cm. of the finely divided oxide. The substance (about 0·5 gram) is now introduced from a long narrow weighing tube which can be inserted into the mouth of the combustion tube, and 5–6 cm. of the finely divided oxide is added and intimately mixed with the substance by means of a long copper wire, the lower end of which has two twists like a corkscrew (Fig. 22). The wire and sides of the tube are rinsed with some of the oxide, and the tube is filled with the granular oxide to within 5–6 cm. of the top, and a plug of cupric gauze inserted. Every care must be taken to prevent absorption of moisture by the cupric oxide. The remainder of the operation is conducted as described above, and when combustion is complete the drawn-out end of the tube is connected with a drying apparatus, the tip broken off inside the caoutchouc tube, and a current of oxygen and afterwards of air passed through the apparatus.

FIG. 21.

FIG. 22.

In whichever way the combustion is made it is found that the percentage of hydrogen is always about 0·1–0·15 too high, a result attributed to the difficulty of perfectly drying the cupric oxide, &c. It is frequently stated that an open tube rarely gives correct results the first time it is used; but this is solely due to neglect of the precaution of first heating in a current of oxygen.

Combustion with lead chromate. Substances such as graphite, resins, &c. which are oxidised with great difficulty, should be burnt with lead chromate, or in extreme cases with lead chromate containing 10 p.c. of potassium bichromate; these oxidising agents can be employed in either open or closed combustion tubes. The chromate is precipitated by adding potassium bichromate to a solution of lead nitrate, washed, dried, fused, and then granulated. It is heated immediately before being used, and the tube is filled in the same manner as with copper oxide in B. The efficiency of the lead chromate depends mainly on the fact that at a high temperature it fuses. After being used it is heated with nitric acid in order to remove the reduced oxides, and is washed, dried, and again ignited.

Carbon and hydrogen in presence of nitrogen, halogens, &c. When nitrogen is present it is partly converted into nitrogen oxides, which are absorbed by the caustic potash. In order to avoid this source of error, the front of the tube contains plugs of copper wire gauze or a layer of granulated metallic copper 12–15 cm. in length reduced in carbonic oxide. The copper is heated to redness throughout the operation, and the nitrogen oxides are decomposed with absorption of oxygen and liberation of nitrogen. A silver gauze plug is preferable to the copper, because if the latter is reduced in hydrogen, it is apt to retain water, and if in methyl alcohol, it may also contain carbon (Zeitsch. anal. Chem. 1906, 14, 741).

Perkin (Chem. Soc. Proc. 1880, 37, 457) employs precipitated manganic oxide made into a paste with a saturated solution of potassium chromate containing 10 p.c. of dichromate, dried and granulated. A layer of this mixture 15 cm. long is placed in the front of the tube and heated to 200°–250° C. All nitrogen oxides are absorbed, but if the mixture is heated too strongly they are partially expelled. After each analysis the manganic oxide is heated more strongly whilst a current of air is passed through the tube, and the nitrogen oxides are more or less completely driven off.

The halogens, when present, form halide copper salts, which are somewhat volatile and are liable to be carried into the absorption apparatus. In such cases the front layer of copper may be replaced by silver foil or gauze, which decomposes the nitrogen oxides and also absorbs the halogens. Compounds of this kind may also be burnt by means of lead chromate, (*v. supra*), or a mixture of the substance with lead chromate may be placed in a porcelain boat and burnt in a current of oxygen in the usual way (*cf.* Amer. Chem. J. 1906, 35, 531).

Sulphur forms sulphur dioxide, which is absorbed by caustic potash. Compounds containing this element may be burnt with lead chromate, care being taken that the front of the tube is not too hot; or the front of the tube may contain a somewhat longer layer of manganic oxide and potassium chromate, the front half being kept at 200°–250° to absorb nitrogen oxides, whilst the rear half is heated to dull redness and absorbs the sulphur dioxide (Perkin, *l.c.*).

Combustion in presence of a contact substance. The use of a special combustion furnace may be obviated by bringing a mixture of oxygen and the vapour of the organic substance heated to a suitable temperature, into contact with some active material, such as platinum, platinised quartz, platinised asbestos, palladium, or even finely divided copper oxide. This process, which has been applied successfully by Dennstedt and his collaborators to a varied series of organic substances, is carried out in a hard-glass or quartz combustion tube, about 86 cm. in length and 16–18 mm. in diameter, the contact material being placed about the middle of the tube. Platinised quartz is prepared by soaking thoroughly clean and dry quartz fragments in an alcoholic solution of pyridine platinichloride and igniting them over the blow-pipe. A layer of about 3 cm. of this material can be used in the combustion, or platinum foil or wire may be employed, one of the most efficient forms of this metal being a six-rayed star of platinum foil, about 10 cm. in length. The combustion is most conveniently effected in a double supply of oxygen. The boat containing the substance is placed in the hard-glass inner tube (18 cm. in length) shown in Fig. 23, which is open at one end and at the other terminated by a wide capillary tube, through which a current of dry oxygen can be introduced. This inner tube has a diameter of about 14 mm., and oxygen can be passed through the annular space by means of the T-tube fitting over the capillary tube as shown in the figure.

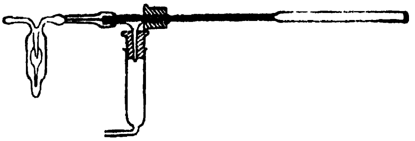

FIG. 23.

By means of this apparatus the supply of oxygen required for vaporising and burning the substance can be carefully regulated. When the organic compound contains nitrogen, sulphur, or halogens, a large boat containing lead peroxide is placed in the combustion tube and heated to 300°–320°. The sulphur is absorbed in the form of lead sulphate, and may be estimated by extracting the lead peroxide with 5 p.c. sodium carbonate solution, and estimating the sulphate in the filtrate. The estimation of chlorine and bromine may be similarly effected. Iodine is not entirely absorbed by lead peroxide, and, accordingly, 'molecular' silver must be employed to take up this element (Dennstedt, Zeitsch. angew. Chem. 1905, 18, 1134; 19, 517; Chem. Zeit. 1905, 29, 52; 1909, 33, 769; Analyst, 1905, 135; Ber. 1908, 41, 600; Baumert, Ber. 1907, 40, 3475). Walker and Blackadder recommend a furnace 60 cm. long, with granular copper oxide partly placed in the combustion tube and partly mixed with the weighed substance. The combustion is carried out in about 30 minutes, and the tube can be heated with Bunsen burners on an ordinary working bench (Chem. News, 1909, 99, 4; *cf.* Marek J. pr. Chem. 1906, 73, 359).

Electrical method. In this process the electric current is used as the source of heat, and platinum as the catalyst. A Dennstedt inner tube is employed to contain the boat Z with the weighed substance, and the spiral of platinum-iridium wire NJ is wound round a porcelain or quartz tube held in position in the combustion tube by a nickel tube DE, passing through the indiarubber stopper C. The coil is heated to redness by the passage of the current through DKJOP, and the absorption apparatus is fitted on to the outer end of the nickel tube DE. A divided stream of oxygen is employed as in the Dennstedt process, and the time required for complete combustion varies from 15 to 40 minutes.

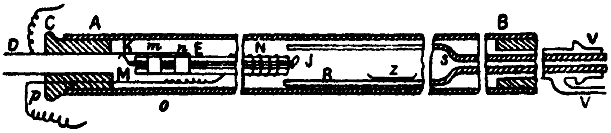

FIG. 24.

The consumption of electrical energy in this method of carrying out combustions is small, amounting to about 3·6 amperes at 54 volts (194·4 watts) during the time when the highest temperature is obtained (Breteau and Lerona, Bull. Soc. chim. 1908, [4] 3, 15; *cf.* B. Blount, Analyst, 1905, 30, 29; Morse and Taylor, Amer. Chem. J. 1905, 33, 591; Morse and Gray, Amer. Chem. J. 1906, 35, 451; Carrasco and Plancher, Gazz. chim. ital. 1906, 36, 492; Lippmann, Chem. Zeit. 1905, 29, 487, 174; Tucker, J. Amer. Chem. Soc. 1907, 29, 1442).

Nitrogen. This element is determined in the form of ammonia (Will and Varrentrapp, Ruffle, Kjeldahl), or in the form of nitrogen gas, which is collected and measured, the weight being calculated from the volume (Dumas, Maxwell Simpson).

A. *Will and Varrentrapp's method.* The substance is heated with soda-lime and the nitrogen is evolved as ammonia, which is absorbed in hydrochloric acid and precipitated as ammonium platinichloride or estimated volumetrically. This method is not applicable to azo-, diazo-, nitro-, and nitroso- derivatives, and to certain albuminoid substances.

Soda-lime is prepared by slaking 2 parts of good quicklime with a strong solution of 1 part of sodium hydroxide free from nitrates or sulphates. The mixture is dried by heating in an iron vessel, granulated, and preserved in well-closed bottles. A mixture of equal parts of calcium hydroxide and anhydrous sodium carbonate may also be used.

A glass tube about 50 cm. long and 12 mm. diameter, sealed at one end, is filled to a depth of about 5 cm. with a mixture of anhydrous oxalic acid and granular soda-lime, and a short plug of recently ignited asbestos is inserted. The substance is intimately mixed with sufficient finely powdered soda-lime to form a layer about 15 cm. long, and is quickly introduced into the tube. The mortar is rinsed with a small quantity of soda-lime, which is also put in the tube, and the latter is then filled with granular soda-lime to within 5 cm. from the end and a loose asbestos plug inserted. The tube is tapped to form a channel over the powdered soda-lime for the escape of the gases, and is placed in a furnace, which may be considerably shorter than that used in the estimation of hydrogen and oxygen. The combustion tube is attached by means of a perforated cork to an apparatus for absorbing the ammonia. This may consist of the bulbs originally devised by Will and Varrentrapp, or of an ordinary bulb U-tube. Winkler has devised a combination of bulb and flask which is especially convenient for estimations by titration, since the liquid need not be transferred. Ordinary dilute hydrochloric acid or a definite volume of standard acid is placed in the bulb. The tube is gradually heated to redness, beginning at the end near the U-tube, and when decomposition is complete the oxalic acid at the back is heated, and the ammonia in the tube is driven out by the current of carbonic oxide and carbon dioxide. The excess of acid is then determined by standard alkali; or the liquid is evaporated with platinic chloride as in an ordinary estimation of ammonia, and the precipitate is washed with ether containing a small quantity of alcohol, dried, heated in a crucible till completely decomposed, and the nitrogen calculated from the weight of the residual platinum. $Pt = N_2$. The nitrogen frequently forms volatile bases other than ammonia, and hence the platinum precipitate cannot be weighed as such. The ratio of platinum to nitrogen is, however, the same in all cases. The precipitate is washed with ether, because if such bases are present, it may be soluble in alcohol.

It is important that the front part of the tube be heated sufficiently to secure complete decomposition, but the temperature must not be too high, otherwise part of the ammonia itself is decomposed, and the results are too low. Substances rich in nitrogen should be mixed with some pure sugar in order to dilute the ammonia and prevent too rapid absorption.

Various modifications of Will and Varrentrapp's method have been introduced in order to make it more generally applicable, but these processes have been superseded by Kjeldahl's method (*cf.* Ruffle, Chem. Soc. Trans. 1881, 39 87; Arnold, Ber. 1885, 18, 806).

B. *Dumas' method.* In this process the hydrogen and carbon are burnt by means of cupric oxide and the liberated nitrogen collected and measured. A glass tube 80 cm. long, 12 to 15 mm. diameter, sealed like a test-tube at one end, is filled to a length of 12–15 cm. with dry sodium hydrogen carbonate, 4 cm. of cupric oxide is added, and then an intimate mixture of the substance (0·3–0·6 gram) with cupric oxide, then the cupric oxide used to clean the mortar, a layer of granular cupric oxide, and finally a layer of reduced granulated copper or copper-wire gauze not less than 15 cm. in length. The tube is connected by means of a cork and bent tube with an apparatus for collecting the nitrogen. The sodium hydrogen carbonate is first heated until all air is expelled and the issuing gas is completely absorbed by potash solution. The copper is then heated to redness, the heat being gradually applied to the whole tube as far as the carbonate. When combustion has ceased, the carbonate is again heated until all the nitrogen has been expelled.

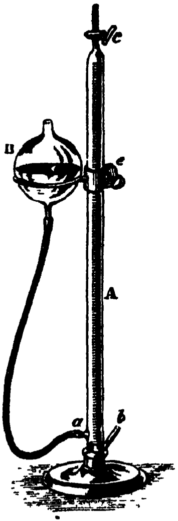

FIG. 25.

The most convenient form of apparatus for collecting the nitrogen is that devised by H. Schiff (Zeitsch. anal. Chem. 7, 430), or a similar form described by Groves (Chem. Soc. Trans. 1880, 37, 500). The former consists of a burette, A, fitted with a heavy foot and provided with a stop-cock, *c*, at the top. Close to the bottom is a tubulus, *b*, inclined at an angle of about 45°, and on the other side is another tubulus, *a*, connected by means of a caoutchouc tube previously soaked in paraffin with a globular reservoir, B, which is attached to the burette by a clip, and the height of which is readily adjusted. Mercury is poured into the burette through the lower tubulus to a height of 2 or 3 mm. above the lower opening, and the reservoir is then filled with a solution of caustic potash in its own weight of water, the lower tubulus being closed with a cork. The stopcock is opened and the reservoir raised until the burette is completely filled with the alkaline solution. The stopcock is then closed and the reservoir lowered to the bottom of the burette. The tubulus may now be opened without the mercury or alkaline solution being forced out. When the air has been expelled from the combustion tube the end of the delivery tube is inserted through the tubulus and the nitrogen collected. At the close of the operation the temperature of the gas is allowed to become constant, the reservoir is raised so that the level of the liquid is the same as in the burette, and the volume of the nitrogen is read off, together with the temperature and the height of the barometer. The weight of the nitrogen, P, is then calculated from the volume by means of the formula

$$P = \frac{V(B-f)0{\cdot}001251}{(1+0{\cdot}00366t)760},$$

where V is the observed volume, B the height of the barometer, f the tension of aqueous vapour at the temperature t, and 0·001251 the weight of 1 c.c. of nitrogen at 0° and 760 mm.

Gatterman (Zeitsch. anal. Chem. 24, 57) collects the nitrogen in an apparatus similar to Schiff's, but not graduated. A bent tube of small diameter completely filled with water is attached to the jet of the burette by means of caoutchouc tubing. By closing the lower tubulus, raising the potash reservoir, and opening the stopcock, the gas is driven over into a graduated tube standing over water, and is measured. The error due to the unknown vapour tension of the potash solution is thus avoided, but the vapour tension of the water at the particular temperature must of course be taken into account. Other forms of apparatus are described by Zulkowsky (Annalen, 1876, 182, 296; Roscoe and Schorlemmer's Chemistry, 3, pt. 1, 74) and Schwarz (Ber. 1880, 13, 771).

C. *Maxwell Simpson's modification of Dumas' method* (Chem. Soc. Trans. 1853, 6, 290; Annalen, 1855, 95, 74). In order to avoid the formation of carbonic oxide and nitric oxide, the substance is burnt with a mixture of cupric oxide and mercuric oxide. Into a tube similar to that used in Dumas' method is introduced about 12 grams of manganese carbonate or granulated magnesite mixed with 2 grams of precipitated mercuric oxide, followed by a plug of asbestos. Another gram of mercuric oxide is introduced, and then an intimate mixture of 0·5 gram of the substance with 45 parts of a previously prepared and thoroughly dry mixture of 4 parts of ignited cupric oxide and 5 parts of precipitated mercuric oxide. The mortar and the sides of the tube are rinsed with a similar mixture and another asbestos plug is introduced. A layer of granular cupric oxide about 9 cm. in length and a layer of not less than 20 cm. granulated copper, kept in position by another asbestos plug, fill the remainder of the tube. After the air has been expelled by heating the manganese carbonate or magnesite, the tube is gradually heated to redness, beginning from the front. The metallic copper not only decomposes nitrogen oxides, but also absorbs the excess of oxygen. The gas is collected as in Dumas' method, the magnesite or manganese carbonate providing the carbon dioxide.

Certain organic compounds (*e.g.* hydroaromatic series), when analysed for nitrogen, evolve a portion of their carbon as methane, which, being burnt only imperfectly, adds to the volume of the nitrogen. In these cases lead chromate is recommended as the oxidising agent, or the substance may be mixed with cuprous chloride and copper oxide (Haas, Chem. Soc. Proc. 1906, 22, 81).

Various modifications of Dumas' process have been proposed. Thudichum and Wanklyn use a mixture 5 parts of normal sodium carbonate and 13 parts of fused potassium bichromate in place of sodium hydrogen carbonate. Groves (*l.c.*), with a view to using the same tube repeatedly, places the mixture of carbonate and bichromate in a small tube connected with the combustion tube by an indiarubber joint. The portion of the cupric oxide mixed with the substance is separated from the layer remaining always in the tube by means of a tight plug of asbestos and copper gauze, the latter keeping a free passage for the gas.

The combustion tube may be open at both ends, the rear being connected with an apparatus for generating carbon dioxide, but special precautions must be taken to obtain this gas free from air (*v.* Warington, Chem. Soc. Trans. 1882, 41, 346).

The carbon dioxide required for this modification of Dumas' process may be generated in a Kipp's apparatus by the action of hydrochloric acid on marble or calcite. These minerals should, however, be boiled with water before being used, in order to free them from air. The dioxide may also be generated by dropping a concentrated solution of potassium carbonate (sp.gr. 1·5) into a mixture of water and concentrated sulphuric acid. A convenient apparatus in which to effect this operation is shown in the accompanying figure (Young and Caudwell, J. Soc. Chem. Ind. 1907, 26, 184). The carbonate solution flows from the dropping funnel into the mercury trap and out into the Woulff's bottle through the small hole *a*. The rate of evolution is regulated by the exit tap, and *s* is a safety tube.

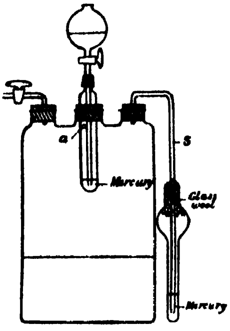

Fig. 26.

In both Dumas' method and Simpson's modification the combustion tube may be drawn out at the front end and connected with a Sprengel mercury pump by glass tubing joined by short pieces of caoutchouc tubing, the joints being surrounded by short wide tubes filled with water or glycerol. A bulb is blown on the horizontal part of the glass tube at the end near the combustion tube, and this bulb is kept cool during the operation, and serves to condense the water which is formed. The combustion tube is made vacuous, and when no more air issues from the end of the pump, the combustion is conducted in the ordinary way, the gas which is evolved being pumped out by the Sprengel pump and collected in a suitable tube. No magnesite need be used. The copper oxide keeps the exhausted tube from collapsing when heated.

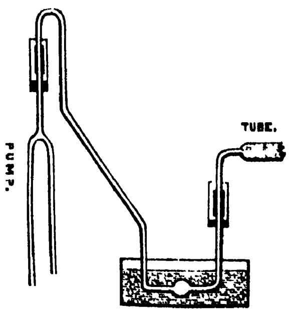

Fig. 27.

In many cases, especially with nitro- derivatives, the gas generated in the exhausted tube is a mixture of nitrogen with nitric oxide, the latter being sometimes present in considerable quantity. It is advisable, therefore, to decompose the nitric oxide by using either a layer of reduced copper or a long plug of silver gauze placed between the copper oxide and the exit, and by keeping this material heated throughout the combustion.

Liquids in which nitrogen is to be determined may be enclosed in bulbs which are dropped into the combustion tubes as in the determination of hydrogen and oxygen.

The copper oxide used in nitrogen determinations should be prepared by heating metallic copper in air and never by ignition of the nitrate, since in the latter case it is apt to contain basic nitrates which evolve nitrogen on heating.

The copper used in nitrogen determinations, &c., should not be reduced in hydrogen, since it is liable to occlude this gas. It may be reduced in the mixture of carbon monoxide and carbon dioxide obtained by heating oxalic acid with strong sulphuric acid. Plugs of copper gauze may also be reduced by heating them to redness and dropping them into a test-tube containing a few drops of formic acid or methyl alcohol. The reduced copper is carefully dried at 100°–110°.

When no carbonate is used and the gas is simply pumped out of the tube and collected over mercury, it consists of a mixture of carbon dioxide and nitrogen. If the former is estimated by absorption with caustic potash, a determination of the carbon may be combined with that of nitrogen.

Jannasch and Meyer have described a method for the simultaneous estimation of carbon, hydrogen, and nitrogen (Ber 1886, 19, 949; Annalen, 1886, 233, 375; Zeitsch anal. Chem. 1887, 26, 86; *cf.* Bull Soc. chim. 1905, 33, 951).

D. *Kjeldahl's method* (Zeitsch. anal. Chem. 1883, 22, 366) The substance is heated with concentrated sulphuric acid to a temperature approaching the boiling-point of the latter, and when decomposition is complete, an excess of solid potassium permanganate is added. The nitrogen is thus converted into ammonium sulphate, which is then distilled with excess of alkali and the ammonia collected and estimated. This method is economical, requires no combustion furnace or special apparatus, is rapid, and requires comparatively little attention, so that a large number of determinations can be carried on at the same time. The substance need not be in a very fine state of division, and the method is especially suitable for liquid and pasty substances such as extracts.

It is important that the sulphuric acid employed for these determinations should be protected from ammonia, and the caustic soda solution should be well boiled in order to expel any ammonia which it may contain. The purity of the reagents is best ascertained by making an experiment with pure sugar. If a small quantity of ammonia is present, the same quantity of the reagents should be used in each experiment, and a correction made for the ammonia which they contain.

In order to prevent bumping during distillation a small piece of zinc may be placed in the flask, but it is essential that the soda should be free from nitrates and nitrites, which would be reduced and yield ammonia.

The time required for the operation may be considerably shortened by using sulphuric acid containing sulphuric anhydride or phosphoric anhydride.

The method as thus carried out is applicable to all substances which can be analysed by Will and Varrentrapp's process, and to many others.

Heffter, Hollrung, and Morgen (Zeitsch. f. Chem. 8, 432) treat 1·0–1·5 grams of substance with 20 c.c. of a mixture of 4 vols. ordinary sulphuric acid and 1 vol. of fuming acid, and 2 grams of phosphorus pentoxide. Kreusler (Zeitsch. anal. Chem. 1885, 24, 453) uses sulphuric acid containing 200 grams of phosphorus pentoxide per litre.

Wilfarth (Chem. Zentr. [3] 16, 17, 113) finds that the oxidation of the organic matter takes place much more rapidly in presence of certain metallic oxides. Mercuric oxide is the most efficient, but cupric oxide answers almost equally well. The former produces mercuri-ammonium derivatives, which are not readily decomposed by caustic soda, and hence the alkaline liquid must be mixed with some potassium sulphide to decompose the mercury compounds The mercuric sulphide formed makes the liquid boil regularly without the addition of zinc. Ulsch recommends the use of ferrous sulphate instead of potassium sulphide; it may be added before the caustic soda.

Warington (Chem. News, 1885, 52, 162) removes nitrites and nitrates by boiling with ferrous sulphate and hydrochloric acid.

With a view to secure the reduction of nitro-derivatives, &c., and thus make the process generally applicable, Asboth (Chem. Zentr. [3] 17, 161) mixes 0·5 gram of the substance with 1 gram of pure sugar in the case of readily oxidisable compounds, and with 2 grams of benzoic acid in the case of nitrates and similar derivatives. Most probably the benzoic acid first forms nitro- derivatives, which are afterwards reduced. He adds Rochelle salt with the caustic soda in order to prevent precipitation of manganese, &c., and thus avoids bumping during distillation. With these modifications the method is applicable to all nitrogen compounds except those of the pyridine and quinoline series. E. Arnold (*ib.* p. 337) uses 0·5 gram of anhydrous cupric sulphate and 1 gram of metallic mercury in place of the oxides as recommended by Wilfarth, and heats 1 gram of the substance with these and 20 c.c of sulphuric acid containing 20–25 p.c. of phosphoric oxide.

C. Arnold (Arch. Pharm. [3] 24, 785) confirms Asboth's statements, but finds that in addition to pyridine and quinoline compounds, azo- derivatives and nitrites yield unsatisfactory results. He heats 0·5 gram of substance with 0·5 gram of anhydrous cupric sulphate, 1 gram of metallic mercury, 2 grams of phosphoric oxide, 1 gram of sugar, and in case of nitrates, &c., 2 grams of benzoic acid, and 20 c.c. of sulphuric acid.

Reitmair and Stutzer (Rep. Anal. Chem. 5, 232; Zeitsch. anal. Chem. 1886, 25, 582) use about 0·7 gram of mercuric oxide and 20 c.c of sulphuric acid, with a small fragment of paraffin in the case of substances rich in fat. They regard the use of phosphoric oxide as unnecessary, and the use of fuming sulphuric acid as undesirable on account of its liability to contain nitrogen oxides.

Jodlbauer (Chem. Zentr. [3] 17, 433) uses phenolsulphonic acid in place of benzoic acid, and reduces with zinc dust. He thus obtains good results even with nitrates. Reitmair and Stutzer (Rep. Anal. Chem. 7, 4) find that the nitrate must be somewhat finely divided; 0·5 to 1·0 gram of the substance is mixed with 50 c.c. of sulphuric acid containing 20 grams of phenol per litre, allowed to stand for a short time with occasional agitation, mixed with 2–3 grams of dry zinc powder and 1 or 2 drops of metallic mercury, and heated in the usual way. Conversion into ammonium sulphate requires one and a half hours.

A most important improvement in the Kjeldahl process due to Gunning (Zeitsch. anal. Chem. 28, 188), consists in the addition of potassium sulphate to the concentrated sulphuric acid. The solution of potassium hydrogen sulphate in concentrated sulphuric acid boils at a temperature considerably above the boiling-point of the strong acid and the oxidation of the organic matter is thereby greatly facilitated. Various oxidising and catalytic agents may be employed in conjunction with this mixture, and the following are among the many which have been suggested in addition to those already mentioned: platinic chloride, ferric chloride, manganese dioxide, magnesia, and sodium phosphate. The use of potassium permanganate has now been abandoned, and, in the case of refractory substances, oxidation is now generally induced by the catalytic action of mercury or its oxide. The following process is described by Dyer (Chem. Soc. Trans. 1895, 67, 811). The substance (0·5–5 grams) is introduced into a round-bottomed Jena flask, and heated gently with 20 c.c. of concentrated sulphuric acid containing a small globule of mercury. After the initial action has subsided, the temperature is raised to boiling, and in 15 minutes 10 grams of potassium sulphate are added, and the boiling continued till the solution is clear and colourless. The flask is closed with a loosely fitting bulb stopper, from the internal projection of which the condensed sulphuric acid drops back into the flask. There is, therefore, little loss of acid except through reduction to sulphurous acid. The product is rinsed into a capacious Jena distilling flask, rendered strongly alkaline with sodium hydroxide, with the addition of a small quantity of sodium sulphide, and the liquid distilled in a current of steam, the ammonia being collected and estimated in the usual way.

When nitrates are present, Jodlbauer's modification is employed, but the phenol may conveniently be replaced by salicylic acid. When the solution of this substance in concentrated sulphuric acid is poured quickly on to the weighed material, the loss due to the formation of lower oxides of nitrogen is avoided, and satisfactory results are obtained even when ammonium nitrate is present. This circumstance is of great importance in connection with the analysis of compound fertilisers containing both ammonium salts and alkali nitrates. Then zinc and mercury are added while the solution is still cold, and the former metal allowed to dissolve before the mixture is heated. Other reducing agents, such as sugar and sodium thiosulphate, may be used either alone or in conjunction with zinc. By the aid of this modified process satisfactory results are obtained in the analysis of organic nitro-, azo-, and hydrazo-derivatives. It has not been found possible to obtain correct estimations of nitrogen in sodium nitroprusside, phenylhydrazine and its derivatives, and in mixtures containing large proportions of chlorides and nitrates (*cf.* J. Amer. Chem. Soc. 17, 567; Analyst, 1905, 314; Ber. 1905, 38, 559; Chem. Soc. Proc. 1901, 25, 351; 1903, 27, 988).

The literature of nitrogen determinations is extremely voluminous. Summaries of contributions to this subject will be found in Zeitsch. anal. Chem. 1884, 23, 551; 24, 439; 25, 424 and 571; 26, 249; and Chem. News, 1888, 57, 62, *et seq.* In addition to the references already given, papers relating to Kjeldahl's process may be found in Zeitsch. anal. Chem. 24, 199, 388, and 393; 25, 149 and 155; 26, 92; 27, 222 and 398.

Chlorine, bromine, and iodine.

By lime. A tube about 40 cm. long and 7 mm. diameter, sealed at one end like a test-tube, is filled to a depth of 5 cm. with pure granulated quicklime. The substance is weighed into the tube and mixed with finely powdered lime by means of a copper wire twisted at the end like a corkscrew. The wire and tube are rinsed with lime, the tube is filled to within 5 cm. of the open end with granulated lime. The tube is gradually heated to redness from the front. When cold the contents of the tube are dissolved in water slightly acidified with nitric acid, filtered, and the halogen precipitated by silver nitrate.

In the case of iodine the substance is dissolved in water, filtered, mixed with silver nitrate, and finally acidified, in order to avoid liberation of iodine. A further precaution consists in adding a little sodium sulphite before each addition of nitric acid.

When the substance contains nitrogen, cyanides may be formed; but this is avoided by using pure soda-lime in place of lime. If the lime contains sulphates, some sulphide is liable to be produced. (On the preparation of pure lime, *see* Zeitsch. anal. Chem. 4, 51 and 15, 5.)

Liquids are contained in small bulbs with capillary openings, which are dropped into the tube before filling up with lime. The tube must be very gradually heated, and should be longer than usual.

Carius's method (Annalen, 1860, 116, 1; 1865, 136, 129; Ber. 1870, 3, 697). The substance is oxidised by heating with nitric acid in sealed tubes in presence of silver nitrate. In many cases acid of sp.gr. 1·2 and a temperature of 120°–200° will suffice; but substances which are more difficult to oxidise require acid of sp.gr. 1·42, mixed in special cases with some potassium dichromate, or the fuming acid of sp.gr. 1·5 may be used. If necessary the tubes may be heated as high as 300°. The quantity of acid used should not be more than twice that theoretically required for complete oxidation, and the tube must not contain more than 4 grams of nitric acid for each 50 c.c. of its volume. If the operation is prolonged, it is desirable to reduce the pressure in the tube by opening it from time to time by heating the capillary end of the previously cooled tube in a flame until it softens, when the gas forces its way out.

The weighed substance is enclosed in a narrow tube of thin glass of such length that its mouth projects above the nitric acid in the tube, and the acid does not come in contact with the substance until the tube is sealed. The tubes used should be about 15 mm. in diameter and 1·5–2 mm. thick in the glass. After introduction of the substance they are drawn out to a capillary tube with thick walls, which is then sealed. The sealed tubes are heated in a pressure tube furnace tilted at one end so that the capillary ends of the tubes do not come into contact with the liquid. After being heated, the tubes should on no account be removed from the protecting iron or steel tube until they have been opened. For this purpose the tubes are held in position by means of a cork collar through which the capillary ends project out of the furnace. The capillary end is first gently warmed to volatilise any condensed acid, and then heated more strongly until the gases under pressure blow a hole through the softened tip of the sealed capillary. In this operation the pressure of the imprisoned gases is very great, and it is extremely dangerous to attempt to open the tube with a file. The tube furnace should only be used for this purpose within a well-protected enclosure (Fig. 28), so as to minimise the personal risks arising from explosions of the heated tubes.

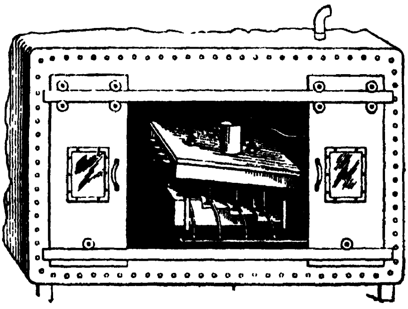

Fig. 28.

The silver salt formed is rinsed out of the opened tube and treated in the usual way.

For the estimation of iodine in organic compounds this method is to be preferred to the lime process, but as the silver nitrate and silver iodide frequently form a fused yellow mass, the mixture must be extracted thoroughly with hot water in order to remove the former salt. The silver halide obtained by the Carius method is collected in a tared Gooch crucible, washed successively with water and alcohol, dried at 100°, and weighed.

Stepanow's method. The substance is boiled with alcohol (20–40 c.c.) and sodium is added at such a rate that a vigorous reaction is maintained. A large excess of the metal is essential

$$XCl+2Na+C_2H_5{\cdot}OH=XH+NaCl+C_2H_5{\cdot}ONa.$$

When all the sodium has dissolved, 20–40 c.c. of water are added, and the alcohol removed by distillation. The aqueous solution is acidified with nitric acid, and the halogen estimated gravimetrically, or volumetrically by Volhard's method (Ber. 1906, 39, 4056; cf. Bacon, J. Amer. Chem. Soc. 1909, 31, 49). By using the latter method and weighing the mixed silver halides, the two halogens can be estimated indirectly in the same compound.

Pringsheim's method consists in burning the organic substance with sodium peroxide. Compounds containing more than 75 p.c. of carbon are mixed with 18 parts of this oxidising agent, and those with 50–75 p.c. of carbon with 16 parts. Substances containing less than 25 p.c. of carbon are mixed with sugar or naphthalene, and treated with 16–18 parts of the peroxide. The mixture is placed in a steel crucible surrounded by water and having a perforated lid through which a glowing iron wire is thrust to cause ignition. The product is extracted with water, acidified with nitric acid, and the halogen estimated in the usual way (Ber. 1903, 36, 4244; 1904, 37, 324; 1905, 38, 2459; Amer. Chem. J. 1904, 31, 386; *cf.* Moir, Chem. Soc. Proc. 1907, 23, 233; Baubigny, Bull. Soc. chim. 1908, (iv.) 3, 630).

Sulphur and phosphorus.

Non-volatile substances. Pure caustic potash is fused in a silver dish with about one-sixth its weight of potassium nitrate and a little water. When cold the substance is weighed into the dish, which is again heated, the substance being mixed with the alkali by means of a silver spatula. When oxidation is complete, the mass is allowed to cool, and is then dissolved in water acidified with hydrochloric acid, and the sulphuric or phosphoric acid estimated in the usual way.

Carius's method is carried out exactly as in the estimation of the halogens. Sulphur is oxidised to sulphuric acid and phosphorus to phosphoric acid. It is advisable to remove the greater part of the nitric acid before precipitating barium sulphate or magnesium ammonium phosphate.

Another method applicable to volatile and non-volatile substances is as follows:—Into a combustion tube 40 cm. long, sealed at one end, is introduced 2–3 grams of pure mercuric oxide, then a mixture of the substance with equal proportions of mercuric oxide and pure anhydrous sodium carbonate, and the remainder of the tube is filled with sodium carbonate mixed with a small quantity of mercuric oxide. The open end of the tube is closed by a cork carrying a glass tube dipping under water, in which the mercury is condensed. The tube is carefully heated so that the front layer of sodium carbonate is red hot before the substance begins to volatilise. The substance is then rapidly heated, so that decomposition is complete in about fifteen minutes, and finally the mercuric oxide at the rear end of the tube is heated until oxygen issues from the end of the delivery-tube (Russell, Chem. Soc. Trans. 1854, 7, 212; J. pr. Chem. 1855, 64, 230). The contents of the cooled tube are dissolved in water, a small quantity of bromine water added to oxidise any sulphide, the solution acidified with hydrochloric acid, boiled to expel bromine, and the sulphuric acid or phosphoric acid estimated in the usual way.

Many non-volatile substances may be oxidised by heating with pure concentrated caustic potash solution, diluting with twice the volume of water, and treating with a current of chlorine. After complete oxidation the solution is acidified, heated to expel chlorine, and the sulphuric or phosphoric acid determined.

Arsenic. The estimation of this element in organic compounds has recently acquired increased importance owing to the application of these substances in therapeutics. One of the earliest methods, due to La Coste and Michaelis (Annalen, 1880, 201, 224), consisted in mixing the substance with soda-lime, and heating the mixture in a stream of air or oxygen. The residue was dissolved in nitric or hydrochloric acid, the arsenic precipitated as sulphide, and afterwards converted into magnesium pyroarsenate. Monthoulé recommends destroying the organic matter with nitric acid containing magnesium nitrate, when a final ignition leads to the formation of magnesium arsenate (Ann. Chim. anal. 1904, 9, 308).

Pringsheim oxidises the organic arsenic derivative with sodium peroxide, and estimates the arsenic as magnesium pyroarsenate (Amer. Chem. J., 1904, 31, 386).

The following procedure has been shown to be applicable to the organic arsenical drugs now on the market. The substance (0·2–0·3 gram) is mixed with 10–15 grams of sodium peroxide and sodium carbonate in equal proportions, the mixture heated gently in a nickel crucible for 15 minutes, and the temperature then raised to dull redness for 5 minutes. The product is extracted with water, 25–31 c.c. of sulphuric acid (1 : 1) added, and the solution concentrated to 100 c.c., when 1 gram of potassium iodide is added and the liquid boiled down to 40 c.c. After destroying any trace of iodine with a few drops of sulphurous acid, the solution is diluted considerably with hot water, and the arsenic precipitated as sulphide. The precipitate, after washing three times with hot water, is dissolved with 20 c.c. of $N/2$-sodium hydroxide, and the filtered solution treated with 30 c.c. of hydrogen peroxide (20 vols.), the excess of this reagent being destroyed by heating on the water-bath. A few drops of phenolphthaleïn are added followed successively by 11 c.c. of sulphuric acid (1 : 1) and one gram of potassium iodide; the solution is evaporated down to 40 c.c. and the pale-yellow colour removed by sulphurous acid. Cold water is then added, and the diluted solution neutralised with $2N$-sodium hydroxide, and just acidified with sulphuric acid. The arsenite solution is now titrated with standard iodine solution and starch in the presence of sodium hydrogen carbonate or sodium phosphate (Little, Cahen, and Morgan, Chem. Soc. Trans. 1909, 95, 1477).

Antimony. When present in organic compounds, this element may be estimated by acidifying the product of the sodium peroxide fusion (*v. Arsenic, supra*), and precipitating as sulphide, this precipitate being collected, washed, and weighed in the manner indicated under *Gravimetric determinations.*

Oxygen. No satisfactory method has yet been devised for the direct determination of this element, and it is usually estimated by difference (*v.* v. Baumhauer, Annalen, 90, 228; Zeitsch. anal. Chem. 5, 141; Stromeyer, Annalen, 117, 217; Mitscherlich, Zeitsch. anal. Chem. 6, 136; 7, 272; 13, 74, and 15, 371; Ladenburg, Annalen, 135, 1; Maumené, Compt. rend. 55, 432; and Cretin, Zeitsch. anal. Chem. 13, 1).

Proximate analysis of carbon compounds. The methods to be adopted for the separation of the constituents of any particular mixture will depend entirely upon the nature of the mixture. It is only possible to describe the general methods which are found to be most useful in organic analysis. To a certain limited extent these operations are applicable to the proximate analysis of complex inorganic mixtures.

Fractional distillation is available for the separation of liquids which differ considerably in their boiling points (*v.* DISTILLATION).

Distillation in a current of steam is frequently employed as a method of proximate analysis. In this way volatile organic acids can be separated from volatile bases by steam-distilling the mixture in the presence of mineral acids. On the other hand, volatile bases are separated from organic acids by distilling in steam the mixture of these substances rendered alkaline by sodium or potassium hydroxide.

Fractional precipitation may be employed for the separation of substances, some of which are precipitated by a given reagent, whilst the others are not; or for the separation of substances which differ in the *order* of their precipitation. If, for example, silver nitrate is added in successive small quantities to a solution containing an iodide, bromide, and chloride, the first portion of the precipitate contains the greater part of the iodine; the middle portion contains the greater part of the bromine; and the last portion the greater part of the chlorine. In a similar manner organic acids can, not unfrequently, be separated by taking advantage of differences in the order of their precipitation by silver nitrate or lead acetate. In these cases the separated precipitates can be suspended in water and decomposed by hydrogen sulphide, when the acids are again liberated.

Fractional crystallisation may be adopted in the case of substances which differ in their solubility in one and the same solvent. The solution is concentrated somewhat, and the crystals which separate are removed; the mother liquor is still further concentrated, and the second crop of crystals is removed, this process being repeated as often as the case demands. The least soluble compound is mainly in the first crop of crystals; the most soluble is in the last mother liquor.

Fractional saturation is an analogous process, but is of more limited application. It was employed by Liebig for the separation of volatile organic acids. The mixture of acids is mixed with a quantity of caustic soda or potash insufficient for complete saturation, and is then distilled. The acids of higher molecular weight are first neutralised and converted into salts, which of course remain in the retort, whilst the acids of lower molecular weight are found in the free state in the distillate. Anything like complete separation is only to be obtained by many repetitions of this process.

Fractional solution.—The most useful and most generally applicable method of proximate analysis is based upon the different solubilities of various substances in different menstrua. The mixture is treated successively with various solvents, each of which dissolves some of the constituents, but leaves the others undissolved. Advantage may also be taken of the fact that the solubilities are in many cases modified by a rise of temperature. Further, if two substances differ considerably in their solubility in one and the same liquid, they may be separated by treatment with successive small quantities of the liquid, which removes the more soluble compound but leaves the greater part of the other undissolved. The following is a list of the solvents commonly employed, with indications as to their general properties:—

Water dissolves many salts and acids; inorganic and organic alkalis and their salts; carbohydrates, gums, certain alcohols, polyhydric phenols, and other highly oxidised carbon compounds which are not readily soluble in alcohol, ether, &c. On the other hand, it does not dissolve the carbonates, phosphates, oxalates, and certain other salts of the heavier metals. Very many organic substances are insoluble in this liquid. It decomposes the halogen compounds of the acid radicles and certain other compounds, and converts many normal metallic salts into basic salts, part of the acid passing into solution in the free state.

Dilute acids will dissolve many salts, and also some organic substances which are insoluble in water.

Alcohol dissolves many salts, caustic alkalis, hydrocarbons, fatty acids, resins, and a very large number of carbon compounds. It reacts with many haloid substitution derivatives, and hence is not a suitable solvent for this class of compounds.

Ether dissolves a few salts, and is an excellent solvent for hydrocarbons, fats, resins, alkaloids, and almost all organic compounds which are insoluble in water. It reacts with very few substances, and boils at a low temperature, so that it can readily be distilled off and the dissolved substance recovered.

Benzene dissolves iodine, sulphur, phosphorus, oils, fats, wax, camphor, resins, caoutchouc, gutta-percha, &c., and is especially useful as a solvent for haloid derivatives, on which it has no action. In certain instances this hydrocarbon may be replaced by its homologues, toluene, and the xylenes.

Carbon disulphide shares with ether the advantage of being readily volatile. It should always be purified from dissolved sulphur before being used. The best plan is to mix it with a small quantity of white wax, and then distil off the disulphide on a water-bath. It dissolves sulphur, phosphorus, iodine, fats, essential oils, resins, caoutchouc, &c.; but its solvent powers are comparatively limited, and almost all salts and very many carbon compounds are insoluble in it.

Light petroleum consists of the more volatile hydrocarbons of the paraffin series. It occurs in commerce in several varieties under different names. *Petroleum ether* boils at 50°–60°; *petroleum benzene*, at 70°–90°; *ligroïn*, at 90°–120°. They are excellent solvents for oils and fats, but dissolve very few other compounds. Three grades of light petroleum are now obtainable for use as solvents, boiling respectively at 40°–60°, 60°–80°, and 80°–100°.

Chloroform readily dissolves oils, fats, and similar substances, and is especially useful as a solvent for alkaloids.

The chloro- derivatives of ethane and ethylene have been introduced as useful non-inflammable solvents for oils, fats, or resins; these liquids give a wide range of boiling-points and solvent action (Koller, 7th Congress Applied Chemistry, 1909). A large number of other solvents are applied in certain special cases, and among those more commonly employed may be mentioned, acetone, ethyl acetate, amyl alcohol, pyridine, aniline, and nitrobenzene.

The treatment of a solid with a volatile solvent must be conducted in a special apparatus, especially if the liquid is to be heated. Various forms of apparatus have been devised for this purpose, but there is none more efficient than that of Soxhlet (Dingl. poly. J. 232, 461). It consists of a short wide test tube (E), open at the top but closed at the bottom, to which is sealed a narrower tube (N) which can be fitted into a small weighed flask by means of a cork. Communication between the two tubes is made by means of (1) a narrow side tube (*s*) which opens into the bottom of the wider upper tube, forms a siphon, and descends through the lower tube nearly to the bottom of the flask; and (2) a wider side tube (*t*) which enters the upper tube near the top and the lower tube near the junction (Fig. 29). A weighed quantity of the substance to be treated is placed in a cylinder of filter paper open at the top, and introduced into the upper tube, or the bottom of the tube is packed with purified cotton wool, and the substance is placed upon this. A quantity of the solvent rather more than sufficient to fill the upper tube to the level of the bend in the siphon, is placed in the flask and heated to boiling by means of a water-bath. The upper tube is attached to a reflux condenser, care being taken that the condensed liquid falls directly into the cylinder containing the substance. The vapour passes up the wide side tube, is condensed, falls upon the substance, and filters through the paper or cotton wool. As soon as the liquid rises to the bend of the siphon, the latter draws off the clear solution into the flask, and the liquid is again volatilised whilst the dissolved matter remains in the flask. The process goes on automatically, and the substance can be extracted many times with a small quantity of liquid. When extraction is complete, the flask is connected with an ordinary condenser, the liquid is distilled off, and the residue dried and weighed if necessary.

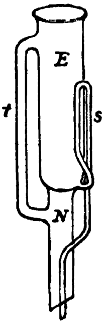

Fig. 29.

Fig. 30.

A convenient apparatus for treatment with solvents in dishes has been described by A. W. Blyth (Chem. Soc. Trans. 1880, 37, 140).

In many cases substances in solution can be removed and separated by agitating the liquid with some non-miscible solvent. The alkaloids and many amines can be removed from aqueous solutions by means of ether, whilst metallic salts are left; fatty substances can be removed from liquids by means of light petroleum, and so on. Extractions of this kind are best made in a separator consisting of a somewhat wide tube contracted at one end, which is fitted with a cork or stopper, whilst the other end is drawn out into a narrow tube provided either with a stop-cock or an indiarubber tube and a pinch-cock (Fig. 30). The liquid and the solvent can be completely mixed by agitation, and after they have separated the lower layer can be drawn off. If it is required to remove the supernatant liquid in this or any similar case, a somewhat narrow tube is bent twice at right angles, and one limb is fitted by means of a cork into a distilling or other flask, which is connected with an aspirator, whilst the other limb of the tube is placed in the liquid. When the aspirator is set in action, the liquid is drawn over into the flask, from which it can be distilled. With care a very accurate separation can be made, and the tube is readily rinsed by drawing some of the fresh solvent through it. This method may be rendered approximately quantitative by calibrating the above cylindrical separator (Fig. 30).

The microscope is of the greatest service in ascertaining whether a substance is a single compound or a mixture, and a microscopic examination of the various products obtained in the course of a proximate analysis affords valuable information as to the extent to which separation has been effected.

ESTIMATION OF RADICALS COMMONLY OCCURRING IN ORGANIC COMPOUNDS.

In this section it is only possible to indicate briefly a few of the most general methods by which certain typical radicals present in organic compounds can be estimated.

Hydroxyl. A known weight of the hydroxylic compound is treated with excess of magnesium methyl iodide (Grignard's reagent), and the amount of methane evolved is measured in a gas burette (Fig. 31).

$$R\cdot OH+CH_3\cdot MgI=R\cdot OMgI+CH_4.$$

The organic magnesium compound is dissolved in dry amyl ether or phenetole, and if the hydroxylic compound is too insoluble in either of these solvents, it may be dissolved in dry pyridine. (Hibbert and Sudborough, Chem. Soc. Trans. 1904, 85, 933; and Zerewitinoff, Ber. 1907, 40, 2023.)

This process has been extended to the estimation of sulphydryl- (SH), imino-, and amino- groups, and for all active hydrogen atoms (cf. Ber. 1908, 41, 2233 and 3025).

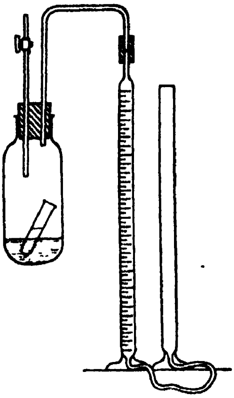

Fig. 31.

Methoxyl.

The estimation of methoxyl, a radical present in many naturally occurring organic compounds, is generally accomplished by Zeisel's method, which consists in heating the substance with concentrated hydriodic acid or with a mixture of this acid and acetic anhydride. Methyl iodide is evolved and absorbed in alcoholic silver nitrate, with the result that silver iodide is precipitated, each molecular proportion of this substance being equivalent to one methoxyl group. Zeisel's original apparatus (Monatsh. 1885, 6, 989; 1886, 7, 406) has been modified subsequently by several investigators (M. Bamberger, Monatsh. 1894, 15, 904; Perkin, Chem Soc. Trans. 1903, 83, 1367; Hesse, Ber. 1906, 39, 1142; Decher, Ber. 1903, 36, 2895; Hewitt and Moore, Chem. Soc. Trans. 1902, 81, 318). Of these modifications Perkin's (Fig. 32) is probably the simplest; it consists of a distilling flask, A, with a very long neck (20–25 cm.) heated in a glycerine bath at 130°–140°, a current of carbon dioxide being passed through the mixture of substance and concentrated hydriodic acid. The heating is continued for one hour, and the temperature finally raised, so that the hydriodic acid boils gently, but without distilling into the side tube of the distilling flask. The methyl iodide is collected in two flasks, B, containing alcoholic silver nitrate. The precipitated silver iodide is treated with nitric acid, the alcohol evaporated, and the precipitate collected and weighed in the usual manner.

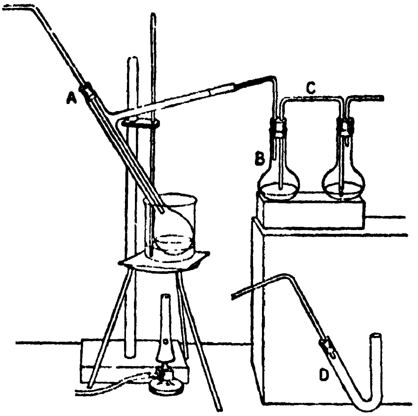

Fig. 32.

Hewitt and Jones (Chem. Soc. Trans. 1919, 115, 193) combine the methyl iodide with pyridine, thus obtaining the iodide in an ionisable form whereby it can be estimated volumetrically. The pyridine and its methiodide are diluted with water, acidified with nitric acid, a known amount of silver nitrate added, and the excess of the latter determined by thiocyanate according to Volhard's method.

Zeisel's method and its modifications are applicable to the estimation of ethoxyl, but the results obtained are generally less accurate.

Methyl.

A further modification of Zeisel's method renders it available for the estimation of methyl groups attached to nitrogen. The substance is heated with concentrated hydriodic acid and dry ammonium iodide, and the methyl iodide evolved dealt with in the manner indicated above (Herzig and H. Meyer, Ber. 1894, 37, 319; Monatsh. 1894, 15, 613; 1895, 16, 599; 1897, 18, 379; Kirpal, Ber. 1908, 41, 820).

Acetyl.

It is only possible in comparatively few cases to determine with certainty by ultimate analysis the number of acetyl groups existing in organic compounds. For example, the mono-, di-, and tri- acetyl derivatives of the trihydroxybenzenes have approximately the same percentage composition. These and other similar acetyl derivates are hydrolysable by standard caustic alkalis employed in alcoholic solutions, even when they are not readily attacked in aqueous solutions (Benedikt and Ulzer, Monatsh. 1887, 8, 41; Van Romburgh, Rec. trav. chim. 1882, 1, 48; R. Meyer and Hartmann, Ber. 1905, 38, 3956). Acid hydrolysis may be employed in a large number of cases and the volatile acetic acid distilled into standard alkali, the excess of which is determined by alkalimetry. According to Wenzel's process, the acetyl derivative is first hydrolysed by moderately strong sulphuric acid (1 : $2H_2O$), and the mixture treated with monosodium phosphate and boiled down to dryness; the sulphuric acid is fixed as sodium sulphate, and the acetic acid is distilled into a known excess of standard alkali, the distillation being carried out under reduced pressure (Monatsh. 1893, 14, 478; 1897, 18, 659).

The destructive action of strong sulphuric acid on organic compounds may be avoided by the use of the aromatic sulphonic acids as hydrolytic agents. The acetyl compound is distilled in steam in a 10 p.c. solution of benzenesulphonic acid or one of the naphthalenesulphonic acids; the distillate, which contains all the acetic acid furnished by the hydrolysis, is titrated with standard barium hydroxide (Sudborough and Thomas, Chem. Soc. Trans. 1905, 87, 1752).

A. G. Perkin hydrolyses the acetyl compound with alcoholic sulphuric acid, adding fresh alcohol from time to time. The ethyl acetate obtained in the distillate is then hydrolysed with a known amount of standard caustic alkali, and the excess of the latter ascertained with standard acid (Chem. Soc. Trans. 1904, 85, 1462; 1905, 87, 107; 1907, 91, 1230)

Carboxyl.

In many cases the number of carboxyl (CO_2H) groups in an organic compound can be determined by the analysis of its neutral salts. For this purpose the silver salts are generally selected, as they are usually anhydrous, and indicate the normal basicity of the organic acid. The aromatic hydroxy-carboxylic acids (*e.g.* 1 : 5-dinitro-*p*-hydroxybenzoic acid) take up two atoms of silver, one replacing the carboxylic, and the other the phenolic hydrogen. Some silver salts of organic acids are sensitive to light, and others are very explosive. The more stable ones can be analysed by direct ignition and weighing the residual silver. In other cases the organic matter must be destroyed with nitric acid, and the silver estimated as chloride in the acid liquid.

Other metallic salts are frequently employed in determining the basicity of carboxylic acids, and it is advisable before arriving at a final conclusion to estimate the metals in a series of these compounds.

If the molecular weight of a carboxylic acid is known, the basicity can often be determined by titration with aqueous or alcoholic sodium, potassium, or barium hydroxide; the indicators generally employed are phenolphthaleïn, methyl orange, and lacmoid.

The following indirect method has been recommended (P. C. McIlhiney, Amer. Chem. J. 1894, 16, 408) for the estimation of carboxyl groups. The substance (1 gram) is dissolved in excess of alcoholic potash, the alcohol being at least 93 p.c. The solution is saturated with carbon dioxide until the excess of alkali is precipitated as carbonate or bicarbonate. The precipitate is collected and washed with alcohol, the filtrate is distilled to remove the solvent, and the residue containing the potassium salt of the organic acid is distilled with 10 p.c. aqueous ammonium chloride, the ammonia evolved being estimated in the usual way. Each molecular proportion of ammonia corresponds with one carboxyl group. This method is applicable to the weaker fatty acids.

Carboxyl can be estimated by a method based on the following reaction:—

$$6R{\cdot}CO_2H+5KI+KIO_3=6R{\cdot}CO_2K+3I_2+3H_2O$$

The weighed substance is digested for 12 hours with an aqueous solution of pure potassium iodide and iodate in a stoppered vessel. The mixture containing the liberated iodine is rinsed unto the generating vessel of a gas volumeter and treated with alkaline hydrogen peroxide, when the oxygen evolved

$$I_2+2KOH+H_2O_2=2KI+2H_2O+O_2$$

is a measure of the carboxyl groups originally present ($6CO_2H \equiv 3O_2$) (Baumann-Kux, Zeitsch. anal. Chem. 1893, 32, 129; Annalen, 1904, 335, 4; *cf.* Gröger, Zeitsch. angew. Chem. 1890, 3, 353, 385). It should be noticed that acidic substances not containing carboxyl groups (*e.g.* picric acid) liberate iodine from the iodide-iodate mixture.

Carbonyl.

The carbonyl group, whether present in aldehydes $R{\cdot}CO{\cdot}H$ or ketones $R{\cdot}CO{\cdot}R'$, can be detected by means of the following colour-reaction. An aqueous or alcoholic solution of the substance is treated with a 0·5 to 1 p.c. solution of the hydrochloride of an aromatic meta-diamine (meta-phenylenediamine or its homologues), when in a few minutes an intense green fluorescence is developed, which attains its maximum intensity after two hours. All aldehydes give this reaction, but the mixed ketones and ketonic acids do not (Windisch. Zeitsch. anal. Chem. 1888, 27, 514).

Practically all aldehydes restore the colour to the following solution (Schiff's reagent). A litre of 0·10 p.c. magenta solution is decolourised by adding 20 c.c. of sodium bisulphite solution (30°Bé.) followed after one hour by 10 c.c. of concentrated hydrochloric acid. (For the exceptions, *cf.* Bittó, Zeitsch. anal. Chem. 1897, 36, 375.) The reaction has also been utilised quantitatively (McKay Chase, J. Amer. Chem. Soc. 1906, 28, 1472; Schimmel & Co., Ber. 1907, 123).

Phenylhydrazine condenses with aldehydes and ketones, yielding phenylhydrazones. When the mixture is treated with Fehling's solution (70 grams $CuSO_4,5H_2O$, 350 grams Rochelle salt, and 260 grams KOH, in 2 litres), the excess of phenylhydrazine is decomposed, evolving nitrogen:

$$C_6H_5{\cdot}NH{\cdot}NH_2+O=C_6H_6+H_2O+N_2,$$

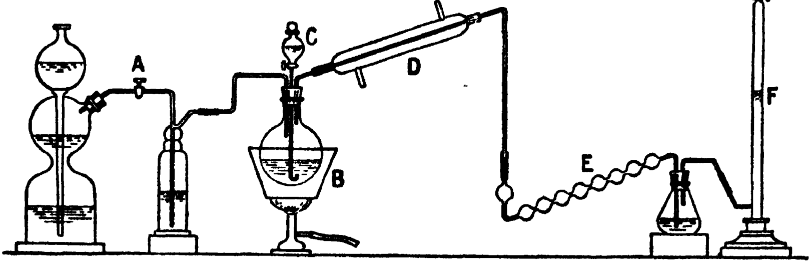

FIG. 33.

while the phenylhydrazone remains unchanged. The estimation is carried out in a flask, B, connected with a carbon dioxide generator, A (Fig. 33). A known volume of Barreswil's solution is introduced and covered with a layer of petroleum to prevent the caustic potash from absorbing the carbon dioxide. A blank experiment is first made with the standard solution of phenylhydrazine hydrochloride and aqueous sodium acetate, the nitrogen evolved on heating the solutions together being collected in a Schiff's nitrometer, F. The experiment is then repeated with the same solutions of phenylhydrazine and sodium acetate *plus* the carbonyl compound; the difference between the two volumes of nitrogen collected is a measure of the carbonyl present in the compound (Strache, Monatsh. 1891, 12, 524; 1892, 13, 299; 1893, 14, 270; Watson Smith, Chem. News, 1906, 93, 83).

When the carbonyl compound (*e.g.* pyruvic acid) condenses readily with phenylhydrazine or its hydrochloride in aqueous solution, the excess of this base can be estimated by adding excess of *N*/10-iodine solution, and titrating the remaining iodine with standard sulphurous acid or thiosulphate, using starch as indicator. This estimation is based on the following reaction:—

$$C_6H_5\cdot NH\cdot NH_2+2I_2=3HI+C_6H_5I+N_2.$$

The phenylhydrazone is not affected by the iodine solution (E. v. Meyer, J. pr. Chem. 1887, [2] 36, 115; *cf.* Petrenko-Kritschenko, Ber. 1901, 34, 1699; and Annalen, 1905, 341, 15, 150).

Organic amines.

The organic amines are divisible into three classes, primary, secondary, and tertiary, containing their nitrogen atoms combined respectively with one, two, and three organic groups. These groups may be either aliphatic or aromatic, and the reactions of each of the three classes of amines depend very largely on the nature of the organic groups to which the basic nitrogen atom is attached.

Primary amines. The primary amino-group $C\cdot NH_2$ may be detected by the carbylamine reaction (Hofmann, Ber. 1870, 3, 767), irrespective of the nature of the organic group, which may be either aliphatic, aromatic, or hydroaromatic (*cf.* Monatsh. 1896, 17, 397). The test consists in warming the substance in alcoholic solution with chloroform and caustic potash, when a carbylamine (iso-nitrile) is produced, which has a pungent disagreeable odour:

$$R\cdot HN_2+CHCl_3+3KOH=R\cdot NC+3KCl+3H_2O.$$

The primary amines all interact with nitrous acid, but the aliphatic bases are immediately converted into hydroxyl derivatives (alcohols), whereas the aromatic bases furnish diazo-derivatives from which the nitrogen is evolved rapidly on warming or slowly at the ordinary temperature.

In the case of the aliphatic primary amines, this nitrogen can be collected, and the amount indicates the proportion of amino- groups present. As nitrous acid itself decomposes readily, evolving oxides of nitrogen, Staněk recommends the use of nitrosyl chloride, obtained by adding fuming hydrochloric acid to 40 p.c. aqueous sodium nitrite (Zeitsch. physiol. Chem. 1905, 46, 263). This reagent can be mixed with saturated salt solution without undergoing decomposition; the aliphatic amino-carboxylic acids (glycine, &c.) can be readily decomposed by it in a current of carbon dioxide, and the nitrogen evolved is freed from the former gas and traces of oxides of nitrogen by passing the mixed gases through alkaline permanganate solution. Half the nitrogen measured in the gas burette corresponds with that originally present in the amino-acid.

In the case of the aromatic primary amines, the acid solution of the base is carefully diazotised at 0° with standard sodium nitrite; the end-point is reached when a drop of the solution gives a blue colour on starch-iodide paper. The sodium nitrite solution may be standardised with either potassium permanganate, sodium sulphanilate $(NH_2\cdot C_6H_4\cdot SO_3Na,2H_2O)$ or para-toluidine (*cf.* Green and Rideal, Chem. News, 1884, 49, 173; Kinnicutt and Nef, Amer. Chem. J. 1886, 5, 388; Zeitsch. anal. Chem. 1886, 25, 223).

Estimation of imino-groups in secondary amines. A weighed quantity of the substance is mixed with a known excess of acetic anhydride, either alone or diluted with dry xylene or dimethylaniline (Bull. Soc. chim. 1892, [3] 7, 142; Chem. Zeit. 1893, 17, 27, 465). After one hour, water is added and the mixture warmed under a reflux apparatus, so that no anhydride is lost by evaporation. The solution is then titrated with standard barium hydroxide and phenolphthaleïn indicator. The amount of acetic acid present indicates the excess of acetic anhydride left over from the acetylation of the secondary base.

The tertiary amines and the quaternary ammonium salts do not give the reactions of the primary and secondary amines, but the total amount of basic nitrogen present in an organic amine can frequently be ascertained by the analysis of the characteristic salts of the base. The aurichlorides and platinichlorides may frequently be employed for this purpose, as these double salts on ignition leave a residue of the metal, each atomic proportion of gold corresponding to one basic nitrogen atom, while a similar quantity of platinum corresponds with two basic nitrogen atoms. In the majority of cases these double salts have respectively the general formulæ, $RHCl,AuCl_3$ and $(RHCl)_2PtCl_4$, and are obtained in the anhydrous condition; yet, in certain instances, hydrated forms are known and sometimes the salts themselves have an anomalous composition not corresponding with the general formulæ. Evidence obtained in this way should, if possible, be supplemented by the analysis of other salts, and for this purpose the ferrichlorides, chromates, oxalates, thiocyanates, ferrocyanides, picrates, and picrolonates have been employed, as well as the commoner nitrates, sulphates, and halide salts.

Gas analysis.

The experiments of Gay-Lussac established long ago the value, from a scientific point of view, of the determination of the volumetric composition of gases and the products formed by their interaction; but it is only within recent times that the methods of gas analysis have been applied to any great extent for technical purposes. The value of such determinations is now generally recognised on account of the information which they give respecting the efficiency of combustion, the progress of operations in which gases are consumed or produced, and the like.

With few exceptions the volumetric and not the gravimetric composition of the gas is required, and the measurements are essentially measurements of volumes. The gas to be examined is confined over mercury or water in a suitable measuring apparatus, and its composition is determined (1) by treatment with appropriate absorbing reagents and measurement of the contraction produced; (2) by exploding with oxygen or hydrogen and measuring the contraction; (3) by exploding with oxygen or hydrogen, measuring the contraction, and then treating with absorbing reagents, and measuring the second contraction. Sulphur dioxide and some other gases soluble in water are estimated by titration, a definite volume of the gas being drawn through a measured quantity of a standard solution, the excess of which is afterwards determined.

The highly refined and accurate methods of gas analysis employed for purposes of research are of little value for technical purposes on account of the length of time required for their execution. Information respecting these methods may be found in Bunsen's Gasometrische Methoden, 2nd ed. 1887; Sutton's Volumetric Analysis, 9th ed. 1904; Dittmar's Exercises in Quantitative Analysis, 1887; Hempel's Gasanalytische Methoden, 3rd ed. 1900; Travers' Experimental Study of Gases, 1901; *v.* also Thomas (Chem. Soc. Trans. 1879, 35, 213), and Meyer and Seubert (Chem. Soc. Trans. 1884, 45, 581). In this article only those methods will be described which are available for technical purposes.

Measurements.—The volume which a given mass of gas occupies depends on the temperature, the pressure, and the proportion of moisture which it contains. The temperature is ascertained by means of a thermometer attached to or suspended near to the measuring vessel. Measurements are usually made under atmospheric pressure, and this is determined by means of a barometer placed in the room in which the analysis is made. The siphon barometer is a convenient form of instrument for the purpose, and should stand on the table close to the gas apparatus. In case the level of the mercury or water in the measuring tube is higher than that in the trough or the attached tube, the true pressure upon the gas is given by the height of the barometer *minus* the difference between the mercury level inside and outside the tube. If water is used, the height of the water column divided by 13·6 gives the height of the corresponding column of mercury with sufficient accuracy. It is better to eliminate this correction by adjusting the liquid so that it is at the same level both inside and outside the tube, which is easily done.

The gas must be either perfectly dry or saturated with moisture. If an indefinite quantity of water vapour is present, accurate measurements are impossible. It is more convenient to measure the gas when moist, and hence if the gas is confined over mercury a few drops of water are introduced when the tube is filled with the mercury and this water is taken up by the gas. Under these conditions the surrounding pressure is balanced partly by the gas and partly by the aqueous vapour which it contains, and in order to ascertain the pressure which the gas itself is under, the tension of aqueous vapour at the particular temperature must be subtracted from the height of the barometer. The formula for reducing the volume of gas to the standard temperature and pressure (0° and 760 mm.) is:

$$V_0 = \frac{V + 273 \times (B - f)}{(273 + t) \times 760} \text{ or } V_0 = \frac{V \times (B - f)}{(1 + 0{\cdot}00366t \times 760)}.$$

in which V is the actual reading; *t*, the temperature; *f*, the tension of aqueous vapour at the temperature, *t*, and B, the height of the barometer. The reduction of the height of the barometer to 0° is necessary for accurate calculation, but may usually be omitted. The following table, abbreviated from Bunsen's Gasometrische Methoden, gives the value of 1+0·00366*t* for the ordinary range of temperature:—

t°	Number	Log	*t*°	Number	Log	*t*°	Number	Log
0°	1·00000	0·00000	11°	1·04026	0·01714	21°	1·07686	0·03216
1	1·00366	0·00159	12	1·04392	0·01867	22	1·08052	0·03363
2	1·00732	0·00317	13	1·04758	0·02019	23	1·08418	0·03510
3	1·01098	0·00474	14	1·05124	0·02170	24	1·08784	0·03656
4	1·01464	0·00631	15	1·05490	0·02321	25	1·09150	0·03802

When the estimations are made rapidly, and only approximate results are required, the corrections for temperature and pressure are omitted, since it may be assumed that they remain constant during the analysis.

The following plan, described by Winkler, renders the use of the barometer and thermometer unnecessary, and makes the calculation much simpler. It is an adaptation of Williamson and Russell's method of always measuring the volume of the gas at the same degree of elasticity. A tube about 1 metre long, closed at one end and graduated to 120° c.c. in tenths is moistened internally with a few drops of water, and mercury is poured in in such quantity that when the tube is inverted the mercury stands somewhat higher than 100. The volume which 100 c.c. of air measured at standard temperature and pressure should occupy under the conditions described, is calculated from the expression:

$$V = \frac{(760-4{\cdot}5)100\times(278+t)}{278(B-f)} \text{ or } \frac{(760-4{\cdot}5)100\times1+0{\cdot}00866t)}{B-f}$$

and air is carefully introduced into the tube until, when the mercury is at the same level inside and outside the tube, it stands exactly at the calculated volume. The tube now contains a quantity of gas saturated with moisture, which, under standard conditions, would occupy 100 c.c., but its actual volume varies in the same ratio as the volume of gas to be measured. The two tubes are allowed to stand side by side, and when the levels have been properly adjusted in each case the volume of the gas to be measured and the volume of the air in the comparison tube are read off. The volume (under standard conditions) of the gas under examination is obtained by the proportion

$$V : V_0 : : V_1' : V_0',$$

in which V is the actual volume of air in the comparison-tube; V_0, its volume under standard conditions, which is always 100; V_1', the observed volume of the gas to be measured; and V_0', its volume under standard conditions.

During the operations the temperature should be kept as constant as possible, and the readings should be taken rapidly, otherwise the proximity of the body will cause variations in the temperature of the gas. It is an advantage to have the measuring tube surrounded by a wider tube which is filled with water. The most accurate method is to take the readings through a carefully levelled telescope (a cathetometer) at a distance of about five or six feet. This also avoids parallax. The measuring tube must be kept vertical, and when water is the confining liquid, sufficient time must be given for the liquid to run down the sides of the tube. Not unfrequently this requires several minutes.

Reagents.

All liquid reagents should be saturated with the gases which they do not absorb chemically. It is desirable that the tensions of these gases in the liquids should be approximately equal to their tensions in the gases which are to be analysed, in order to avoid exchanges between the gas and the absorbing liquid. This is best secured by going through the process two or three times without making measurements, whenever the pipettes have been freshly filled. Liquids used for the analysis of, say, flue gases, should not be used for gases of a different character, *i.e.* which contain the constituents in very different proportions.

Bromine water is used for absorbing olefines. It should be well saturated with bromine and kept in the dark.

Cuprous chloride is made by dissolving 50 grams of cupric oxide in hydrochloric acid, adding 50 grams of copper, and boiling for some time with as little exposure to air as possible. The solution is then diluted to 1000 c.c. with hydrochloric acid of sp.gr. 1·12, and allowed to remain in contact with metallic copper in a closed vessel until the solution becomes colourless. This solution attacks mercury rapidly.

Cuproso-ammonium chloride, obtained by dissolving cuprous chloride in ammonia, does not attack mercury.

The stock solution is made by dissolving 200 grams of cuprous chloride and 250 grams of ammonium chloride in 750 c.c. of water; it is kept in stoppered bottles, and, when required, mixed with one-third its volume of ammonia solution (sp.gr. 0·91).

Hydrogen is obtained by the action of dilute sulphuric acid on pure zinc. The granulated zinc may be placed in a small bottle fitted with a capillary delivery tube, which can be closed by a tap or pinch-cock. The bottle has a tubulus at the bottom, and is connected by a caoutchouc tube with a similar bottle containing dilute sulphuric acid. The latter bottle is raised so that the acid runs on the zinc, and the action is allowed to proceed until the air is completely expelled from the first bottle. The tap is then closed, and the acid is driven back into the second bottle by the pressure of the hydrogen. It is advisable to keep the second bottle at a slightly higher level than the first, to avoid any chance of air leaking in. One of Hempel's tubulated absorption bulbs answers admirably (Fig. 41). The zinc is attached to a cork, which is inserted in the tubulus of the first bulb, and the acid is introduced. When all air is expelled, the capillary tube is closed, and the acid is driven up into the second bulb, so that the pipette is always charged with hydrogen under pressure.

Oxygen is obtained in a pure state by heating potassium chloride *without* manganese dioxide. The powdered chlorate is contained in a glass bulb, the neck of which is drawn out to form a narrow delivery tube.

Phosphorus is employed in the form of narrow sticks, which are made by melting it under warm water and drawing it up into narrow glass tubes. The upper ends of the tubes are closed by the finger, and they are plunged into cold water, when the phosphorus solidifies. It may also be used in a granular form, obtained by shaking the phosphorus vigorously with warm water in a well-closed flask until it solidifies.

Caustic potash (*or soda*) for Orsat's apparatus is dissolved in three parts of water, and the solution kept in well-stoppered bottles. Hempel uses a solution of caustic potash in two parts of water, which will absorb forty times its volume of carbon dioxide. It may, however, be used somewhat more dilute, and is then less liable to attack the glass.

Pyrogallol is kept in the solid state, and only dissolved immediately before being used. Orsat recommends a solution of 25 grams of pyrogallol in a small quantity of hot water, mixed with 150 c.c. of a solution of 1 part of caustic soda in 3 parts of water. Hempel uses a mixture of 25 c.c. of a 20 p.c. solution of pyrogallol with 75 c.c. of 33·3 p.c. caustic potash solution. This quantity will absorb 200 c.c. of oxygen.

Shipley (J. Amer. Chem. Soc. 1916, 38, 1687) found the most effective solution was prepared by adding 40 c.c. of water to 100 grams pyrogallol and adding 100 c.c. of 49 p.c. sodium hydroxide solution. No carbon monoxide is evolved from a solution of this strength.

Anderson (J. Ind. and Eng. Chem 1915, 7, 587) recommends a solution of 15 grams pyrogallol in 100 c.c. potassium hydroxide solution of sp.gr. 1·55.

Sulphuric acid of sp.gr. 1·84 is used as a drying agent and for the absorption of nitrogen oxides. Acid of the same strength mixed with so much sulphuric anhydride that it remains liquid at the ordinary temperature but solidifies if cooled, is used for absorbing ethylene and other hydrocarbons.

Water, which is very largely used for confining the gases, should be well saturated with air, but should not contain carbon dioxide. Distilled water is preferable, but any potable water of good quality may be used.

Standard solutions used in the estimation of gases by titration are known as *normal gas solutions* when they are of such strength that 1 c.c. of the solution is equivalent to 1 c.c. of the gas under standard conditions. A normal gas solution of iodine for the estimation of sulphur dioxide would contain 11·333 grams of iodine per litre, and the thiosulphate solution used in conjunction with it would be of equivalent strength.

In many cases it is the weight of the absorbed constituent per cubic metre or cubic foot of gas that is required, and the ordinary standard solutions may be used.

Methods of estimation.

Ammonia, by titration.

Benzene, by absorption in fuming nitric acid boiling at 86°, the nitrogen oxides being then removed by caustic potash. Fuming nitric acid also absorbs carbon dioxide and carbon monoxide. Like the olefines, benzene is absorbed by fuming sulphuric acid and by bromine water, and in fact no absorption method is at present known by means of which benzene and the olefines can be separated (Ber. 1888, 21, 3131).

Carbon dioxide, by absorption in potassium or sodium hydroxide.

Carbon monoxide, by absorption in a saturated solution of cuprous chloride in hydrochloric acid or ammonia. It seems (Ber. 1887, 20, 2754) that these solutions are liable to give off part of the dissolved carbon monoxide, especially after they have been used repeatedly. The error is less with the ammoniacal solution, and is reduced if the solution remains in contact with the gas for some time. The cuprous chloride solution should always be tolerably fresh, and should be saturated with hydrogen, nitrogen, and the other gases which usually occur with carbonic oxide (Ber. 1888, 21, 898). If the amount of carbon monoxide is small, it should be converted by combustion (*v. Hydrogen*) into carbon dioxide, which is afterwards absorbed by caustic potash. If the amount of carbon monoxide is large, the greater part may be absorbed by cuprous chloride, and the remainder removed by combustion and absorption.

The estimation of small quantities of carbon monoxide in air or other comparatively inert gases can be effected by passing the dried gas over solid iodine pentoxide. At temperatures varying from 40°–150° the following reaction occurs: $I_2O_5+5CO=5CO_2+I_2$. Either of the volatile products can be estimated: the iodine volumetrically by standard thiosulphate, or gravimetrically by absorption in a weighed tube containing copper powder; the carbon dioxide may be absorbed in standard barium hydroxide, and the excess of the latter titrated with oxalic acid. If carbon dioxide is present in the gas under examination, it is first removed by potassium or barium hydroxide. Below 60° no hydrocarbon except acetylene reduces iodic anhydride. At higher temperatures several unsaturated hydrocarbons have an appreciable action. Ethylene hinders the oxidation of carbon monoxide by the iodine pentoxide. The process is applicable to air containing one part of carbon monoxide in 30,000, and is used for estimating the monoxide occluded in steel (Gautier, Compt. rend. 1898, 126, 871, 1299; Jean, *ibid.* 1902, 135, 746; J. Amer. Chem. Soc. 1900, 22, 14; 1907, 29, 1589; Ann. Chim. anal. 1910, 15, 1).

Hydrogen is converted into water by combustion with air or oxygen, and the volume of the hydrogen is represented by two-thirds of the contraction consequent upon combustion. If the gas is confined over mercury, an excess of pure oxygen is introduced, the volume read off, and the pressure on the gas reduced considerably below atmospheric pressure by lowering the mercury in the level tube. The lower end of the explosion tube is closed, and combination is initiated by passing a spark from a coil between the platinum wires which are fused into the tube. The pressure is restored to the normal, and when the gas has cooled the volume is again read off.

When the gas is confined over water it is almost impossible to obtain satisfactory combustion, and it is much more convenient to pass the combustible mixture over gently heated spongy palladium. This is prepared by dissolving about two grams of palladium chloride in a small quantity of water, adding a small quantity of a saturated solution of sodium formate and sodium carbonate until the reaction is alkaline. About 1 gram of long and very soft asbestos fibres is introduced, and the pasty mass is dried at a gentle heat. In this way the asbestos is obtained covered with very finely divided palladium. After being completely dried at 100°, it is carefully washed with water

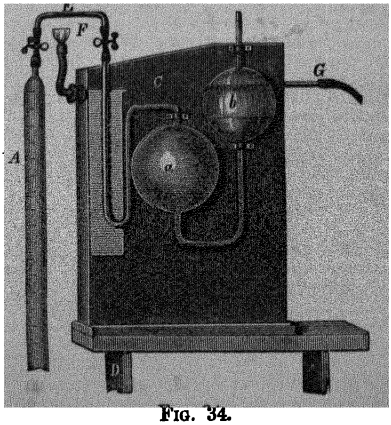

FIG. 34.

to remove soluble salts and again dried. Some of the fibres are moistened and twisted into a thread about 1 cm. long, which is then introduced into the middle of a stout capillary tube, B, about 15 cm. long and 1 mm. internal diameter, and this tube is bent at a right angle at each end, or in any other way convenient for its attachment to the measuring apparatus containing the gas. One end of the capillary is in communication with the graduated tube, A, and the other with a bulb pipette, C, filled completely with water, into which the gas is passed. A small gas or spirit-lamp flame is arranged to heat that part of the capillary which contains the asbestos. When the other gases have been estimated, the mixture of hydrogen and nitrogen which remain is mixed with air by lowering the level-vessel until the pressure is sufficiently reduced, and then putting the measuring tube in communication with the air. The stop-cock is then closed, the asbestos very gently heated, and the gas passed slowly through the capillary into the bulb and back again three or four times. When combustion is complete, the volume of the residual gas is measured.

This method may be employed in estimating hydrogen in the presence of methane, since the latter is not burnt under these conditions, providing that the temperature does not exceed 500° (J. Soc. Chem. Ind. 1903, 22, 925; 1905, 24, 1202; Zeitsch. angew. Chem. 1903, 16, 695).

The palladinised asbestos can be used in promoting the combustion of carbon monoxide.

Drehschmidt (Ber. 1888, 21, 3245) prefers a platinum tube 20 cm. long and 2 mm. thick, with a bore 0·7 mm. diameter. The bore is almost closed by the insertion of a palladium wire extending through the whole length of the tube. The tube is attached to a burette and an absorption pipette in the same manner as the glass tube; 5 to 6 cm. are heated to redness by means of a gas flame, and the gas is passed backwards and forwards until there is no further alteration of volume. No explosions occur even with mixtures of hydrogen and oxygen containing only a slight excess of the latter.

Hempel has applied the well-known absorption of hydrogen by palladium to the estimation of this gas. Pure palladium is indifferent towards hydrogen in the presence of methane and nitrogen, but when it contains a little palladious oxide combustion of some of the hydrogen occurs, and the heat generated ensures the absorption of the remainder. Palladium sponge is heated and allowed to cool slowly so that it becomes superficially oxidised. A U-tube of 4 mm. internal diameter and 20 cm. total length is charged with 4 grams of this oxidised sponge and maintained at 90°–100° by immersion in a beaker of hot water; this tube is interposed between the gas burette and a pipette filled with water. The absorption is effected by siphoning the gas backwards and forwards through the palladium sponge.

Hydrogen chloride, by titration.

Hydrogen sulphide, by titration.

Hydrocarbons other than olefines are estimated by combustion, preferably with oxygen over mercury under reduced pressure. Acetylene and benzene may be burnt over palladium, but require a somewhat high temperature. Methane cannot be burnt in this way even in presence of hydrogen. The combustion of this gas is effected by mixing it with a considerable quantity of air and aspirating the mixture through a short tube containing cupric oxide heated to redness in a small combustion furnace, the carbon dioxide which is produced being absorbed in standard baryta solution, which is afterwards titrated with standard oxalic acid.

Drehschmidt finds (Ber. 1888, 21, 3249) that a mixture of methane and oxygen can readily be burnt in a platinum tube, as above, if the latter is heated to bright redness. The contraction is observed, and the carbon dioxide formed is removed and the volume again measured.

Nitric oxide is converted into peroxide by admixture with oxygen, and the peroxide is absorbed by caustic potash, the excess of oxygen being afterwards absorbed by alkaline pyrogallate. Nitric oxide may also be absorbed by a concentrated solution of ferrous sulphate, but this method does not give such satisfactory results.

Nitrogen peroxide and nitrous anhydride, by titration; by absorption with sulphuric acid of sp.gr. 1·84; or, in absence of carbon dioxide and other absorbable gases, by absorption with caustic potash.

Olefines, by absorption with fuming sulphuric acid, acid vapours being removed by caustic potash; or by absorption in bromine water, bromine vapours being afterwards removed by caustic potash.

Oxygen, by absorption with alkaline pyrogallate. If the oxygen is present in greater proportion than 20 p.c. a small quantity of carbon monoxide is evolved from the pyrogallol during absorption, and hence the results are slightly too low. After treatment with pyrogallol the gas may be passed into the cuprous chloride bulbs in order to remove any carbon monoxide that may have been formed. Usually, however, this error has no material influence on the results. Oxygen may also be absorbed by phosphorus, and this has the advantage that the presence of carbon dioxide is without influence on the result. The temperature, however, must not be below 18°, and the absorption is prevented by the presence of ammonia, olefines, and other hydrocarbons, alcohol, &c.

Sodium hydrosulphite has been recommended as an absorbent for oxygen, the reaction

$$Na_2S_2O_4+H_2O+O=2NaHSO_3$$

taking place readily at low or high temperatures. The solution contains 50 grams of the salt and 40 c.c. of sodium hydroxide (5 : 7) in 250 c.c. of water, and is used in a pipette filled with rolls of iron-wire gauze (Ber. 1906, 39, 2069).

Oxygen may also be estimated by combustion with hydrogen, either explosively by the spark or over palladium-asbestos. The hydrogen should be evolved from commercial 'pure' zinc and pure dilute sulphuric acid, or in special cases from magnesium and sulphuric acid. One-third of the contraction consequent upon combustion gives the volume of the oxygen.

Sulphur dioxide, by titration.

In the ordinary gases from flues, generators, &c., the constituents are estimated in the following order: Carbon dioxide, olefines and benzene, oxygen, carbon monoxide, hydrogen, methane, nitrogen (as residue or by difference).

If acid vapours are present together with one or more of the above gases, the order of absorption, &c., must be determined by circumstances.

Apparatus and manipulation.

Collecting samples.—The gas to be analysed is usually drawn from the flue, chamber, &c., by aspirating it through glass tubes, which may be termed conducting tubes. When the temperature is high, porcelain tubes may be used; or if the gas has no acid properties, iron tubes can be employed. When samples are constantly taken from the same flue, &c., it is convenient to have a short piece of porcelain or iron pipe cemented into the wall and closed at the outer end with a plug, which is readily removed when the sample is taken. In cases where the gases are originally at a high temperature and possibly in a state of partial dissociation, it is important to draw the sample slowly through a somewhat long tube in order that the gas may cool slowly, since rapid cooling of the gases may leave them in a partially dissociated condition and thus lead to erroneous results.

The sample may be conveniently collected in the measuring apparatus itself; but where this is not possible, a cylindrical glass tube A, drawn out at the upper end and connected with a stop-cock and capillary tube, and drawn out at the lower end and connected by caoutchouc tubing with a similar tube B, open at the top, makes a convenient sampler. The collecting tube may with advantage be provided with a stop-cock at the bottom. The vessel A is completely filled with water or mercury by raising B to a higher level, and the upper stop-cock is closed. The capillary tube is connected with the conducting tube, and the vessel B is lowered so that when the stop-cock is slowly opened the gas is drawn into A, and the water or mercury collects in B. When A is filled the stop-cocks are closed. The gas is readily transferred from A to the measuring vessel by raising B and carefully opening the stop-cock.

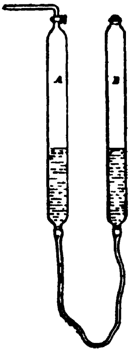

FIG. 35.

In all cases the air in the conducting tube must be expelled, and this is done by placing a T-tube between the end of the tube and the collecting vessel. This T-piece is connected with an aspirator, and the tube is filled with the gas before the stop-cock of the collecting vessel is opened. When the collecting vessel is provided with a three-way cock, the aspirator may be connected directly with the latter. Various forms of aspirator may be used. When the volume of gas to be aspirated is small (*e.g.* in removing air from the conducting tube), a small globular indiarubber aspirating pump is very convenient. For larger quantities of gas, glass bottles with a tubulus or stop-cock at the bottom and a tube or stop-cock at the top, or similar vessels of sheet zinc, may be used (Figs. 36 and 37). They are filled with water, the upper tube being connected with the tube which passes into the flue, and the water is allowed to flow from the tap at the bottom. The volume of gas aspirated is determined by measuring the volume of water which flows from the aspirator, and correcting this volume for temperature, &c., in the usual way (*v.* ASPIRATOR).

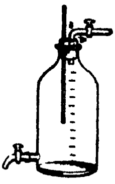

FIG. 36.

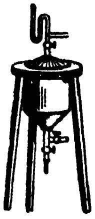

FIG 37.

When aspiration is to be continued for a long time, one of the various forms of water pump may be used. The volume of air aspirated in a given time with a given pressure of water may be determined once for all by direct measurement, or a small gas meter may be placed between the pump and the vessel into which the gas is passed.

If the gas has to be kept for some time before analysis, or if it has to be transported from one place to another, it may be collected in glass tubes which have previously been drawn out at each end. As soon as the tubes are full, the ends are closed by stoppers of indiarubber tubing and glass rod, or are hermetically sealed by fusion. If the quantity of gas is large, cylindrical zinc vessels with conical ends closed by indiarubber corks answer very well.

(For other forms of gas-samplers, *v.* J. Soc. Chem. Ind. 1889, 8, 176; 1903, 22, 190.)

Estimations by titration.—A measured quantity of the appropriate standard solution is placed in a flask or a Woulff's bottle fitted with two tubes, one of which dips into the liquid and is connected with the tube placed in the flue, &c., whilst the other ends just below the cork and is connected with an aspirator. After aspiration has been continued for a sufficient length of time, the excess of reagent is determined by titration. The volume of gas aspirated is determined by the volume of water which has run from the aspirator or by means of a gauge attached to the aspirator. This volume of water, however, represents a volume of gas saturated with moisture and at a temperature and pressure which must be determined by means of a thermometer attached to the aspirator and a barometer in close proximity; the volume under standard conditions is calculated in the usual way. In calculating the percentage composition of the gas, it must be borne in mind that the original volume of the gas was the sum of the volumes of the absorbed constituent and the volume which has passed into the aspirator.

If V_1 is the volume of the absorbed gas, and V_2 the volume which has passed into the aspirator, both under standard conditions, then

$$\frac{100 \times V_1}{V_1 + V_2} = \text{per cent. of } V_1 \text{ by volume.}$$

This method may be applied in the estimation of—

Ammonia, by absorption in sulphuric acid and titration with alkali.

Carbon dioxide (in small quantities), by absorption in standard baryta solution and titration with oxalic acid.

Chlorine, by absorption in a standard solution of arsenious oxide in sodium carbonate, and subsequent titration with iodine after saturating with carbon dioxide.

When hydrochloric acid and chlorine occur together, the latter is determined separately in one quantity, and a second quantity is absorbed in the solution of arsenious oxide in sodium carbonate free from chlorine, and the total chlorine is determined by titration with silver nitrate, using Volhard's thiocyanate method. In calculating the percentage composition, it is important to remember that 1 vol. of chlorine produces 2 vols. of hydrochloric acid.

Hydrochloric acid, by absorption in sodium carbonate and titration with silver nitrate, or, in absence of carbon dioxide and other acids, by absorption in standard caustic potash or soda, and subsequent titration with an acid.

Hydrogen sulphide, by absorption in standard iodine and titration with thiosulphate; or by absorption in bromine water and gravimetric estimation as barium sulphate.

Nitrogen oxides, by absorption in acidified permanganate solution of definite strength, the gas being passed until the solution is just decolourised. This method gives the amount of nitrogen oxides in terms of their reducing power.

Sulphur dioxide, by absorption in standard iodine solution and titration with thiosulphate, or by absorption in bromine water and gravimetric estimation as barium sulphate. The latter plan may be adopted when the proportion of sulphur dioxide is very small and a large volume of gas must be aspirated.

Measuring and absorption apparatus.—Only those forms which have come into general use and are of wide applicability will be described here. Descriptions of the numerous other modifications will be found in Winkler's Chem. Unters. der Industrie-Gase; Winkler and Lunge's Technical Gas Analysis; and in Zeitsch. anal. Chem.

An extremely convenient device which is applied to almost all the forms of apparatus is the three-way stop-cock. This has the usual transverse bore, but the plug itself is elongated in the form of a tube, the bore of which is continued in a curved direction through the plug and opens at the side in the same plane, but in a direction at right angles to the transverse bore. By means of this tap two tubes can be made to communicate with one another, or either of them separately can be put in communication with a third tube or with the air.

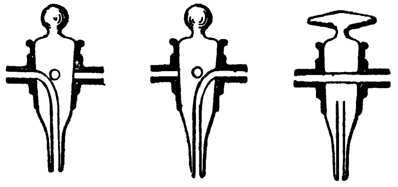

Fig. 38.

Orsat's apparatus.—The measuring tube or burette consists of a cylindrical bulb terminating at one end in a capillary tube and at the other in a narrow tube of uniform bore graduated in tenths of a cubic centimetre. The total capacity of the tube from the zero to the capillary is 100 c.c., and the lower end of the tube is connected by caoutchouc tubing with a 'level-bottle,' the height of which can readily be adjusted. The burette is enclosed in a cylinder which is filled with water at a constant temperature. The capillary from the upper end of the measuring tube is carried horizontally along a wooden support. Other capillary tubes provided with stop-cocks are fused into it at right angles and communicate by means of very short lengths of stout indiarubber tubing with the absorption pipettes, each of which consists of a pair of somewhat large cylindrical bulbs communicating at the bottom by a curved tube. The bulbs nearest the capillary tubes are fitted with short lengths of glass tubing so that a large surface of the reagent may be exposed, and the other bulbs receive the liquids when they are driven out from the first bulbs by the gas. Any number of bulbs can, of course, be attached to the main capillary, and at the end of it there is a three-way tap communicating with the aspirating tube or with the air.

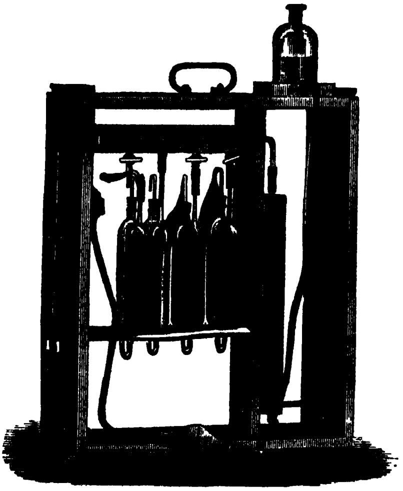

Fig. 39.

The three absorption pipettes indicated in Fig. 39 are generally filled respectively with solutions of caustic potash, alkaline pyrogallate, and cuprous chloride, and serve for the estimation of carbon dioxide, oxygen, and carbon monoxide.

The burette is filled with water by placing the liquid in the level-bottle and raising the latter, and the stopcocks are then closed. The absorption bulbs are rather more than half filled with the liquid reagents, and by opening the stop-cocks and placing the level-bottle below the apparatus the liquids are drawn up so as to fill completely the bulbs connected with the capillaries. The stop-cocks are then closed.

The burette is filled with water up to the capillary tube by raising the level-bottle, and the far end of the capillary tube is connected with the tube along which the gas is to be conducted. The lower end of the three-way tap is connected with an indiarubber aspirator, and the air is removed from the conducting tube by aspirating the gas through it. The level-bottle is then lowered, the tap is turned through 90°, and the gas is drawn into the burette. When a sufficient volume has entered, the tap is closed, the levels inside and outside the burette are adjusted by raising the level-bottle, and the volume of the gas is read off as soon as the temperature is constant. If it is desired to operate upon exactly 100 c.c., the gas is drawn in until the water is a little below the zero, the tap is closed and the level-bottle is raised so that the gas is slightly compressed and the water rises above the zero (time having been given for the liquid to run down from the sides of the burette), and the indiarubber tube is closed by a pinch-cock. The level-bottle is again lowered, and by cautiously opening the pinch-cock the water is allowed to descend exactly to the zero, and the pinch-cock is closed. The tap at the end of the main capillary is opened for an instant, so that the excess of gas may escape and the 100 c.c. remaining in the burette may be at atmospheric pressure.

In order to bring the gas into any one of the absorption bulbs, the level-bottle is raised and the tap of the particular bulb is opened. The gas passes into the bulb, and by alternately raising and lowering the level-bottle the gas can be passed backwards and forwards several times, care being taken that the absorbing liquid does not pass through the stop-cock. The gas is finally drawn off so that the absorbing liquid just reaches the stop-cock, the latter is closed, and, after readjusting the levels, the volume of gas is again read off. After making the necessary corrections, the decrease in volume is, of course, the volume of the gas which has been absorbed. The order in which the absorbing liquids should be applied has already been given (p. 236).

Lunge has added to this apparatus a capillary tube with palladium asbestos, for the estimation of hydrogen, connected with a bulb similar to the absorption bulbs, but containing water only. The apparatus also contains a small spirit-lamp carried by a movable rod for heating the palladium asbestos (Dingl. poly. J. 1882, 245, 512).

Sodeau has introduced a modification of Orsat's apparatus suitable for the analysis of mixtures containing only small proportions of combustible gases (*e.g.* chimney gases). In this modification the cuprous chloride pipette and the palladium combustion tube are replaced by a combustion pipette, the only absorption pipettes present being those containing caustic potash and alkaline pyrogallate. The carbon dioxide is first estimated by means of the former, and the combustible gases burnt by passing an electric current (5 amperes) for a short time through a platinum spiral in the combustion pipette. The contraction is noted, and the carbon dioxide produced is estimated by absorption in the caustic potash. These data give the proportions of carbon monoxide and hydrogen originally present in the gaseous mixture. The residual oxygen may now be estimated by absorption in the alkaline pyrogallate (Chem. News, 1904, 89, 61).

Bone and Wheeler's apparatus is a simple form of gas apparatus capable of giving accurate results with almost all gaseous mixtures ordinarily met with in technical practice. The working liquid is mercury, and the apparatus consists of the following parts: (1) A water-jacketed combination of measuring and pressure tubes, A and B, communicating through the glass tap C with the mercury reservoir D; (2) an absorption vessel, F, standing over mercury in a mahogany trough; (3) an explosion tube, E, fitted with firing wires, and having a separate mercury reservoir, H; (4) a sampling tube, K. The connections between A, E, and F are of capillary bore throughout, with suitable glass taps. Before an analysis the whole of the apparatus, including the connections, is filled with mercury, and the gas may be introduced either from the sampling tube, K, or from the absorption vessel, F.

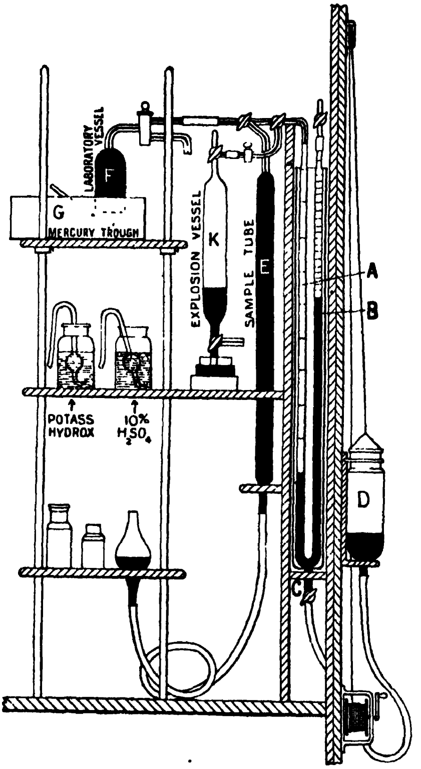

FIG. 40.

The Regnault-Frankland principle of measurement is employed, namely, the measurement of the pressure of the gas (in mm. of mercury) at constant volume. The measuring tube A has a series of constant-volume marks coinciding with the 0, 100, 200, &c., mm. marks on the pressure tube B. These two tubes are moistened with dilute sulphuric acid (1 : 20) as a precaution against the accidental introduction of alkali into the measuring tube. The tap closing the upper end of the pressure tube is connected to it by stout indiarubber pressure tubing; this gives a tight but elastic joint, and obviates risks of fracture. By means of this tap the pressure tube can be rendered vacuous, and, in this way, the measurements are rendered independent of the barometric pressure, and it becomes possible to analyse smaller volumes of gas. The length of the pressure tube provides for the requisite dilution of the explosive mixtures in analyses by explosion. All the absorptions are carried out in the same vessel, F, a comparatively small amount of freshly prepared reagent being used in each operation. The absorption vessel is rinsed out by means of the three-way tap, the lower parallel limb of which is joined to a large bottle connected up with the water pump. In this way a series of absorptions can be carried out without disturbing a single connection in the apparatus. An analysis of producer gas is easily completed in 45 minutes, and one of coal gas requires about an hour (J. Soc. Chem. Ind. 1908, 27, 10). (For other forms of technical gas apparatus, *v.* F. Fischer, Zeitsch. angew. Chem. 1890, 3, 591; Sodeau, J. Soc. Chem. Ind. 1903, 22, 187. *See* also Chem. Soc. Trans. 1894, 65, 43; 1899, 75, 82; Ber. 1902, 35, 3485, 3493; 1907, 40, 4956; J. Soc. Chem. Ind. 1908, 27, 483, 491; Chem. Zeit. 1903, 845; 1904, 086; Zeitsch. angew. Chem. 1907, 20, 22.)

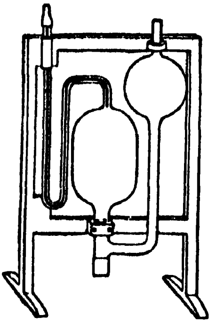

FIG. 41.

Hempel's apparatus.—The measuring apparatus consists of a burette, and a plain tube of the same length and diameter, which serves as a level-tube. The burette holds 100 c.c. from the zero to the capillary, is graduated in fifths of a c.c., and terminates at the top in a capillary tube to which is fitted a short piece of stout-walled caoutchouc tubing closed by a pinch-cock. Both the burette and the level-tube are fixed at the bottom into heavy circular stands, and each has a side tubulus near the bottom over which is slipped the caoutchouc tube by which they are connected. It is advisable to make all the joints secure with copper wire. In order to make the measurements more accurate, the burette may be surrounded by a wider tube filled with cold water (Winkler).

The pinch-cock is opened and both tubes are rather more than half filled with water. The burette is completely filled with water by raising the level-tube until the water runs out of the indiarubber tube at the top, and the pinch-cock is then closed. By means of the indiarubber tube the burette is attached to the conducting tube, which has already been filled with the gas, the level-tube is lowered, and the pinch-cock opened. When sufficient gas has been drawn in the pinch-cock is closed, the levels adjusted, and the volume read off in the usual manner. If it is desired to admit exactly 100 c.c., proceed in the same way as described under Orsat's apparatus.

The reagents are contained in absorption pipettes. Simple absorption pipettes consist of two bulbs which communicate at the bottom by a bent tube, one bulb being at a higher level than the other (Fig. 34). The upper part of the lower bulb terminates in a straight capillary tube, which extends to a slightly greater height than the higher bulb, and serves to connect the pipette with the burette. In the tubulated pipette the bottom of the lower bulb is provided with a tubulus, which can be closed with a caoutchouc stopper, and through which solid reagents such as phosphorus or zinc can be introduced. A composite absorption pipette consists of two similar pairs of bulbs, the second pair containing water or some other liquid which protects the reagent in the first from the action of the air. Composite pipettes are used with alkaline pyrogallate, cuprous chloride solution, bromine water, and similar reagents (Fig. 42)

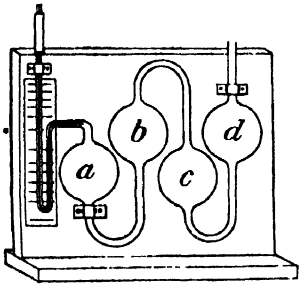

FIG. 42.

Cumming (J. Soc Chem. Ind. 1913, 32, 9) has modified the Hempel double pipette by the addition of a side tube to the top of *b*, which can be closed by a rubber cork. The reagent is poured through the side-tube on *b*, and water is poured in through *d* to form a water-seal.

In making the absorptions the pipettes, which are attached to wooden stands, are placed on a table stand of such height that the top of the capillary of the pipette is level with the top of the capillary of the burette. The burette and pipette are joined by means of short pieces of caoutchouc tubing and a short piece of capillary tube bent twice at right angles. The volume of air contained in this capillary is so small that it does not introduce any appreciable error. Care is taken that the capillary of the absorption pipette is filled just up to the top with the reagent. The connections being made, the level-tube, which should be full of water, is placed on the table stand and the pinch-cock is opened. The gas passes into the pipette, and by raising and lowering the level-tube the whole of the gas can be passed backwards and forwards two or three times; or the gas may be allowed to remain in contact with the liquid in the pipette. When absorption is complete, the level-tube is lowered until the reagent is drawn just up to the top of the capillary of the pipette, the pinch-cock is closed, and a second reading is taken.

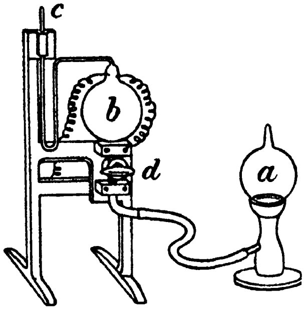

FIG. 43.

When combustions of hydrogen or carbon monoxide have to be made, the capillary tube containing palladium asbestos is inserted between the burette and a simple absorption pipette containing water only. With gases containing both methane and hydrogen, the combustion is conveniently effected in an explosion pipette of spherical form, in which mercury is used as the working liquid. The two bulbs of the pipette are connected by thick-walled indiarubber tubing, and the explosion bulb can be closed by two stop-cocks.

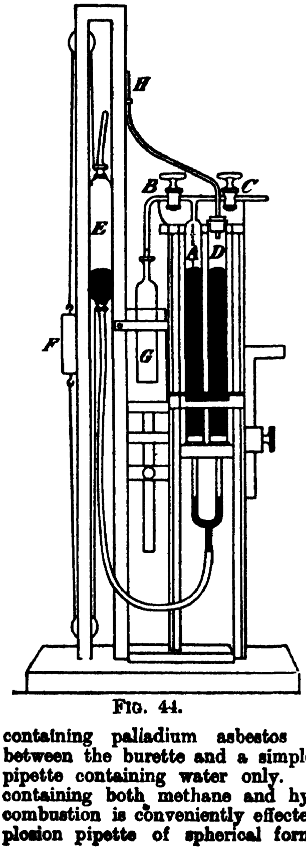

FIG. 44.

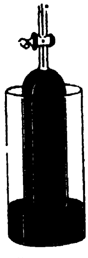

FIG. 45.

When gases very soluble in water have to be measured, a burette is used, provided at the top with a three-way stop-cock, the volume between them being exactly 100 c.c. The burette must be perfectly dry before being filled, an end which is most quickly effected by rinsing the burette with water, then with alcohol, and finally with ether, and passing a current of warm air through it. The lower end of the burette is connected with the conducting tube by means of the three-way tap *d*, the other end is connected with an aspirator, and a current of the gas is drawn through the burette until the air is completely expelled. The stop-cocks are then closed, care being taken that the gas in the tube is at atmospheric pressure. The absorptions, &c., are made in the same way as with the ordinary burette.

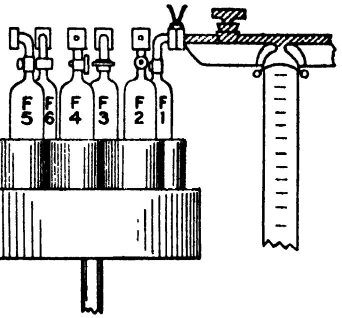

FIG. 46.

Stead's apparatus consists (Fig. 44) of a graduated tube A, in which all measurements are made, fitted with taps B and C, leading respectively to the absorption vessel and the sampling tube. The lower end of A is joined by means of a T-piece to the mercury reservoir E, and to the tube D, which is open to the atmosphere at H. The readings are taken under atmospheric pressure. The gas sample is collected either directly in the laboratory vessel G or in Stead's sampling apparatus (Fig. 45). From either of these reservoirs a portion of the gas is introduced into the apparatus at C, and thence by opening B into the laboratory vessel G, which contains caustic potash solution standing over mercury. If the gas consists practically of carbon dioxide, carbon monoxide, and hydrogen, it is then mixed with a known volume of oxygen,

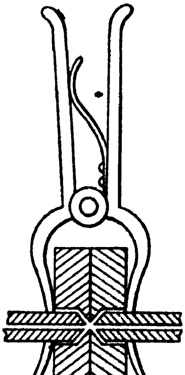

FIG. 47.

and the mixture sparked by means of platinum terminals fused into the upper part of the graduated tube A.

The contraction is ascertained and the carbon dioxide produced is estimated, and from these data the amounts of carbon monoxide and hydrogen are determined.

When other absorbable gases are present, then six absorption vessels are employed, and these are carried on a turn-table, so that each in turn can be brought into contact with the measuring tube (Fig. 46). In this modified form of the apparatus the eudiometer tube and each of the absorption vessels are fitted with a perfectly flat piece of plate glass perforated in the centre. These plates are lightly smeared with oil, and when communication is to be made between the eudiometer and the absorption vessel, these face plates are held together by a spring clip (Fig. 47).

A further improvement consists in the use of the modified form of absorption vessel shown in Fig. 48, in which the reagent is contained in a glass bottle closed by an indiarubber bung carrying a small glass stopper and a pipette furnished with a tap.

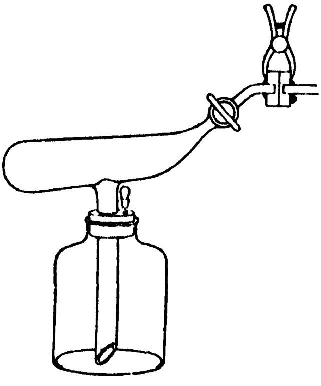

Fig. 48.

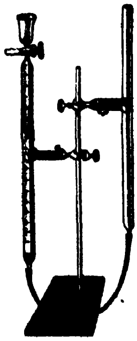

Fig. 49.

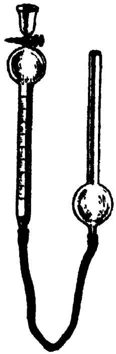

Fig. 50.

By means of these additions Stead's apparatus can be used for the complete analysis of furnace and producer gases and other technically important gaseous mixtures (J. Soc. Chem. Ind. 1889, 8, 178).

The nitrometer, originally devised by Lunge (Ber. 1878, 11, 436) for the estimation of nitrogen oxides in oil of vitriol, is capable of being applied to gas analysis and a large number of other determinations. It consists (Fig. 49) of a burette, fitted at the top with a three-way tap and a cup-shaped funnel, and communicating at the bottom by means of caoutchouc tubing with a plain tube of the same diameter, which serves as a level-tube. When large quantities of gas have to be measured, the upper part of the burette is expanded into a bulb, and there is a similar bulb on the level-tube (Fig. 50).

This apparatus is used with mercury, and is thus suitable for the analysis of gases soluble in water. It can be used in the same way as Hempel's burette, and for all purposes to which the latter is applicable. It may also be used without absorption pipettes, the reagent being introduced by means of the cup, but since the reagents cannot be removed without removing the gas, the latter method is only applicable when the reagents do not interfere with each other—*e.g.* for the absorption of carbon dioxide by caustic potash, followed by the absorption of oxygen by alkaline pyrogallate.

The estimation of nitrogen oxides in solution in sulphuric acid is conducted in the following manner. The apparatus is filled with mercury, so that when the tap is open between the burette and the cup, and the level-tube is raised, the mercury just passes through the tap and stands at a height of about 2 inches in the level-tube. The tap is then closed and 2–5 c.c. of the sulphuric acid, according to the quantity of nitrogen oxides which it contains, is placed in the cup, the level-tube is lowered and the tap is turned so that the acid is nearly all drawn into the burette without any air being admitted. To avoid measuring out small quantities (0·5–1 c.c.) of highly nitrated acid, this liquid should be diluted with a known volume of pure concentrated sulphuric acid, and 5 c.c. of this solution taken for analysis. The cup is rinsed with two successive quantities of 2–3 c.c. of pure acid, which is drawn into the cup with the same precaution as before. The tap being closed, the burette is taken out of the clamp and agitated in such a manner that the liquid is brought thoroughly into contact with the first 10 cm. or so of the mercury, which is broken up into bubbles. Nitric oxide is formed and collects in the upper part of the tube. When no more gas is given off, the levels are adjusted and the volume read off after the froth has subsided. In adjusting the levels the difference between the specific gravity of the acid and the mercury is allowed for by taking 6·5 mm. of acid = 1 mm. of mercury. A small quantity of acid is placed in the cup and the tap opened: if the acid is drawn in the pressure in the burette was too low; if gas escapes, the pressure was too high. It is better to err on the side of too low pressure, which is readily corrected by allowing acid to run in from the cup and taking another reading.

In agitating, care should be taken that the drop of acid which collects in the top of the burette just below the tap does not escape contact with the mercury, otherwise the results will be too low.

To prepare for another estimation, the level-tube is raised and the tap is opened so that all the acid and some of the mercury is driven into the cup, and the tap is then turned so that the acid runs out at the side.

The nitrometer may be used for the valuation of nitrites and nitrates, which are introduced in the form of a concentrated aqueous solution, care being taken that the proportion of water to acid does not exceed 2 parts of aqueous solution to 3 parts of the strongest acid. It may also be used for the estimation of nitrates and nitrites in potable waters, and in fact for almost any determinations in which a definite volume of gas is given off. For example, the estimation of carbonic acid; of urea by hypobromite (the reading being increased by 9 p.c. to correct for solubility of the gas and incomplete decomposition); hydrogen peroxide by an acidified solution of potassium permanganate, or, *vice versa*, the value of a permanganate solution by means of hydrogen peroxide, &c. (*See* Lunge, Ber. 1878, 11, 436; J. Soc. Chem. Ind. 1885, 4, 447, and 1886, 5, 82; Zeitsch. anal. Chem. 25, 309; and the translation of Winkler's Technical Gas Analysis (1885); also Allen, J. Soc. Chem. Ind. 1885, 4, 178.)

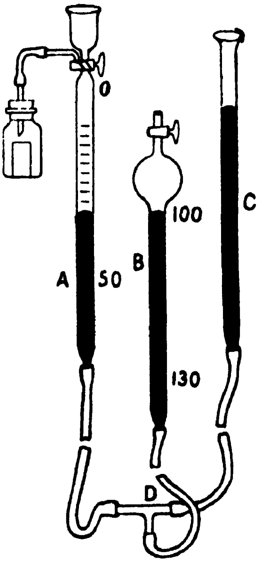

Fig. 51.

The *gas-volumeter*. Several of the estimations referred to in the preceding paragraph are more conveniently carried out in the gas-volumeter devised by Lunge, as in this apparatus the decomposition can be effected in a separate vessel. The measuring tube A and the reservoir C are converted by means of the T-piece D, with the so-called 'reduction' tube B.

At the outset the temperature and pressure are observed, and the volume occupied under these conditions by 100 c.c. of dry (or moist) air measured at 0° and 760 mm. is calculated. The reduction tube is filled with air to this volume, and the tap of the tube closed, or the end of the reduction tube may be terminated by a capillary and sealed off after the volume has been correctly adjusted. A special tap for the reduction tube has been devised by Göckel (Zeitsch. angew. Chem. 1900, 13, 961, 1238). If moist gases are to be measured, a small drop of water is introduced into the reduction tube; if dry gases are under examination, a drop of concentrated sulphuric acid must be introduced into the reduction tube. The formulæ for calculating the volume of gas in the reduction tube are as follows :—

$$V_1 \text{ (dry gases)} = \frac{V_0(273+t)760}{273 \times B}$$

$$V_1 \text{ (moist gases)} = \frac{V_0(273+t)760}{273(B-f)}$$

where V_1 = volume of gas required;
V_0 = normal volume (*e.g.* 100 c.c.);
t = observed temperature;
B = observed barometric pressure;
f = tension of water vapour at observed temperature.

When a decomposition by sodium hypobromite or hydrogen peroxide has been carried out in the auxiliary generating bottle, the gas evolved passes into the measuring tube A. The mercury in A and C are then adjusted to the same level, and the tap *o* closed, the gas being then at the atmosphere pressure. The three tubes are now adjusted so that the mercury in A and B are at the same level when the mercury in the latter tube stands at the 100 c.c. graduation. The gases in A and B are at the same temperature and under the same pressure, and since the gas in B occupies the same volume as it would at 0° and 760 mm. pressure, it follows that the gas in A also occupies the same volume as it would under the standard conditions. In this way, by the use of the gas-volumeter, all thermometric and barometric readings and all reductions by calculations or special tables are avoided; for the volume of gas is read off directly under conditions corresponding to the normal pressure and temperature. It is, however, essential that the reduction tube should be arranged for dry or moist gases according to the nature of the analytical operation involved (*v.* Lunge, Ber. 1890, 23, 440; 1891, 24, 729; 1892, 25, 3157; Zeitsch. angew. Chem. 1890, 3, 129; 1891, 4, 197, 410; 1892, 5, 677; J. Soc. Chem. Ind. 1890, 9, 547. *Cf.* Gruskiewicz, Zeitsch. anal. Chem. 1904, 43, 85).

In addition to the hypobromite and hydrogen peroxide decompositions, Lunge and Marchlewski have adapted the gas-volumeter to the estimation of carbon dioxide in natural carbonates, Portland cement, and other mineral substances, and also to the determination of carbon in iron and steel (Zeitsch. angew. Chem. 1891, 4, 229; 1893, 6, 395; J. Soc. Chem. Ind. 1891, 10, 658). G. T. M.

Electrochemical Analysis.

The first suggestion to apply the electric current to the deposition of metals was made by Cruickshank in 1801 (Nicholson's Journal of Nat. Phil. 1801, 4, 254). He noticed that metals were deposited from acid or alkaline solutions of their salts at the negative pole, and that the metal went into solution at the positive pole. He therefore suggested that the electric current might thus be used as an aid to analysis, particularly for depositing lead, copper, and silver.

In 1812 Fischer suggested its use for detecting small quantities of arsenic (Gilbert's Annalen, 42, 92). In 1840 Cozzi (Arch. delle Scienze med. fis 50, ii. 208) employed the galvanic current (produced by plates of gold and zinc connected together by a wire) to ascertain whether organic fluids, such as milk, contained metallic impurities. Gaultier de Claubry (J.

Pharm Chim. iii. 17, 125) applied it to detect small quantities of arsenic in animal fluids. In 1861, Bloxam (Quart. Journ. Chem. Soc. 13, 12, 338) described an electrolytic method for detecting arsenic and antimony. Becquerel (Ann. Chim. Phys. 1830, 43, 380) found that manganese and lead were readily oxidised, and appeared as oxides on the anode.

All these workers appear to have merely used the electric current as an aid to qualitative analysis. Wolcott Gibbs (Zeitsch. Anal. Chem. 3, 334), in 1864, showed that copper, nickel, zinc, lead, and manganese might be quantitatively determined by means of the electric current. Lucknow (Dingl. Poly. J. 1865, 177, 231, and 178, 42), from 1860, had employed electrolytic methods for the quantitative analysis of copper salts and for commercial copper. From this time forward many workers entered the field, and about 1880 Edgar Smith in America, and Classen in Germany, very much advanced the subject of electro-analysis, and to-day it is one of the most useful helps to the analytical chemist.

Before dealing with the methods of deposition and separation of the metals, it will be well to describe the apparatus used; but only the apparatus most generally employed will be dealt with.

Classen first suggested the employment of a platinum basin as cathode and a platinum disc as anode. A convenient stand for holding the basin, and a method of connecting with the source of current, are shown in Fig. 52. The basin should hold from 150 to 180 c.c. of solution. The inner surface of the basin should be roughened by the sand blast, as this causes better adherence of the deposit, especially in the case of peroxides such as lead and manganese. The base of the stand is of slate or marble, and the brass rod which conveys the — current is hollow; through this brass rod an insulated wire for carrying the + current passes, and is connected at the top of the rod by means of a piece of ebonite. The ring which supports the basin has three little platinum points at equal intervals on its circumference; on these the basin rests, thus ensuring good contact. The positive pole of the source of current is connected with the binding-screw fixed to the slate base, and the negative pole with the binding-screw marked —. In dealing with metals which deposit as oxides on the positive pole the basin is connected with the + pole.

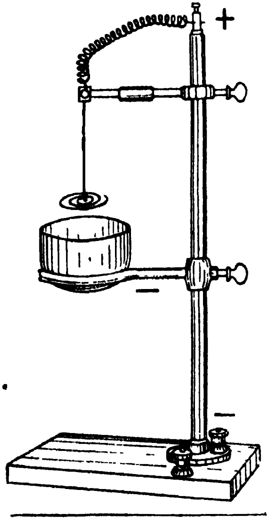

Fig. 52.

Another useful form of electrode is illustrated in Fig. 53. The anode is a stout spiral of platinum and the cathode is a cylinder of platinum gauze. This form of electrode can be employed either for stationary work or for rapid deposition work when the anode is rotated. The vessel in which the electrolysis takes place may either be a beaker or, better, a funnel with a tap such as is illustrated in Fig. 67.

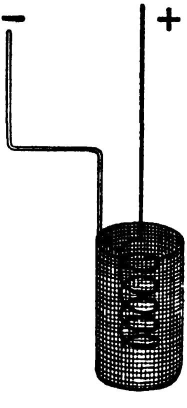

Fig. 53.

For stationary work the Flag electrode of F. Mollwo Perkin (Fig. 54) gives very satisfactory results. The cathode consists of a small sheet of stout platinum gauze, autogenously fastened on to a rigid platinum-iridium frame, both frame and gauze being roughened by the sand blast. The wire holds the electrode in position during the analysis. The loop near the top of the wire serves to hang the electrode on the balance. The anode is made of platinum wire, and is bent upon itself in such a way that when it is placed in position for electrolysis, as illustrated in Fig. 55, an even density is obtained on all parts of the cathode.

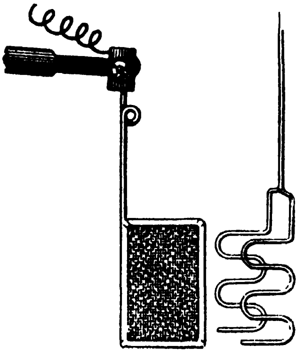

Fig. 54.

It has been found that the rate of deposition of metals from their solutions is very much increased and higher current densities can be employed when either the anode or cathode is rapidly rotated. Frary (Zeit. f. Elektrochem. 1907, 308) has also shown that excellent results can be obtained by electrolysing with stationary electrodes, but causing agitation of the electrolyte by placing the whole apparatus in the field of a powerful electromagnet. The forms of the apparatus are depicted in Fig. 56. From the figure it is seen that the solution is contained in a beaker B, in which is a cylindrical platinum gauze cathode C and a heavy platinum wire as anode A. The beaker is placed in the centre of a spool made from insulated copper wire E. By passing an electric current through the copper wire of the spool, a powerful magnetic field is produced, in the centre of which the beaker stands. If now a current be passed through the electrolyte by means of the electrodes, the electric lines of force are cut at right angles by the magnetic lines of force, and this produces a tendency for the solution to rotate, owing to the vertical magnetic field and radial current lines. The speed of rotation depends upon the ratio between the electric current and the magnetic current. With an electrolysing current of from 6 to 7 amperes, Frary was able to deposit 0·850 gram copper in 15 minutes. The other form, illustrated in Fig. 57, is for electrolysing with a mercury cathode, the use and applications of which will be described later. The electrolysing vessel is ring-shaped, so that it may fit into a hole cut into the pole D of the magnet. An iron rod passes from the other pole up into the centre of the electrolysing vessel. A is the anode and C the cathode. Extremely rapid rotation is thus produced, because the iron core very much facilitates the passage of the magnetic current, there being a radial field with vertical current lines.

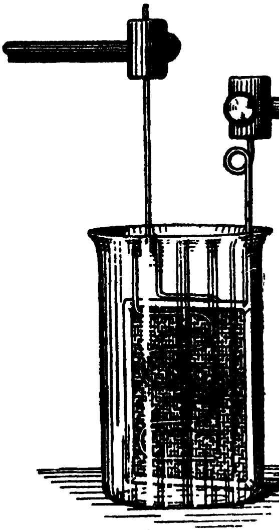

FIG. 55.

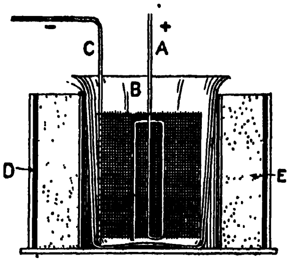

FIG. 56.

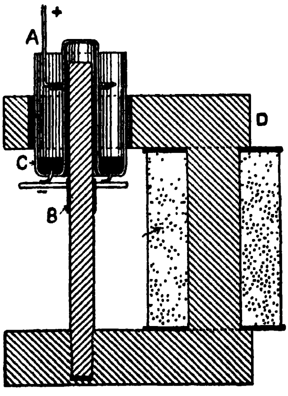

FIG. 57.

The advantages claimed for this method are: rapidity of deposition, and, as there are no mechanical parts which require lubrication, there is no chance of contamination from oil, or grease accidentally falling into the solution. As a matter of fact, however, rapid methods of electrolysis are more frequently carried out by means of a rotating anode or cathode.

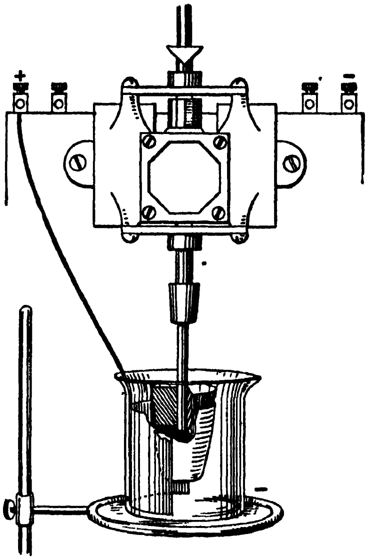

FIG. 58.

Gooch and Medway (Amer. J. Sci. 15, 320) use a rotating cathode. It is made from a platinum crucible of about 20 c.c. capacity. The crucible is attached to the shaft of the electromotor, which is used to rotate it at a speed of from 600 to 800 revolutions per minute by fitting it over a rubber stopper with a central bore, into which the end of the shaft fits tightly. In order to make electrical connection between the crucible and the shaft of the motor, a narrow strip of sheet platinum is soldered to the shaft and bent upwards along the sides of the stopper. This connects the shaft with the inside of the crucible when the latter is pressed over the stopper. The anode consists of a half cylinder of sheet platinum. Fig. 58 represents the arrangement of the apparatus when fitted together.

F. Mollwo Perkin and W. E. Hughes (Trans. Faraday Soc. 1910, 14) use an electrode of sheet platinum spun up so as to form a narrow thimble (Fig. 59), the upper end being open and having a stout iridio-platinum wire fused on to it by means of three short wire supports. This electrode is fixed into a small chuck and rapidly rotated by means of an electromotor, the speed of rotation usually being from 750 to 950 revolutions per minute. When in use, about two-thirds of the length of the thimble is dipped

FIG. 59

into the electrolyte, the active surface being about 16·3 sq. cm. If dipped too deeply into the solution, there is a tendency for the liquid to splash into the interior of the cylinder, and this would, of course, lead to erroneous results. The anode consists of a platinum cylinder of fine mesh. It is, however, frequently more satisfactory to employ a rotating anode and a stationary cathode, and for this purpose the gauze anode is employed as cathode, and the anode consists of a spiral of stout iridio-platinum wire. The simplest arrangement is illustrated in Fig. 53. The electrolysing vessel consists of a tap funnel which, when the electrodes are covered, holds about 60 to 70 c.c. of solution. The advantage of this form of electrolysing vessel is the ease with which the electrolyte can be removed on the completion of the electrolysis and the electrodes washed. The method of procedure is to place a beaker beneath the tap and draw off the solution until about half of it has run in. Distilled water is then run up to the original mark and the solution drawn off as before. The operation is repeated until the ammeter needle sinks to zero. The remaining water is run off, the tap closed, and the funnel filled with pure methylated spirit. This is run off, and, after a final washing with absolute alcohol, carried out in the same manner, the electrodes are removed and the cathode dried in the steam oven.

Another form of rotating cathode devised by Perkin is illustrated in Fig. 60. The cathode consists of a cylinder of platinum gauze. The anode is in the form of a double circle of stout platinum wire, and has four small baffle plates so placed as to prevent it from rotating with the cathode.

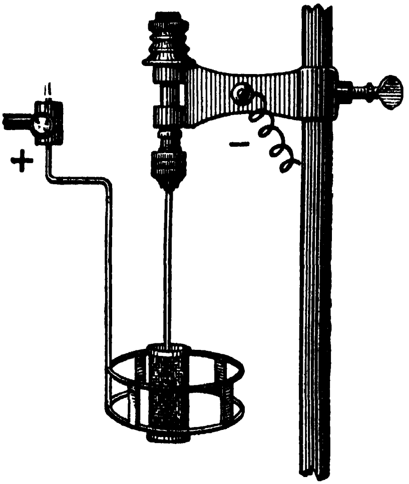

FIG. 60.

In order to rotate the anode (or cathode), it is fixed into a small chuck fastened on to the end of the spindle of a bicycle hub. The barrel of the hub has an arm fastened into it which can be clamped to any suitable support. The upper end of the spindle has a sheaf of pulleys fastened to it, so that it can be rotated by means of a belt from a motor and different speeds be obtained. It is found that the current passes very well through the barrel of the hub and the balls, which are lubricated with oil and graphite, to the spindle, and so to the electrode. When it is desired to obviate all drop in potential, *e.g.* if the apparatus is to be used for graded potentials, then a mercury cup is fastened on to the top of the spindle so that the current passes directly to the spindle.

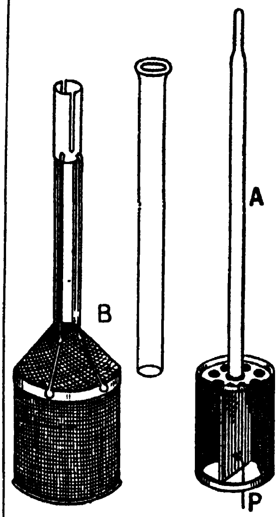

FIG. 61.

The apparatus of H. J. Sand (Trans. Chem. Soc. 1907, xvi. i. 373) is rather more complicated, but gives equally satisfactory results.

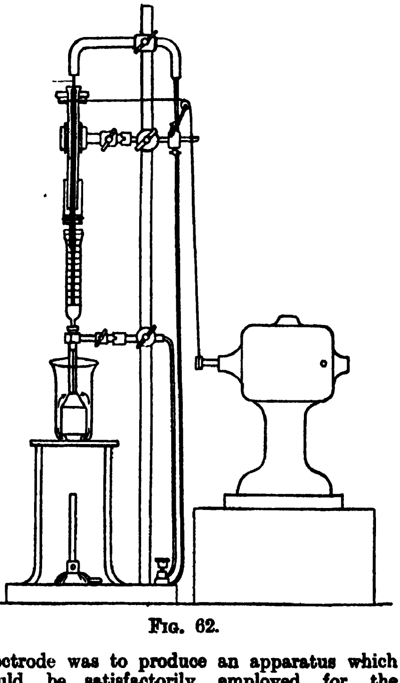

FIG. 62.

The special object in the design of this electrode was to produce an apparatus which could be satisfactorily employed for the separation of metals by graded potentials. It consists of a pair of platinum gauze electrodes (Fig. 61), an inner rotating electrode A, and an outer electrode B. The two are kept in position relatively to each other by means of a glass tube, which is slipped through the collar and the ring of the outer electrode B. It is gripped firmly by the former, but passes loosely through the latter. The hollow iridio-platinum stem A of the inner electrode is passed through the glass tube, in which it rotates freely. The mesh of the gauze is 14^2 per sq. cm. The gauze of the outer electrode almost completely stops the rotation of the liquid. The electrolyte is, therefore, ejected rapidly from the centre of the inner electrode by centrifugal force, and is continually replaced by liquid drawn in from the top and the bottom. So great is the suction thus produced, that when the electrode is moving rapidly, chips of wood or paper placed in the solution are drawn down to the top of the outer electrode. The circulation is practically independent of the size of the beaker employed. As the outer electrode surrounds the inner completely, the lines of flow of the current are contained between the two, and even when strong currents are employed, the potential of the electrolyte anywhere outside the outer electrode is practically the same as that of the layer of liquid in immediate contact with it. Fig. 62 shows the apparatus with stand and motor in working order. Before the method adopted for electrolysing by means of graded potential is discussed, the mercury cathode devised by Smith and Howard will be described.

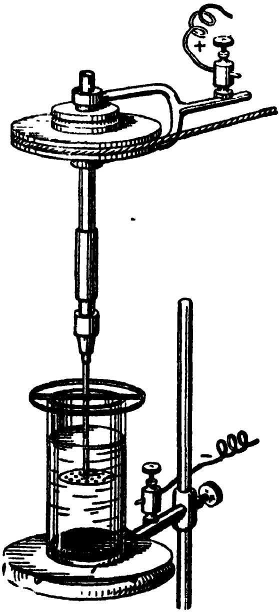

FIG. 63.

WolcottGibbs, in 1880, first suggested the use of metallic mercury as cathode, a definite amount being weighed into a beaker, where it was connected by means of platinum wire with the negative pole of a battery. Various metallic salt solutions were experimented upon, and, in 1883 (Amer. Chem. J. 13, 571), Gibbs stated that 'It was found possible to separate iron, cobalt, nickel, zinc, cadmium, and copper so completely from solutions of the respective sulphates that no trace of metal could be detected in the respective liquids.' Gibbs had in view not only the determination of the metals, but also of the anion left in the solution by titration.

In 1886 Luckow (Chem. Zeit. 9, 338, and Zeitsch. anal. Chem. 25, 113) suggested the addition of a known weight of a solution of a mercury salt to a solution of zinc sulphate, and so to deposit zinc and mercury simultaneously. In 1891 Vortman (Ber. 24, 2749) suggested a similar method, and employed it in the determination of several metals. Drown and McKenna (Amer. Chem. J. 5, 627) further worked at the subject, using an apparatus somewhat similar to Wolcott Gibbs, that is to say, an actual mercury cathode, but the process was first successfully worked out by Edgar Smith and his collaborators (J. Amer. Chem. Soc. 25, 885). The apparatus employed consists of a small tube or beaker of about 50 c.c. capacity, close to the bottom of which a thin platinum wire is introduced by means of which the current is supplied to the mercury cathode (Fig. 63).

The external part of the platinum wire touches a disc of sheet copper on which the beaker rests, and which is connected with the negative source of the current.

The anode is either a perforated disc of platinum or a stout spiral of platinum wire. During the electrolysis the anode is rapidly rotated by means of an electromotor or water turbine.

The chief difficulty in using the mercury cathode is the trouble experienced in washing and drying it. The solution left at the end of the electrolysis is siphoned off, and at the same time distilled water is run in until the needle of the ammeter drops to zero. Then, and not till then, the current is switched off. The inside of the beaker and the amalgam are rinsed with alcohol three times, and finally with dry ether. It is advantageous, in order to drive out thoroughly the last traces of ether, to blow dry air into the beaker for a few minutes. After standing for half an hour, the apparatus is ready for weighing. F. M. Perkin (Trans. Faraday Soc. 1910, 14) uses a small quartz beaker as containing vessel, with an iridium wire fused into it to make contact with the mercury. The advantage of iridium is that it does not amalgamate with the mercury. An advantage of the quartz vessel is that it can be heated to redness for purposes of cleansing. The apparatus is illustrated in Fig. 64. It will be noticed that a siphon tube is fused into one side of the beaker. The layer of mercury must not be sufficient in quantity to close the side tube. A spiral iridio-platinum anode is employed. When the electrolysis is finished, a piece of rubber tube is fastened to the bent end of the siphon. Distilled water is added so that the solution begins to siphon over into a beaker placed below the rubber tube. In order to work with as small a quantity of water as possible and in cases where the solution is required again, *e.g.*

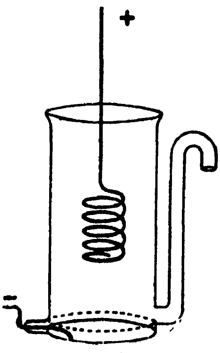

FIG. 64.

in metal separations, the solution is allowed to run out until its level drops almost to the end of the anode. Fresh water is then run in, and the operation repeated until the ammeter needle ponits to zero. For purposes of steadiness the vessel is held between clips on a copper plate.

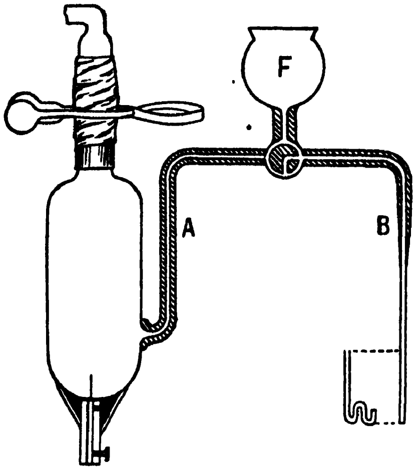

FIG. 65.

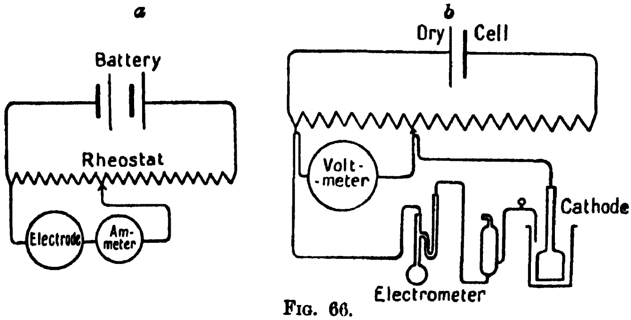

FIG. 66.

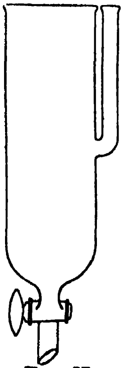

FIG. 67.

By means of the mercury cathode not only can the cations be rapidly and accurately determined, but also the anions remaining in the solution.

Various substitutes for platinum electrodes in electro-analysis have been suggested (*see* Nicolardot and Boudet, Bull. Soc. chim. 1918, [iv.] 23, 387), *e.g.* gold, gold-platinum alloys, copper, and certain proprietary iron-alloys. An alloy of gold (7) and platinum (1) serves well in all circumstances for cathodes. As anodes such electrodes are less satisfactory and must not be used for the anodic deposition of lead, nor with cyanide electrolytes, unless electro-plated with platinum. In ammoniacal solution such electrodes acquire a light brown colour, and increase slightly in weight, but return to their original weight and appearance when heated to 300° (Analyst, 1919, 38).

Method of Graded Potential.

Each metal has a particular potential at which it begins to be deposited; below this potential it is not possible to deposit the metal. It follows, therefore, that when dealing with a solution containing the salts of two or more metals it will be possible, provided the deposition potentials of the metals do not lie too near together, to deposit the metals separately, by first working with the lowest potential at which one of the metals will be deposited. When this metal has been deposited the next one in the potential series will be deposited by raising the potential.

This method of analysis was suggested by Kiliani in 1883, and was further elaborated by Freudenberg working in Ostwald's laboratory (Zeit. physikal. Chem. 12, 97). But it was H. J. S. Sand (Trans. Chem. Soc. 1907, 373) who first worked out the method and used the apparatus with the rotating cathode already mentioned. The potential is kept at constant value by means of an *auxiliary electrode.* Such an auxiliary electrode, designed by Sand, is illustrated in Fig. 65. It is a mercury-mercurous sulphate $2N$-sulphuric acid electrode. The distinctive feature of the electrode is in the funnel F, and connecting glass tube AB. The two-way tap allows the funnel F to be connected with either limb of the glass tube AB, or closes all parts from each other. The limb A permanently contains the $2N$-sulphuric acid solution of the electrode. But the limb B is filled for each experiment from the funnel F with a suitable connecting liquid, generally sodium sulphate solution. The end of B is made of thin tube of about 1½ mm. bore, and is bent round several times to minimise convection. While the electrode is in use, the tap, which must be kept free from grease, is closed, the film of liquid held round the barrel by capillary attraction, making the electrical connection, but towards the end of a determination, a few drops are run out in order to expel any salt which may have diffused into the tube.

Electrical connections.—For separations by graded potential the electrical connections must be made as shown in Fig. 66 *a* and *b*. The battery is connected directly to the two ends of a sliding rheostat, the electrolytic cell to one of them and the slider. It is essential that the sliding contact should be good. The arrangement adopted for the measurement of the potential-difference auxiliary electrode-cathode is one which has been frequently employed in electro-chemical research. The electromotive force to be measured is balanced against a known electromotive force by means of a capillary electrometer. The known electromotive force is drawn from a sliding rheostat, the ends of which are connected with one or two dry cells. The value of the E.M.F. is read directly on a delicate voltmeter (range 1·5 volts). For potential differences greater than 1·5 volts, a Helmholtz 1-volt instrument may be interposed between the auxiliary electrode and the rheostat. The arrangement allows the voltage to be measured almost instantaneously, which is a matter of great importance.

To carry out an experiment, the cathode, anode, and auxiliary electrode are placed in position, the electrolyte is heated to the required temperature, and covered with a set of clock-glasses having suitable openings for the electrodes. For the purpose of a separation, the current is usually started at about 3–4 amperes, and the potential of the auxiliary electrode noted. As a rule, this is only slightly above the equilibrium potential. The current is then regulated so that the potential of the electrode may remain constant. When no side-reactions take place, the current falls to a small residual value (generally about 0·2 ampere), as the metal to be separated disappears from the solution. The auxiliary electrode is then allowed to rise 0·1–0·2 volt, according to the metal.

It is obviously a matter of great importance to know when all the metal has been deposited. Under the conditions just assumed, the amount deposited per unit of time may be taken as roughly proportional to the amount still in solution. This being so, it follows that the amount in solution will decrease in geometrical ratio during successive equal intervals of time. If we, therefore, make the safe assumption that the concentration of the metal has fallen to under 1 p.c. of its original value in the time during which the potential and the current have been brought to their final value, it is clear that by continuing the experiment half as long again, the concentration of the metal will fall to under 0·1 p.c., so that the deposition can be considered finished.

In cases where side-reactions occur, the current does not fall to zero, but it generally attains a constant value which allows it to be seen when all the metal has been removed. In certain cases this can be tested for chemically, and by continuing the experiment for about half as long again as this reaction demands, the metal may be safely assumed to have been deposited completely. This method may be adopted, for example, in the separation of lead from cadmium, the former being roughly tested for by sulphuric acid. If none of these methods is available, the metal must be deposited to constant weight, or else the separation must be carried out under very carefully defined conditions for a length of time proved by previous experiment to be more than sufficient.

Sand has simplified the apparatus necessary for the potential measurements by fitting all the apparatus required for the measurement of the electrode potential into a single box. Full particulars will be found in Trans. Faraday Soc. 1909, 162.

F. M. Perkin uses the apparatus depicted in Fig. 67 for working with graded potentials. The vessel containing the electrolyte has a tube fused into the side. Into this side tube the capillary end of the auxiliary electrode is inserted.

CLASSIFICATION OF THE METALS FOR ELECTRO-ANALYTICAL PURPOSES.

Most metals can be deposited satisfactorily at the cathode, particularly since the introduction of the mercury cathode and of the graded potential methods. Theoretically, by grading the potential, it should be possible to separate any one metal from another. Indeed, in many cases, this can be done, but there are cases in which the potential differences at which two metals can be deposited, that is to say, the minimum potential at which they will both be deposited, lie so close together that it is not possible to so adjust the conditions that a separation can be effected.

GROUP I.—Copper, silver, mercury, gold, palladium, rhodium, platinum, iridium, bismuth, antimony, tin, (arsenic), tellurium. These metals are more electronegative than the hydrogen electrode, and, consequently, can theoretically be deposited quantitatively from acid solutions.

GROUP II.—Cadmium, zinc, and indium. These metals are more electropositive than hydrogen, but, owing to the supertension of the hydrogen evolution in acid solution, it is actually possible to deposit them from weak acid solutions.

GROUP III.—Iron, nickel, cobalt. These metals are more electropositive than hydrogen, but, as the supertension of hydrogen is very low, these metals cannot be deposited completely from acid solutions. They can, however, be deposited from acid solutions if a mercury cathode is employed.

GROUP IV.—The metals of this group can either be deposited as oxides at the anode, or as oxides at the cathode. The group comprises the following metals: lead, thallium, manganese, chromium, molybdenum, uranium. Some of them can, however, be satisfactorily deposited as an amalgam on a mercury cathode.

GROUP V.—The metals of this group are the most strongly electropositive, and can only be deposited by using a cathode of mercury; but even then it is not possible in all cases to obtain a quantitative separation. The metals of this group are aluminium, glucinum, calcium, strontium, barium, magnesium, potassium, sodium, lithium, rubidium, cæsium.

GROUP VI.—These are all anions, and their estimation has been rendered possible mainly through the work of Edgar Smith, who completely deposits the metals by means of a mercury cathode and estimates the anions by titration or other appropriate method. The most important anions analysed by this method are F', Cl', Br', I', SO_4'', CO_3'', $Fe(CN)_6''''$, $Fe(CN)_6'''$, PO_4''', NO_3'.

It has not been found possible to analyse organic anions by electrolytic methods, because they are either decomposed or various reactions more or less complicated take place. Thus, for example, when the acetate anion is given up at the anode, ethane is produced, which, of course, is given off in the form of a gas.

Nature of Deposit.

Sand (Trans. Chem. Soc. 1907, 383) has theoretically and practically worked out the conditions necessary for obtaining adherent metal deposits.

The production of a *uniform deposit* over the electrode depends entirely upon the relation between polarisation and the E.M.F. required according to Ohm's law to force the current from one part of the solution to the other (Zeitsch. Elektrochem. 1904, 452). The case of metals such as cadmium and zinc, which require a higher potential for their precipitation from most of their solutions than hydrogen, is a question of supertension. The metals can only be deposited by virtue of the supertension which is required to liberate hydrogen as a gas. This supertension varies with the material of the electrode, and may even vary at different parts of the same electrode, owing to different states of its surface. Consequently, it may happen that the metal is deposited on a portion of the electrode which has a high supertension, and will continue to grow there; but at rougher parts of the electrode, where the supertension is lower, hydrogen alone will be evolved. This is, for example, particularly noticeable in the case of zinc, which, instead of being evenly deposited over the surface of an electrode, apparently perfectly smooth and even, often comes out in patches, parts of the electrode being absolutely free from deposit. Some solutions also of the same metal appear to be more sensitive to variations in the quality and character of the electrode than others. Thus with ordinary electrodes when the potential is not graded, it is a matter of the greatest difficulty to obtain an adherent deposit of copper when the electrolyte is sulphuric acid. On the other hand, with electrolytes of potassium cyanide or nitric acid, an even deposit is readily produced.

The nature of the deposit.—Electrolytic deposits may be spongy, coarsely crystalline, or finely crystalline. The last is the only form in which metals may be deposited in order to yield satisfactory quantitative results. Sand considers (*l.c.*) that spongy deposits are most probably due to the metal being deposited in the form of an unstable hydride, which gradually decomposes with evolution of gas.

The difficulty of hydride formation is got over by keeping the potential of the electrode under control. Vigorous stirring of the electrolyte, small current density, and the presence of some oxidising agent, tend to keep the potential low. But, by using an auxiliary electrode and rapid rotation, it is possible to obtain metals from solutions from which, under ordinary circumstances, they cannot be deposited.

Copper.

Copper may readily be deposited from solutions which contain considerable quantities of nitric or sulphuric acid. But good deposits can also be obtained from cyanide solutions, and it is possible to employ solutions containing an excess of ammonia.

The solutions which give the best results are those containing nitric acid or potassium cyanide. Indeed, it is a matter of considerable difficulty to obtain satisfactory results in presence of free sulphuric acid, excepting when a mercury cathode is employed. For stationary work, either the gauze flag electrode or the cylindrical gauze electrode is to be recommended.

Nitric acid.—About 1 gram of the copper salt is dissolved in about 140 c.c. of water and 5–10 c.c. of nitric acid (sp.gr. 1·42) added to the solution; that is, from 8 to 10 p.c. of the acid. If the flag electrode is employed, usually about 120 c.c. of water is sufficient, in which case proportionately less nitric acid must be used. The solution may either be electrolysed at ordinary atmospheric temperature, or heated from 45°–50°; in the latter case the time required for the complete deposition of the metal is considerably lessened. The best C.D. to employ is from 0·8 to 1·2 amperes, when the E.M.F. will be from 1 to 2·8 volts. A bright red film will be seen to flash across the cathode almost immediately the circuit is completed. In cold solutions, from 2½ to 3 hours will be required to completely deposit the metal; with hot solutions the rate of deposition is considerably accelerated. To ascertain when the whole of the copper has been deposited, withdraw about 1 c.c. of the solution by means of a pipette, transfer to a test-tube, make alkaline with ammonia, then acid with acetic acid, and add a few drops of potassium ferrocyanide; the formation of a brown precipitate or colouration shows that there is still some copper left in the solution, in which case, of course, it is necessary to continue the electrolysis until, on further testing with the reagent, no colouration is produced.

If the electrolysis is run overnight there is a tendency to form nitrous acid owing to cathodic reduction. In such cases a small quantity of urea should be added and the electrolysis continued for about half an hour. Otherwise a portion of the copper remains in solution. The urea decomposes the nitrous acid.

Washing the deposit.—As the electrolyte contains an excess of free nitric acid in which the copper deposit is readily soluble, the washing has to be carried out with caution. Some workers prefer to siphon off the electrolyte without breaking the circuit, and to run in water at the same time, until the ammeter points to zero. The current is then cut off and the cathode removed, finally washed with distilled water and dipped into a beaker of absolute alcohol. It is then dried in the steam oven, and, after cooling for 20 minutes, weighed. When the gauze cylindrical electrode is used, a stoppered funnel as illustrated in Fig. 67 is very convenient.

The solution is drawn off until only about one quarter of the electrode is immersed. Distilled water is then run in, and the operations repeated until the ammeter shows zero. By operating rapidly, the cathode may be removed, and, if dipped at once into a beaker of water and then washed under the tap or in several changes of water and then in alcohol, absolutely accurate results can be obtained.

The deposit obtained from nitric acid is bright red, and generally has a more or less crystalline appearance. If the C.D. has been too high, it may be 'burnt,' and have a brownish appearance, and may be powdery and non-adherent. When it is desired to electrolyse over-night—and this is often found very convenient—a C.D. of from 0·2 to 0·3 of an ampere is used. It is generally advisable in this case to add more nitric acid, because, owing to the reducing action of the hydrogen liberated at the cathode, the nitric acid becomes converted into ammonia. This formation of ammonia causes the deposit to be spongy and of a bad colour, when it is difficult to wash and weigh. For running over-night about 2 c.c. extra of nitric acid should be added for every 100 c.c. of solution.

The deposits obtained with sulphuric acid are generally not satisfactory, but of all the copper deposits that obtained from solutions containing potassium cyanide is the most beautiful.

Potassium cyanide.—The colour of the deposited metal is pinkish red, and perfectly smooth. But, from other points of view, the deposition from cyanide solutions has no advantage over the deposits obtained from solutions containing nitric acid. The copper salt is dissolved in about 30 or 40 c.c. of distilled water, and then a freshly prepared solution of potassium cyanide added, until the precipitate first produced is dissolved. Slightly more potassium cyanide than is necessary to dissolve the precipitate should be used, but any considerable excess must be avoided. Generally speaking, from 1 to 1·5 grams of potassium cyanide should be used for every gram of copper salt taken.

The C.D. employed should be from 0·8 to 1·2 amperes. The E.M.F. required in cold solutions will be found to be about 5–6 volts; in warm solutions, from 4 to 5 volts. The whole of the copper is deposited in 2 to 2½ hours.

Rapid methods.—By employing rotating electrodes, either rotating anode or cathode, copper may be completely deposited in a few minutes. Thus Sand, by using his apparatus, was able to completely deposit the copper from 0·25 gram copper sulphate in 6 minutes, the number of revolutions of the anode per minute being about 800; in that of Fischer the copper from 0·3 gram copper sulphate was deposited in 10 minutes, the speed of revolution being 1000 to 1200. In the one case a rotating anode was employed and in the other the cathode was rotated. The electrolyte in both cases contained free nitric acid. Cyanide solutions give, however, equally satisfactory results.

Edgar Smith, by employing a rotating anode and mercury cathode, has deposited quantitatively 0·789 gram of copper in 10 minutes, and as much as 0·3945 gram per 4 minutes, the solutions containing sulphuric acid. The advantage of the mercury cathode is that almost any electrolyte can be employed equally satisfactorily. Indeed, the pure salt of the metal may be dissolved in water and electrolysed without the addition of any acid or other electrolyte. When the whole of the metal has been deposited, the solution is run off, and may then be titrated in order to determine the anion, *e.g.* SO_4''.

Silver.

Silver can best be deposited from solutions containing potassium cyanide. From solutions containing other electrolytes it is apt to be deposited in a crystalline feathery form, and consequently does not adhere well to the cathode. There is, however, a tendency for the results to be slightly too low when cyanide solutions are employed. It is very important that only the purest potassium cyanide be used in making up the solutions. For 0·5 gram of a silver salt about 3–4 grams of potassium cyanide will usually be found sufficient. With a C.D. of 0·5 to 1·0 ampere, and a temperature of 50°–60°, the silver will be deposited in from 1 to 2 hours. Using a cold solution and with a C.D. of from 0·2 to 0·35 ampere, the time required is from 4 to 4·5 hours. The deposit should either be washed by siphoning, or the electrode must be very rapidly removed from the electrolyte and dipped into water, in order to avoid loss by the solvent action of the potassium cyanide.

With rotating electrodes the silver can be deposited within a few minutes. By using an auxiliary electrode and rotating the anode vigorously, Sand was able to deposit silver from ammoniacal solutions in 7 to 8 minutes.

Smith, by using a mercury cathode and rapidly rotating anode deposited 0·2240 gram of silver from silver nitrate in 4 minutes. At the commencement of the operation an anodic deposit of silver peroxide was obtained, but after a minute or two this disappeared.

Mercury.

Many methods have been devised for precipitating mercury on platinum cathodes, and some of them give quite satisfactory results. When mercury is deposited on a platinum dish, or on a wire gauze electrode, it spreads evenly over the surface as a thin metallic film, which, however, is inclined to run together as the amount of mercury on the electrode increases in quantity. After the mercury has been deposited, the electrode is washed with water in the usual way, then in absolute alcohol, and finally in absolute ether. The last traces of ether may be removed by blowing dry air on to the electrode.

On no account may the mercury-coated electrode be heated. If the electrode is washed once in 90 p.c. alcohol, and then placed in a beaker of anhydrous acetone for a minute, it may then be dried without using ether. It is always advisable, before weighing, to place the electrode in a desiccator for 20 minutes. The desiccator should have a dish in it containing a little metallic mercury, because even at ordinary temperatures mercury volatilises to a small but appreciable extent.

The mercury can be removed from the electrode by heating in the Bunsen flame, but owing to the tendency for electrolytically deposited mercury to alloy with platinum, the electrode is almost invariably marked with black stains, and a slight loss in weight takes place. For this reason some workers prefer to plate the electrode with copper or silver before using. These difficulties are, however, entirely eliminated by using a mercury cathode; in fact, it is strongly recommended to employ always a mercury cathode when dealing with mercury.

Many electrolytes have been suggested, and all give more or less satisfactory results. Thus, the mercury salt may be dissolved in water and electrolysed in presence of a small quantity of sulphuric, hydrochloric, or nitric acid. With sulphuric acid, from 1 to 2 c.c. of the concentrated acid are added to each 100 c.c. of solution, and electrolysis conducted with a C.D. of 0·3–0·8 ampere per square decimeter, which is finally increased to 1 ampere towards the end of the operation. With rotating electrodes, currents of from 4 to 6 amperes per square decimeter may be employed. The temperature of the electrolyte may be 50°–60°, but not higher.

Sometimes, owing to the reducing action of the hydrogen given off at the cathode, mercurous salts are precipitated. The addition of small quantities of ammonium persulphate will cause them to go into solution again. The conditions with the other acids mentioned are very similar to those required for sulphuric acid. Potassium cyanide is not to be recommended, owing to slight solution of the anode taking place.

Sodium sulphide gives very satisfactory results, but care must be taken to employ a very pure solution of salt. From 25 to 30 c.c. of the concentrated solution of sodium sulphide are required for every 100 c.c. of solution. The solution should be heated to about 65°, and for stationary electrodes a C.D. of 0·15–0·25 ampere per square decimeter used. With rotating electrodes from 3 to 6 amperes per square decimeter may be used.

With mercury electrodes rotating anodes are almost invariably used, and high-current densities can be safely employed. The whole of the mercury can be deposited in from 15 to 25 minutes.

Cinnabar may be dissolved in *aqua regia*, the solution evaporated to dryness. The residue is then taken up with water, filtered from gangue, and then directly electrolysed after the addition of a small quantity of nitric acid.

Gold.

Gold may be deposited from its solution in cyanide or in sodium or potassium sulphide, or in ammonium thiocyanate. The drawback to using potassium cyanide is the tendency for the anode to go into solution. But with low-current densities, this only takes place to a small extent. The solution is made up by adding rather more than the quantity necessary of potassium cyanide to bring the gold salt into a clear solution. With stationary electrodes a C.D. of 0·6–0·8 ampere is employed at a temperature of 50°–60°, the metal being deposited in the course of 2 to 3 hours. With rotating electrodes a current of about 3 amperes may be employed, when the metal will be deposited in about 30 minutes.

Sodium sulphide.—From 20 to 25 c.c. of a saturated solution of sodium sulphide are used for every 100 c.c. of solution. With a C.D. of from 0·1 to 0·3 ampere the metal will be deposited in from 4·5 to 5·5 hours. With rotating electrodes and high-current densities, the results are too high, owing to deposition of sulphur along with the gold.

Ammonium thiocyanate.—5 to 7 grams of ammonium thiocyanate are dissolved in about 80–90 c.c. of water at 70° to 80°, and the gold solution run slowly in with constant stirring. The clear solution is electrolysed at a temperature of 40°–50° with a C.D. of 0·2–0·55 ampere, the metal being deposited in from 1·5 to 2 hours. This method has not been tried with rotating electrodes. The precipitation of small quantities of yellow canarine in the electrolyte during electrolysis does not interfere with the reaction.

E. F. Smith obtains good results by electrolysing a gold chloride solution, using a mercury cathode. In order to prevent the chlorine evolved attacking the anode, from 10 to 12 c.c. of toluene are added. The time required to deposit 0·15–0·2 gram of gold is about 5 to 7 minutes.

Most solvents for gold will also attack the platinum cathode. *Aqua regia*, for example, cannot be used to dissolve the gold from the platinum. F. M. Perkin recommends a dilute solution of potassium cyanide to which is added 4–5 c.c. of hydrogen peroxide, or from 2 to 3 grams of an alkali persulphate. On gentle warming the deposit is removed in a few seconds.

$$2Au+4KCN+H_2O_2=2KAu(CN)_2+2KOH.$$

Platinum.

Like gold, platinum can be deposited from solutions containing free mineral acids, but unlike gold, which from these solutions is deposited in a non-adherent form, it may be deposited with very feeble currents in a hard and reguline condition. With high currents and with stationary electrodes the metal is always deposited as platinum black. With a current of from 0·01 to 0·05 at a temperature of 50°–60°, about 0·1 gram of platinum can be deposited in 4·5 to 6 hours. Julia Langness (J. Amer. Chem. Soc. 1907, 459), by using a rotating cathode, deposited 0·2 gram of platinum from a solution of K_2PtCl_6 in 5 minutes. But the current, 17 amperes, must be looked upon as excessive for analytical purposes.

Before depositing platinum it is advisable to coat the cathode with silver.

Rhodium.

This metal may be deposited on to a silver-coated electrode from solutions acidified with phosphoric acid. A current of 0·18 ampere is used. As the process continues, the purple colour of the solution gradually disappears and becomes colourless, when the deposition is finished. With a rotating anode the metal may be deposited from solutions weakly acidulated with sulphuric acid in about 15 minutes with a current of 8 amperes, and with a current of 14 amperes in 5 minutes. The deposited metal has a black colour, but is quite adherent.

Palladium.

In order to obtain a dense and firmly adhering deposit of this metal from acid solutions, it is, according to Amberg (Zeit. f. Elektrochem. 1904, 386, 853, and Annalen, 1905, 235), necessary that the potential should not exceed 1·25 volts. With stationary electrodes the process is very slow, and polarisation at the anode takes place, owing to the formation of oxy- compounds. On the other hand, by using a rotating electrode and solutions of palladium ammonium chloride with 30 p.c. by weight of sulphuric acid and a C.D. of from 0·23 to 0·50 ampere, as much as 0·3–0·9 gram may be deposited in from 3·5 to 5 hours.

Julia Langness, by using currents of from 15 to 17 amperes, and an ammoniacal solution, has obtained quantitative deposits in from 3 to 5 minutes.

Antimony.

This metal may be deposited from its thiosalts, particularly sodium thioantimonite, a method originally suggested by Classen. During the electrolysis there is, however, a danger, owing to the deposition of sulphur at the anode, for sodium thioantimoniate to be formed, and this prevents the quantitative deposition of the metal. A. Fischer (Ber. 1903, 2474) recommends the addition of potassium cyanide to the electrolyte, which prevents the formation of the thioantimoniate, thus:

$$N_2S_4+3KCN=3KCNS+Na_2S.$$

There is one difficulty when sodium sulphide is used—the results obtained are usually slightly too high. This is due to the occlusion of small quantities of sulphur along with the metal. For this reason large quantities of metal should not be deposited by this method. The antimony salt is dissolved in 60–80 c.c. water made just alkaline with sodium hydroxide, any precipitate being ignored, then 20–25 c.c. of a fresh saturated solution of sodium sulphide added, and 2·5–3 grams of potassium cyanide. The solution is then electrolysed at from 30°–40°. With stationary electrodes the metal is deposited in from 4·5 to 6 hours; when rotating electrodes are used, in 30 to 45 minutes.

F. M. Perkin and H. D. Law (Trans. Faraday Soc. *i.* 262) recommend neutral tartrate solutions. The antimony salt is dissolved in water, and from 8 to 10 grams of ammonium tartrate added; if necessary, the solution is neutralised with dilute ammonia. At a temperature of from 70° to 80°, and a C.D. of 0·25–0·55 the metal can be deposited with stationary electrodes in from 2·5 to 3 hours.

Sand (Chem. Soc. Trans. 1908, 1572) dissolves the metal in 20 c.c. of hot conc. sulphuric acid, and dilutes the cold solution to 80 c.c. The solution becomes turbid owing to hydrolysis, but this disappears during the electrolysis, and does not affect the result. The auxiliary electrode potential is kept at from 0·55 to 0·65, but may be increased to 0·75 toward the end of the process. The time required to deposit 0·35–0·45 gram of metal is from 20 to 35 minutes with an anodic rotation of about 800 revolutions per minute. Small quantities of hydrazine sulphate (0·5–0·6 gram) are added to reduce any antimonial salts which may be formed.

Bismuth.

Until the advent of rotating electrodes, and particularly of the method of graded potential, bismuth was one of the most difficult metals to deposit, since it almost invariably came down in a powdery and non-adherent form. These remarks do not apply to the mercury cathode. According to Kollock and Smith (J. Amer. Chem. Soc. 27, 1539) to a solution containing about 0·2 gram of the metal as nitrate, the volume of which should not exceed 12 c.c., 0·5 c.c. of strong nitric acid is added. A current of about 4 amperes is passed, and the whole of the bismuth will be precipitated in from 12 to 15 minutes. The anode should be very rapidly rotated, so that the mercury may take up the bismuth as it separates, otherwise it may collect in a black mass beneath the anode.

Sand (Chem. Soc. Trans. 1907, 373) uses a solution containing tartaric acid; any excess of nitric acid, which may be in the original solution, is removed by the addition of sodium tartrate. By means of the auxiliary electrode, the cathode potential is maintained between 0·63 and 0·9 volt. The anode is rotated at 800 revolutions per minute. In one case the amount of metal in the solution was 0·2 gram, 2·5 c.c. of nitric acid (1:4) was added, and 8 grams of sodium tartrate. With a current varying from 0·2 to 3 amperes the metal was deposited in 9 minutes.

A. Fisher uses an electrolyte containing for each 0·5 gram metal, 10 grams of potassium oxalate, and 5 grams of Rochelle salt. By means of an auxiliary electrode, the cathode potential is kept at 0·8 volt. Temperature of solution, 75°; time required, 11 to 15 minutes.

Tin.

Tin can be satisfactorily deposited from an ammonium sulphide solution. Sodium sulphide is not satisfactory; indeed, tin is not thrown out from strong solutions at all. Hence, we have here a method of separation of antimony and tin. If the tin solution is acid, it is first neutralised with ammonia, and then sufficient yellow ammonium sulphide is added to dissolve the precipitate and form a clear solution. With stationary electrodes and a current of 1·0–1·8 amperes, the tin will be deposited in from 3 to 4 hours.

With rotating electrodes the metal can be deposited in from 15 to 35 minutes, depending upon the current employed, and the temperature of the electrolyte. Currents of from 1·8 to 8 amperes have been successfully employed.

A mercury cathode also gives very good results. The tin salt is dissolved in dilute sulphuric acid, and electrolysed with a current of from 2 to 5 amperes. From 0·5 to 0·8 gram can be deposited in from 8 to 12 minutes.

When platinum electrodes are employed, considerable difficulty may be experienced in removing the deposit. The simplest method is to make the electrode on which is the deposit, the cathode in dilute sulphuric acid, a piece of copper wire serving as cathode. Some workers prefer to coat the electrode with copper, and then the copper with tin, the tin being deposited from an ammonium oxalate solution; this proceeding, however, is tedious.

Tellurium.

Finely powdered tellurium is dissolved in a few c.c. of conc. sulphuric acid. The white anhydride so obtained is washed with a little freshly boiled water into the electrolysing vessel, and then 80 c.c. of a 10 p.c. solution of pyrophosphoric acid or sodium pyrophosphate added. The solution is then electrolysed with a C.D. of 0·1 ampere. Time of deposition, 4 to 5 hours When a rotating electrode is employed, the time of deposition is much accelerated.

GROUP II.—**Zinc.**

Zinc is rather a difficult metal to deposit satisfactorily and quantitatively, and a very large number of methods have been suggested by different workers. Although it is +0·77 volt more positive than hydrogen, it can be deposited from slightly acid solutions, owing to the high supertension of hydrogen evolution from the surface of zinc, the supertension of hydrogen being 0·70 volt.

With zinc it is advisable always to employ rotating electrodes. The electrodes need not, however, be made of platinum; nickel, particularly in the form of gauze, answers equally well.

Price and Judge (Trans. Faraday Soc. 1907, 88) use an electrolyte containing sulphuric acid which must not be more than $\frac{1}{6}N$ and sodium sulphate.

It is, in fact, better to keep the normality of the acid rather lower than one-sixth. By starting with a C.D. of 0·25 ampere and increasing to 2·0 amperes about 0·2 gram of metal can be deposited in 40 minutes.

Owing to acetic acid being much less dissociated than sulphuric acid, solutions containing considerable quantities of this acid may be used. Thus, Exner (J. Amer. Chem. Soc. 1903, 896) deposited 0·25 gram zinc with a current of 4 amperes in 15 minutes. The electrolyte contained 3 grams sodium acetate and 0·30 p.c. acetic acid. A. Fischer (Chem. Zeit. 1907, 25) takes 1 c.c. conc. sulphuric acid, 3·5 c.c. conc. ammonia, 1·5 c.c. acetic acid, and 2·5 grams ammonium acetate. A. Classen (Quant. Analyse d. Elektrochem. 1897, 156) uses a solution of potassium oxalate, the zinc solution is added to a solution of from 4 to 5 grams of potassium oxalate. As soon as the electrolysis has started, it is advisable to add a few c.c. of a 1 p.c. solution of oxalic acid. Ammonium salts must be absent.

Kollock and Smith use a mercury cathode, and a solution of zinc sulphate or zinc sulphate acidified with sulphuric acid.

Zinc adheres somewhat firmly to platinum electrodes, and, if left on for some time, seems to alloy with the electrodes. If, however, it is removed shortly after the electrolysis, no ill effect is produced. The best method to remove the deposit is to warm the electrode in a strong solution of sodium hydroxide.

Cadmium.

Although cadmium is electropositive to hydrogen by as much as 0·42 volt, yet, owing to the high supertension of hydrogen with this metal, it is possible to deposit it from acid solutions. Owing, however, to the depolarising action of nitric acid, nitrates should not be present; on the other hand, small amounts of chlorides do not seem to matter.

Cadmium may be deposited from solutions containing small quantities of free sulphuric acid. It is usually advisable to add, after the bulk of the cadmium has been deposited, the equivalent amount of sodium hydroxide to neutralise the sulphuric acid which has been set free through the deposition of the metal. In 100 c.c. of solution, 1 c.c. of concentrated sulphuric acid may be added before commencing the electrolysis. With stationary electrodes and a current of 0·1 to 0·35 ampere, the metal is deposited in from 3 to 4 hours; with a rotating electrode and a current of 4 to 5 amperes, the deposition is complete in 20 minutes. The deposition from cyanide solutions is the simplest and most easy to carry out. A solution of potassium cyanide is added to the cadmium solution until the precipitate first produced is dissolved, and then about half the quantity already added is run in. It is advisable also to add about 2 c.c. of a normal solution of sodium hydroxide. With stationary electrodes and a current of 0·15–0·35 ampere at a temperature of 50°, the deposit is complete in from 4·5 to 5·5 hours; with rotating electrode and a current of from 5 to 8 amperes, in from 15 to 30 minutes.

Group III.—Iron.

It is not often that the analyst requires to deposit iron electrolytically, owing to the very satisfactory methods of titration and precipitation. Iron cannot be deposited from acid or even from neutral salt solution upon a platinum electrode, owing to its being so much more electropositive than hydrogen—0·34 volt, while the supertension of hydrogen is only 0·08 volt. Kollock and Smith (Proc. Amer. Phil. Soc. 44, 149, and 45, 261) have, however, succeeded in depositing iron from weak acid solutions by means of a mercury cathode, the iron as it is deposited amalgamating with the mercury. The method described by these authors is as follows:—

Five c.c. contained 0·2075 gram of iron. Three drops (40 drops = 1 c.c.) of concentrated sulphuric acid were added to it, when it was electrolysed with a current of 3 to 4 amperes and 7 volts. The anode made from 500 to 900 revolutions per minute. The iron was completely deposited in 7 minutes. The water was then siphoned off and the amalgam washed, as in all previous cases, with alcohol and water.

From its oxalate, tartrate, or citrate solutions, iron may be satisfactorily deposited, but in all cases traces of carbon are deposited along with the metal. By employing low-current densities, the amount of carbon deposited from oxalate and tartrate solutions is negligible, but from citrates the results are almost always considerably too high.

Ammonium oxalate.—This method was first suggested by Classen (Zeit. f. Elektrochem. i. 288), and is the one most generally employed. The iron solution, which should be free from chlorides and nitrates, must be poured into the solution of ammonium oxalate, if it is in a ferrous condition, otherwise a precipitate of ferrous oxalate may be formed which is difficult to dissolve. With ferric salts the order of adding does not matter.

Dissolve 5–7 grams of ammonium oxalate or acid ammonium oxalate in a small quantity of hot water, and to this add the iron salt also dissolved in a little water. The solution is then made up to the required bulk, and electrolysed with a C.D. of from 0·6 to 1·2 amperes. Time of deposit from cold solutions and with stationary electrodes, 4 to 5 hours; from solutions at 50°–60°, in 2 to 2·5 hours. As the electrolysis proceeds, it will sometimes be noticed that a small quantity of ferric hydroxide separates. This is due to the solution becoming slightly alkaline, owing to the decomposition of the oxalate by the current. Should the hydroxide be thrown out, small quantities of oxalic acid must be added.

With rotating electrodes the time of electrolysis is from 14 to 20 minutes.

With tartrate solutions the results are equally good. The method of procedure is similar to that described for oxalates, ammonium tartrate being used in place of the oxalate. The advantage of the tartrate method is that ferric hydroxide is never deposited; consequently, it is not necessary to add tartaric acid, and thus less attention is required.

Nickel.

Nickel and cobalt are difficult to determine by general analytical methods, but they can both be readily and accurately analysed by electrochemical means.

Although many methods have been suggested for the deposition of nickel, few of these are of practical importance. Most of them depend upon the use of the salts of organic acids. In such cases there is a tendency for traces of carbon to be deposited with the metal. The most useful and generally applicable method for depositing nickel is that of Fresenius and Bergmann (Zeit. f. Anal. Chem. 33, 9), in which the double salts of potassium and nickel or ammonium sulphate together with excess of ammonia are used.

The nickel salt is dissolved in water and mixed with an aqueous solution of from 4 to 5 grams of ammonium sulphate, and from 30 to 35 c.c. of strong ammonia. If more than 1 gram of the nickel salt is employed, larger quantities of ammonia should be added. As, however, large quantities of strong ammonia are apt to contaminate the atmosphere, it is better to work with smaller quantities of nickel. Nitrates should be absent, as their presence considerably retards the rate of deposition. With a current of 1–1·5 ampere per sq. dcm., the metal will be deposited in from 2 to 2·5 hours; at a temperature of 50°–60°, the time will be from 1·5 to 2 hours; with rotating electrodes, in from 15 to 30 minutes, depending upon the conditions and the form of apparatus. The metal is usually deposited as a brilliant plating on the electrode. The deposit is at times somewhat difficult to remove, and, owing to its appearance being rather like polished platinum, it is not always easy to ascertain whether it has been completely dissolved off. The best method of removing the metal is to warm the electrode in moderately strong sulphuric or nitric acid.

Other methods employed are the double oxalate method of Classen and Von Reiss (Ber. 14, 1622); ammonia and ammonium borate, by F. M. Perkin and W. C. Prebble (Trans. Faraday Soc. 1904, 103). Kollock and Smith (Proc. Amer. Phil. Soc. 45, 262) have used a mercury cathode successfully, the time of deposition being from 7 to 20 minutes. An amalgam of 40 grams mercury and 1 gram nickel has the consistency of soft dough, and is bright in appearance.

Cobalt.

Cobalt may be deposited from an ammonium sulphate, ammonium hydroxide solution similar to that used in the case of nickel. But as a rule the results obtained are too low, owing to the tendency for peroxide to be formed on the anode.

F. M. Perkin and W. C. Prebble (Trans. Faraday Soc. 1905, 103) use a solution containing dihydrogen sodium phosphate and phosphoric acid. The solution is made up by adding 2 c.c. of a 5 p.c. solution of phosphoric acid to the solution of the cobalt salt in 70–80 c.c. water and then 20–25 c.c. of a 10 p.c. solution of dihydrogen sodium phosphate. The electrolysis should be commenced cold with a current density of 0·2–0·3 ampere per sq. dcm.; after about 50 minutes the solution is warmed to 50° or 60°, and the current increased to 1·2 ampere. If, as often happens, some peroxide is deposited on the anode, it can be removed by the addition of 0·2–0·3 gram of hydroxylamine sulphate. After the solution has become colourless, about 1 c.c. of *N*/1-ammonia should be added. The time necessary with stationary electrodes is from 4 to 5 hours. The deposit is extremely bright, resembling polished platinum.

The only methods which have been tried with rotating electrodes are solutions containing ammonium acetate and solutions with sodium formate. With currents of 8 amperes, L. Kollock and E. F. Smith (J. Amer. Chem. Soc. 29, 797) succeeded in depositing 0·3 gram of cobalt in from 30 to 40 minutes.

Group IV.—Lead.

Owing to its ready oxidisability, it is difficult to deposit lead satisfactorily on the cathode. Except in cases of separation from other metals, indeed, it is of no advantage to deposit it at the cathode. Sand has, however, found it a convenient method to separate lead from cadmium and bismuth (Chem. Soc. Proc. 22, 43).

From dilute solutions of nitric acid lead is partially deposited as metal on the cathode, and partially as peroxide at the anode. It is therefore necessary to have about 20 c.c. of nitric acid (1 : 4) to every 100 c.c. of electrolyte. Arsenic, manganese, selenium, and bismuth should be absent, and according to Vortmann (Annalen, 351, 283), antimony, silver, mercury, zinc, iron, cobalt, aluminium, and the alkali metals also cause the results to be high. Chromic acid should also be absent, and phosphoric acid retards the deposition. The lead salt is dissolved in water, and from 25 to 30 c.c. of strong nitric acid added. The electrodes used, whether stationary or rotating, should be roughened by the sand blast. With stationary electrodes and a current of from 1·3 to 1·8 ampere at a temperature of 60°–70°, the deposition will be complete in from 1 to 1·5 hours. At the commencement of the electrolysis a yellowish deposit is obtained which becomes orange or red, and finally dark-brown or black.

With rotating electrodes, the time of deposition is from 10 to 25 minutes.

At the end of the electrolysis the electrode is well washed by placing it in hot water, then washed with alcohol and ether, and heated to 220° in the air-bath for an hour. It must be cooled in a desiccator; the weight of the deposit is multiplied by the factor 0·866.

The best method to remove the deposit from the electrode is to warm it with equal volumes of nitric acid and water to which 4–5 grams of glucose has been added.

Lead does not give satisfactory results with a mercury cathode.

Manganese.

Manganese can only be deposited as oxide at the anode. It is, however, much more difficult to deal with than lead, as the deposit is apt not to adhere well. It is absolutely essential to employ roughened electrodes. Mineral acids cannot be employed. The most satisfactory electrolyte is one containing ammonium acetate, and Engels (Zeit. Elektrochem. ii. 413) has shown that the addition of small quantities of chrome alum helps to cause the deposit to adhere more firmly, probably owing to a depolarising effect. The manganese salt is dissolved in 40–50 c.c. of water, 8–10 grams of ammonium acetate added, and the solution electrolysed at a temperature of 75°–80°, with a current of 0·6 to 1 ampere. The deposition will be complete in from 1·5 to 2 hours.

With rotating electrodes the time will be about 30 minutes. In this case it is as well to add 10 c.c. alcohol to prevent frothing (J. Koster, Zeit. f. Elektrochem. 10, 553).

The best way to ascertain if all the manganese has been deposited, is to employ the permanganate test. Withdraw 1 or 2 c.c. of the solution, add 3 c.c. conc. nitric acid, and about 1 gram of red lead. Boil for a minute or two and dilute. A pink colouration indicates that the whole of the manganese has not been removed.

When all the manganese has been deposited, the electrode is washed as usual, and then strongly heated in order to convert the hydrated manganese peroxide into trimanganese tetroxide Mn_3O_4. It is necessary to heat until the black deposit becomes a dull orange red. The weight of the deposit multiplied by 0·72 gives the weight of metallic manganese.

Chromium.

This metal cannot be deposited on the anode as peroxide; neither under ordinary conditions is it possible to obtain a cathode deposit. Kollock and Smith (Trans. Amer Chem. Soc. 27, 1905, 1255) have succeeded in depositing it in the form of an amalgam by employing a mercury cathode. The electrolyte consisted of dilute sulphuric acid. With a current of 1–3 amperes 0·12 gram was deposited in 20 minutes. This method is useful for separating chromium from aluminium, which latter metal is not deposited as an amalgam.

Classen (Ber. xxvii. 2060) oxidises chromic salts to chromates in an ammonium oxalate solution. This method is useful for separating chromium from iron, nickel and cobalt, and in the analysis of chromium steels and of chrome iron ore. The chromic acid produced can be estimated iodometrically or by precipitation as lead or barium chromate.

The solution containing the iron and chromium salt has excess of ammonium oxalate added to it, and if free mineral acid is present is neutralised with ammonia. It is then electrolysed, when the iron is deposited at the cathode and the chromium oxidised to chromate. The iron, when deposited in presence of chromium salts, is usually very brilliant like polished platinum. When all the iron is deposited, the solution is removed, the iron deposit dried and weighed, and the chromium determined. If the whole of the chromic salt has not been oxidised during the deposition of the iron, the solution is again electrolysed. By using a rotating anode it is possible to completely oxidise 0·15 gram of a chromic salt, such as $Cr_2(SO_4)_3$ or Cr_2Cl_6 in 90 minutes, the volume of the solution being 120 c.c. and the amount of ammonium oxalate 15 grams. The electrolyte should be heated to 80°, and a current of from 5 to 5·5 amperes employed (Elektronalytische Schnellmethoden, p. 180).

Uranium.

Uranium is deposited at the cathode as oxide from solutions containing acetic acid or ammonium carbonate. The deposit consists of $U_3O_4,3H_2O$. At the end of the operation this is heated strongly to convert it into U_3O_8.

Wherry and Smith (Trans. Amer. Chem. Soc. 29, 806), by using a rotating cathode and an electrolyte containing in 125 c.c. 2·5–5·5 gram sodium acetate, deposited 0·25 gram of uranium in from 15 to 30 minutes, the current employed being 3–5 amperes, the electrolyte being either cold or heated to 50°.

Molybdenum.

From solutions containing dilute sulphuric acid, molybdenum can be deposited as peroxide at the cathode, but the deposit cannot be weighed as such. Wherry and Smith (Trans. Amer. Chem. Soc. 29, 806), therefore, oxidise it by means of nitric acid and weigh as MoO_3.

Thallium.

Many methods have been suggested for the electrolytic analysis of thallium, but only one can be considered satisfactory, and that is, by using a mercury cathode. By depositing the metal into pure mercury, it is found that portions are lost on weighing; but if the mercury contains a small quantity of zinc, this is not the case. Smith recommends to deposit the zinc and mercury simultaneously. In order to do this a definite volume of zinc sulphate solution of known strength is added to the solution before electrolysis. The electrolyte consists of dilute sulphuric acid. The amount of zinc necessary to protect the thallium is very small, and need not be more than 0·001 gram. With a current of 5 amperes it is possible to deposit as much as 0·2 gram in about 10 minutes. It is, however, advisable to electrolyse for a longer time.

GROUP V.—**Sodium.**

E. F. Smith (Trans. Amer. Chem. Soc. 25, 1903, 890) was the first to show that the metals of the alkali group could be analysed electrolytically. The method is based on the removal of the halogen anion of the metal by causing it to unite with silver, the alkali metal remaining in the solution as hydroxide is determined by titration; by ascertaining the increase in weight of the silver anode, the halogen can be also determined.

An ingenious apparatus has been devised by Hildebrand (Trans. Amer. Chem. Soc. 29, 1907, 447) for the analysis of the cations of the alkali metals, and of barium and strontium; and at the same time of various anions. In principle the cell resembles that of the Castner-Kellner process employed in the manufacture of sodium hydroxide.

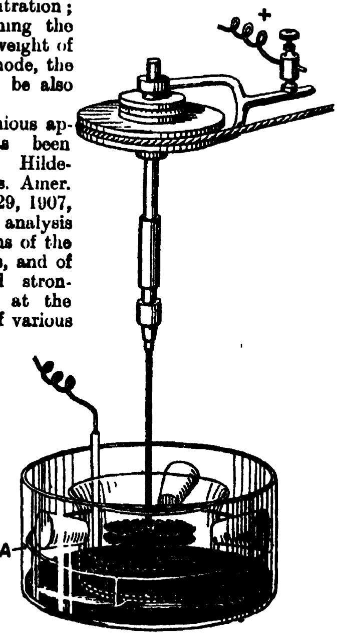

FIG. 68.

The outer cell (Fig. 68) consists of a crystallising dish, 11 cm. in diameter and about 5 cm. deep; a beaker 6 cm. in diameter and 4·5 cm. high, with the bottom cut off, is placed inside and rests on a triangle of glass rod placed on the bottom of the crystallising dish. The beaker is kept in position in the middle of the dish by means of three rubber stoppers fitted radially between it and the outer dish. Two compartments are thus formed, which are sealed off by means of mercury. In the outer compartment there is a ring consisting of six turns of stout nickel wire, provided with three legs dipping into the mercury and serving to maintain the lowest winding of the nickel about 1 cm. above the surface of the mercury, when sufficient is placed in the dish to seal off the two compartments. By means of a platinum wire passing through a glass tube the mercury is made the cathode. The anode consists of two discs of platinum gauze heavily plated with silver.

Pure mercury must be used, and the cell must be kept scrupulously clean. Before starting the cell, mercury is poured in so that its level is about 3 mm. above the lower edge of the inside beaker. The solution to be electrolysed is then put into the inner compartment. In the outer one enough distilled water to cover the nickel wire is placed, and to this 1 c.c. of a saturated solution of common salt. By this arrangement the amalgam formed in the inner compartment is immediately decomposed in the outer one. The sodium chloride serves merely to make the liquid a conductor, so that the action may proceed more rapidly at the commencement. Unless this is done, the amalgam is not entirely decomposed in the outer compartment, because pure water does not attack it rapidly enough to prevent the partial decomposition in the inside cell. After the electrolysis is complete, the entire contents of the cell are poured into a beaker, the cell rinsed, and the alkali titrated. After titration the mercury is washed, the water decanted, and the metal poured into a large separating funnel from which it can be drawn off clean and dry.

The annexed table gives the results which were obtained by Hildebrand.

The weighed gauze anode is clamped to the shaft. The latter is lowered into the cell till the lower gauze is about 5 mm. from the surface of the mercury. The most convenient speed for the motor is about 300 revolutions per minute. The anode does not require washing, as the water after electrolysis is pure. It may be at once dried in the steam oven.

Time: Mins.	Volts	Amperes	Sodium in grams		Chlorine in grams	
			Present	Found	Present	Found
30	4·0–2·5	0·50–0·02	0·0461	0·0459	0·0708	0·0704
45	3·5–2·5	0·34–0·01	0·0461	—	0·0708	0·0706
40	3·5–3·0	0·50–0·01	0·0461	—	0·0708	0·0704
45	4·0–3·5	0·65–0·01	0·0461	—	0·0708	0·0716
30	4·0–2·5	0·76–0·02	0·0461	—	0·0708	0·0713
55	3·0	0·26–0·02	0·0461	—	0·0708	0·0709

By means of this apparatus the halogen salts of the alkali metals can be analysed. Also the halogen salts of barium and strontium. In fact, any anion with any metal which will unite with silver to form an insoluble salt can be analysed, provided, of course, that the metallic salt is soluble, and that the metal will form an amalgam with the mercury. In the case of the alkali metals and of strontium and barium, the hydroxides of which are soluble in water, the cations are analysed by titration. With other metals forming amalgams which are not readily decomposed this method of analysis is not to be recommended, because, in the first place, the considerable quantity of mercury necessary is inconvenient to weigh, and, secondly, it requires to be kept very pure, consequently the continual purification of such large quantities of mercury would be tiresome.

Analysis of anions when united with heavy metals. The SO_4 anion in such salts as copper sulphate may be analysed by electrolysing a known weight of copper sulphate dissolved in water with a mercury cathode and a platinum anode as already described. When all the copper has been deposited, the solution is siphoned off, the amalgam washed with water, and the wash water added to the original solution. The whole of the anode solution is then titrated with *N*-sodium hydroxide. The copper can, of course, be estimated by weighing the amalgam.

Separation of sodium from calcium and magnesium. When calcium and magnesium salts are electrolysed in Hildebrand's apparatus, it is found that the hydroxides of these metals are precipitated in the inner cell. It has therefore been found possible to separate sodium from these metals by means of this apparatus. The outer cell contains all the sodium as hydroxide, and the sodium can be determined by titration. The analytical results obtained are practically theoretical.

In a similar manner barium can be separated from calcium and magnesium.

Arsenic.

It is not possible to deposit arsenic quantitatively in the metalloid condition, neither can it be precipitated at the anode as oxide. Arsenic is readily converted by nascent hydrogen into arseniuretted hydrogen, its gaseous hydride, AsH_3; hence, electrolytic methods of analysis are not usually employed for analysing arsenic compounds. It is, however, possible to estimate very small quantities of arsenic contained in food, &c., by electrolysis. The process consists in evolving electrolytic hydrogen in presence of the arsenic, whereby the arsenic is converted into arseniuretted hydrogen. The gaseous hydride is then passed through a glass tube, heated by a small Bunsen burner, as in the Marsh apparatus, whereby the arsenic is deposited upon the tube in the form of a mirror. In order to estimate the amount of the arsenic, the mirror is then compared with mirrors prepared from known quantities of arsenic.

In 1812 Fischer (Gilbert's Ann. 42, 92) suggested the employment of the electric current to detect the presence of very small quantities of arsenic. It was again suggested by Bloxam (Quart. Journ. Chem. Soc. 1861, 13, 12 and 338) in 1861, but the apparatus had several disadvantages, and never came into practical use. Since then various modifications have been suggested by different authors, and, in 1903, Thorpe (Journ. Chem. Soc. 1903) describes a new form of apparatus which has been successfully employed for the analysis of traces of arsenic in food, beer, and other substances. It consists of a platinum cathode hung in a glass cylindrical vessel, which is open at the end, and fits into a Pukal porous cell. The porous cell is surrounded by the anode, and stands in an outer vessel. The upper portion of the cylinder is open, and has a ground neck for the insertion of the drying tube filled with anhydrous calcium chloride, and also carries the funnel, which is fitted with a tap, through which the solution to be tested is run in. A capillary tube is connected to the end of the calcium chloride tube. The middle of this tube is heated by means of the small Bunsen burner, and is surrounded where the flame heats it with a piece of platinum or iron-wire gauze, to prevent the tube being fused. The whole apparatus is placed in a vessel containing cold water, to prevent undue heating during electrolysis.

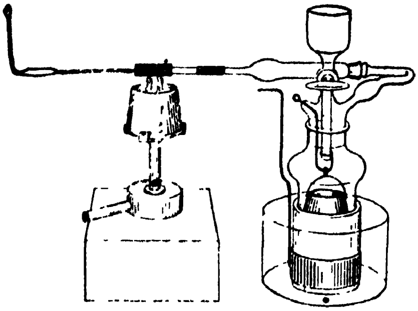

FIG. 69.

Method of working. The apparatus is carefully washed with distilled water. The outer cell E is filled with dilute sulphuric acid (30 p.c.), then the inner cell. (The porous cell should be soaked in dilute sulphuric acid for about half an hour before being used.) As soon as all the connections are made, the Bunsen burner is placed in position, but not lighted, and the current is passed. A current of about 5 amperes should be used; the escaping hydrogen thereby produces a flame of about 3 mm. in size. As soon as all the air has been driven out, which usually occupies about 10 minutes, the issuing hydrogen is ignited and the Bunsen burner lighted. If after about 15 minutes no brown ring makes its appearance, the reagents may be considered free from arsenic. At the end of 30 minutes the capillary tube is sealed off, and the open end also fused together. The mirror is then compared with the standard mirrors as above described.

Preparation of standard mirrors. Pure resublimed arsenious oxide is ground in an agate mortar and dried at 100°. Then 0·1 gram is carefully weighed and washed into a 1-litre flask, the flask being filled to the mark with distilled water. Each 1 c.c. of this solution contains 0·0001 arsenious oxide; 100 c.c. of this solution are diluted to 1 litre. This second solution contains 0·00001 gram of arsenious acid in each 1 c.c., or 0·01 mg. Standard tubes containing 0·004, 0·006, 0·008, 0·010, &c., mg. can then be prepared.

When foodstuffs are being examined for arsenic, Thorpe considers it advisable to take a portion of the foodstuff—arsenic free—and mix it with the known quantity of arsenic before proceeding to electrolyse it. The standard mirrors are thus prepared under the same conditions as those under which the suspected foodstuff is tested.

S. R. Trotman (J. Soc. Chem. Ind. 23, 177) recommends the adoption of a parchment membrane in place of the porous Pukal cell, as he considers this decreases the resistance, and thus makes the apparatus more sensitive. It is, however, not so convenient to use.

Sand and J. E. Hackford (Chem. Soc. Trans. 85, 1018) use the parchment membrane, but they also employ a heavy lead cathode and a lead anode. Their apparatus is thereby much cheaper than that used by Thorpe, and is said to be equally accurate.

Metallic Separations.

A large number of separations of metals by electrolytic methods have been worked out, but in many cases a purely chemical procedure or a combination of electrolytic and chemical methods is easier. There are, however, cases in which satisfactory and rapid electrolytic separations can be carried out. A few of the more important are given below.

Copper from nickel. By employing a rotating anode with an auxiliary electrode, and maintaining the cathode potential at 0·7–0·75 volt, copper can be deposited from solutions containing sulphuric acid. The solution is then made alkaline with ammonia, when the nickel can be deposited. If the cathode potential is not regulated, small quantities of the nickel are deposited along with the copper.

Exner (J. Amer. Chem. Soc. 25, 896) finds that by employing a solution containing nitric acid and ammonium nitrate (volume of solution 125 c.c.; HNO_3, 0.25 c.c.; 3 gram NH_4NO_3) and using a rotating anode, it is possible to deposit as much as 0·25 gram copper in 15–20 minutes; the nickel, which may be of equal weight, remains in solution, and can be afterwards deposited.

Copper from lead. Since lead is deposited from solutions containing nitric acid as peroxide on the anode, whilst copper is deposited as metal at the cathode, it might be supposed that there would be no difficulty in depositing both metals concurrently. It must, however, be remembered that unless there is a considerable concentration of nitric acid, a portion of the lead will be deposited as metal at the anode. On the other hand, in presence of copper, the tendency to reduction of the lead and its appearance at the cathode is decreased; that is to say, in presence of copper a lower concentration of nitric acid is required. It has, therefore, been found possible to separate the two metals. The volume of solution employed was 85 c.c., and contained 1 c.c. HNO_3 (1 : 4). With a rotating anode and a current of 2 amperes, the whole of the lead was deposited in 5 minutes. The current was then increased to 10 amperes, when the last traces of copper were removed. The washing and drying of the anode deposit requires care, since the peroxide when deposited from weak acid solutions does not adhere so well as from stronger solutions (Sand).

Copper and arsenic. McCay finds the following conditions give a satisfactory deposit of copper in presence of arsenic. The arsenic remaining in the solution cannot, however, be estimated electrolytically, unless present in very small quantities.

To the solution 20 c.c. ammonium hydroxide (sp. gr. 0·91) and 2·5 gram ammonium nitrate are added, the volume of solution being 125 c.c. The solution is then electrolysed at a temperature of 50°–60°, with 0·5 ampere per 100 sq. decm. of electrode surface. As much as 0·22 gram of copper will be deposited in 3 hours. With a rotating anode about 15 minutes are required. In this solution the arsenic should be present as arsenate. Copper and arsenic may also be separated electrolytically from solutions containing potassium cyanide. If acid, the solution is neutralised, and then sufficient potassium cyanide added to just redissolve the precipitate first produced. With a current 0·25–0·27 ampere, the whole of the copper is deposited in about three hours.

Antimony from tin. Tin can be quantitatively deposited from solutions containing excess of ammonium sulphide. It cannot, however, be deposited from solutions containing excess of sodium sulphide. Antimony, on the other hand, can be deposited from solutions containing excess of sodium sulphide. It is therefore possible to separate antimony from tin by adding excess of sodium sulphide to a solution containing the two metals. If the solution is acid, it is first made slightly alkaline with sodium hydroxide before the sodium sulphide is added. It is, however, better to first precipitate the two metals as sulphides, and then dissolve them in a concentrated solution of sodium sulphide. The tin should be in the stannic state. The solution is electrolysed at a temperature of 50°–60° with a current of from 0·2 to 0·9 ampere per sq. dcm. of electrode surface. In from 2 to 4 hours the whole of the antimony is deposited. It is, however, almost always contaminated with small quantities of tin.

In order to deposit the tin, the sodium sulphide must be decomposed. This is done by adding about 25 grams of ammonium sulphate, and boiling until no more hydrogen sulphide is evolved. The tin is now deposited by electrolysing with a current density of from 0·3 to 0·5 amperes.

The best method of separating antimony and tin is that of Sand, by means of graded potential and a rapidly rotating anode (Chem. Soc. Trans. xciii. (2) 1908, 1572). From solutions containing strong sulphuric acid (1 : 1) antimony is deposited at an auxiliary potential of 0·65 volt when the temperature is kept above 100°, and a small quantity of hydrazine sulphate is added. Tin, on the other hand, under similar conditions, is not deposited below 0·8 volt. The method of procedure when dealing with alloys of antimony and tin is as follows:—

The alloy is dissolved in a mixture of 40 c.c. conc. sulphuric acid, 5 c.c. water, and 2 c.c. nitric acid (1:42); on heating to 180°–200° solution rapidly takes place. It is necessary to remove the nitric acid because it causes the formation of antimonic acid, which is only slowly reduced to the metallic state electrolytically. In order to decompose the nitric acid (nitrosulphonic acid), a current of 5 amperes is passed, and the liquid heated to 250°–270°. After the current has been passed for 5 to 10 minutes at the high temperature, it is stopped. The solution is cooled to 100°, and 0·5 gram of hydrazine sulphate added. (N.B.—The amount of hydrazine sulphate added should be equal to the weight of metal taken.)

The temperature is then raised to 300°. It is again cooled to 100°, when from 30 to 40 c.c. of water and another 0·5 gram of hydrazine sulphate are added.

The anode [1] is then rotated to ensure mixing of the solution, the temperature of which rises to about 120°. The analysis is now begun, the auxiliary potential having first been adjusted to 0·53–0·65 volt. The current will vary between 3–4 amperes, and, at the end of the electrolysis, will drop to 0·4–0·5 volt. Time of electrolysis from 20 to 30 minutes.

The tin is determined as follows: The solution after the antimony has been deposited is mixed with about 4 grams of oxalic acid, and is neutralised with strong ammonia. In order to prevent loss by spurting the electrodes are placed in position, the rotating stem being passed through a hole drilled in a clock glass. The ammonia is poured on the clock glass and runs down the stem of the electrode into the solution, the anode or inner electrode being at the same time rotated. Considerable ebullition ensues, but none of the liquid is spurted out. Exact neutralisation is ascertained by the use of methyl orange as indicator. Litmus cannot be employed, since its colloidal nature hinders the deposition of the tin. After neutralisation, 0·5–0·75 c.c. of sulphuric acid are added for every gram of oxalic acid previously added.

The solution is electrolysed at a temperature of 70° with a current of 3–4 amperes. Time of deposit, 60–80 minutes.

Silver and copper. (Smith and Frankel, Amer. Chem. J. 12, 104.) To a neutral solution of the silver and copper salt, add 2–3 grams of pure potassium cyanide. Electrolyse at a temperature of 65° with a current of 0·03–0·05 ampere, and maintain the potential at 1·1–1·6 volt. The silver will be completely deposited in from 4 to 5 hours. After the silver has been weighed, the electrode is replaced, the current and voltage increased, when the copper will be deposited.

Silver may also be separated from copper in ammoniacal solutions by using an auxiliary electrode, and keeping the potential below 0·5 volt.

Iron from other metals. Iron can readily be separated from aluminium, vanadium, glucinum, uranium, thorium, and many other metals with which it may be alloyed by dissolving in sulphuric acid, filtering from any residue, nearly neutralising with ammonia, and electrolysing with a mercury cathode.

Cadmium from zinc. These metals can be separated by means of graded potential. The solution is made up by adding first 2 c.c. of conc. sulphuric acid, then 3·33 grams of sodium hydroxide, and 1 c.c. of glacial acetic acid. The auxiliary electrode is kept at a potential of 1·15–1·20 volts, and the solution electrolysed at a temperature of 30°. The whole of the cadmium will be deposited in 11–14 minutes. The potential is afterwards raised, when the zinc can be deposited in about 30 minutes.

---

[1] After the metal has dissolved, the subsequent operations are carried out with the electrodes in position.

ANAMIRTA COCCULUS or **A. PANICULATA** (Colebr.). The former is the superseded name, and the latter the true name, of the Indian Menispermaceous liane, whose dried fruits (Grains of Paradise) are supplied under the name of *Cocculus indicus* (*v.* COCCULUS INDICUS).

ANAMIRTIN *v.* PICROTOXIN.

ANANAS, OIL or **ESSENCE OF.** A solution of ethyl butyrate in 8 to 10 times its weight of alcohol. It possesses the odour of the pineapple (*Ananas sativus* (Schult.)), and is employed in confectionery and perfumery; also to imitate the flavour of rum (Hofmann, Annalen, 81, 87).

ANANDONIS GREEN. *Hydrated chromium sesquioxide* (*v.* CHROMIUM).

ANASPALIN. Trade name for a form of wool-fat.

ANATASE or *Octahedrite.* One of the trimorphous forms of titanium dioxide (TiO_2) met with as crystallised minerals; the others being rutile and brookite. It is found as small, isolated crystals of a steel-blue or honey-yellow colour, in schistose rocks, particularly in the Alps; and as microscopic crystals is of common occurrence in sedimentary rocks. L. J. S.

ANCHIETA BARK. The root bark of *Anchietea salutaris* (A. St. Hil.), one of the Violaceæ, a bushy shrub growing at Rio de Janeiro. It contains *anchietine*, a substance crystallising in straw-coloured needles, having a nauseous taste. Used for syphilis and quinsy (Peckolt, Arch. Pharm. [2] 97, 271).

ANCHUSIN (*Alkannin*) *v.* ALKANNET.

ANCYLITE. A hydrated basic carbonate of cerium, lanthanum, and didymium, and strontium $4Ce(OH)CO_3 \cdot 3SrCO_3 \cdot 3H_2O$, found as small, yellow, orthorhombic pyramids with curved faces in syenite-pegmatite at Narsarsuk in the Julianehaab district, south Greenland; sp.gr. 3·95.

An allied mineral, with the formula

$$4(Ce,La,Di)_2(CO_3)_3 \cdot 5SrCO_3 \cdot (Ce,La,Di)_2O_2,$$

has been found as orthorhombic grains forming, with celestite, monazite, felspar, &c., a constituent of crystalline limestone at Ambatoarinina in Madagascar. This has been named ambatoarinite (A. Lacroix, 1916). L. J. S.

ANDA-ASSU, OIL OF. An oil obtained from the seeds of *Joannesia Princeps* (Vell.), belonging to the Euphorbiaceæ, growing in Brazil. It is clear, slightly yellowish, odourless, with a taste at first nauseating and then sweet. It solidifies at 8°, its sp.gr. at 18° is 0·9176 (Pharm. J. [3] 12, 380).

ANDALUSITE. One of the three modifications of crystallised aluminium silicate Al_2SiO_5, and belonging to the orthorhombic system; the other modifications being the minerals kyanite and fibrolite. Andalusite occurs in crystalline schists and metamorphic rocks, the variety chiastolite being specially abundant in the baked clay-slates surrounding intrusive igneous masses. It is also found as small crystals and grains in some granites, due probably to fragments of the surrounding slates having been incorporated in the igneous magma. Grains of andalusite are found in the sands and sedimentary rocks derived from these primary rocks. The pleochroism, from olive-green to rose-red, is a characteristic feature of the mineral under the microscope. D 3·18, H 7½. Large, rough opaque crystals are well known from Lisens-Alp in the Tyrol. Clear transparent pebbles of a rich brown colour are found in the Rio Jequitinhonha in Minas Geraes, Brazil; this material when cut as a gem-stone displays the strong pleochroism. The variety known as chiastolite shows in cross-sections of the prismatic crystals a dark cross of carbonaceous material enclosed in the lighter coloured andalusite; such material is cut as a gem-stone or charm. Large crystals of chiastolite have been found in considerable numbers at Bimbowrie, near Olary in South Australia. L. J. S.

ANDAQUIES WAX *v.* WAXES.

ANDESINE. A soda-lime felspar belonging to the group of plagioclase-felspars (*v.* FELSPAR). L. J. S.

ANDESITE. A group of volcanic rocks of intermediate composition, containing on an average 60 p.c. of silica, and corresponding to the plutonic diorites. They are usually dark-coloured, compact rocks, sometimes with a porphyritic structure or a vesicular texture; and are composed essentially of plagioclase-felspar with a ferromagnesian mineral, and sometimes a glassy base. According to the ferromagnesium mineral present, the varieties hornblende-andesite, biotite-andesite, and pyroxene-andesite are distinguished. When quartz is present the rock grades into the dacites. Sp.gr. 2·6–2·8. They are of wide distribution. The Andes of South America and the Cordilleras of Central and North America are built up largely of andesites; and here, as well as in Hungary, ore-deposits, particularly those of gold and silver, frequently occur in connection with them. In the British Isles they are abundant in the Midland Valley of Scotland, the Cheviot Hills, the Lake District, and in North Wales, and in these districts are quarried for road-stones. On the Continent they are also used for building stone and mill-stones. L. J. S.

ANDORITE. Sulphantimonite of silver and lead $AgPbSb_3S_6$, crystallising in the orthorhombic system. The mineral was independently described in 1892 from Felsőbanya in Hungary, and Oruro in Bolivia, under the names andorite, sundtite, and webnerite. It is dark steel-grey with metallic lustre, and a shining black streak; no cleavage; sp.gr. 5·35; H 3½. Analyses show 10–11·7 p.c. of silver (according to the formula Ag = 12·42 p.c.), there being small amounts of copper also present. At Oruro, in the San José and Itos Atocha mines, it occurs rather plentifully as well-formed crystals and as a massive silver ore (Prior and Spencer, Mineralog. Mag. 1897, xi, 286; Spencer, *ibid.* 1907, xiv, 316). L. J. S.

ANDROGRAPHIS PANICULATA (Nees) or

Karyat. An Indian plant; is used as a tonic, and is similar to quassia in its action.

ANDROPOGON OILS *v.* OILS, ESSENTIAL.

ANDROSIN *v.* GLUCOSIDES.

ANESIN (*Aneson*). An aqueous solution of acetonechloroform, having marked anæsthetic and hypnotic properties (Apoth. Zeit. 1897, 12, 608) (*v.* ACETONECHLOROFORM).

ANETHOL *v.* OILS, ESSENTIAL.

ANGELICA OIL *v.* OILS, ESSENTIAL.

ANGELINE $C_{10}H_{13}O_3N$ (surinamine, geoffroyine, andirine, rhatanine) (Hiller-Bombien, Arch. Pharm. 1892, 230, 513; Goldschmidt, Monatsh. 1913, 33, 1379; 34, 659), m.p. above 233° (indefinite). Identical with *n*-methyl-*l*-tyrosine $[\alpha]_D^{21}+19{\cdot}75°$. Synthesised by Fischer and Lipschitz (Ber. 1915, 48, 360).

ANGICO RESIN. A Brazilian gum obtained from *Piptadenia rigida* (Benth.) [*Acacia Angico*]; soluble in water and proof spirit. Used in chest complaints (Symes, Pharm. J. [3] 13, 213). Angico wood is that of another Brazilian leguminous plant, *Enterolobium ellipticum* (Benth).

ANGIONEUROSIN. Syn. for nitroglycerin as used in pharmacology.

ANGLESITE. Native lead sulphate ($PbSO_4$), forming brilliant, colourless, orthorhombic crystals, isomorphous with barytes ($BaSO_4$) and celestite ($SrSO_4$). It occurs in the upper oxidised zones of veins of lead ore, having resulted by the alteration of galena (PbS). It is less common than cerussite ($PbCO_3$), with which it has sometimes been mined as an ore of lead. Good crystals have been found at many localities, perhaps most abundantly at Broken Hill, in New South Wales. The mineral takes its name from the Isle of Anglesey, where crystals were found by W. Withering, in 1783, in the Parys copper-mine. L. J. S.

ANGOSTURA BARK or **ANGUSTURA BARK** *v.* CUSPARIA BARK.

ANHALAMINE, ANHALINE, ANHALONIDINE, ANHALONINE, *v.* MEZCALINE.

ANHALONIUM · **(CACTUS) ALKALOIDS.** Seven different bases have been isolated from various species of cactus and have been investigated chiefly by Heffter. They are derivatives of β-phenylethylamine. *Anhaline* is β-*p*-hydroxyphenyldimethylethylamine,

$$HO\,C_6H_4\,CH_2{\cdot}CH_2{\cdot}N(CH_3)_2$$

identical with *hordenine*. *Mezcaline* is β-3·4·5-trihydroxyphenylethylamine. *Anhalamine*, *anhalonidine* and *pellotine* are methylated 3·4·5-trihydroxyphenylethylamines, but *anhalonine* and *lophophorine* each contain two of their three oxygen atoms in a different kind of linking (E. Späth, Monatsh. Chem. 1919, 40, 129).

ANHYDRITE. A mineral consisting of calcium sulphate $CaSO_4$, so named to distinguish it from the more common hydrated calcium sulphate, gypsum. From a pure aqueous solution calcium sulphate crystallises as gypsum, but when the solution is highly charged with salts (sodium, potassium, and calcium chlorides, and magnesium sulphate) it separates as anhydrite. Anhydrite crystallises in the orthorhombic system, but in its crystallographic characters it shows little analogy with the orthorhombic barium and strontium sulphates, barytes, and celestite, with which it would be expected to be isomorphous An important character is the cleavage in three directions parallel to the axial planes of symmetry; the mineral, therefore, breaks up into cubes like rock-salt. Well-formed crystals are not common; they have been found in the salt-deposits of Germany and Austria, and in dolomite-rock in the Simplon tunnel, in Switzerland. Usually, the mineral occurs as compact, granular masses of a white, grey, reddish, or bluish colour, and resembling marble in appearance. Sp.gr. 2·9–3·0; hardness 3–3½, being considerably higher than gypsum. It is of frequent occurrence as layers interbedded in deposits of gypsum and rock-salt. The 'anhydrite region' forming the base of the Prussian salt-deposits consists of alternating beds of anhydrite and rock-salt. Bands of anhydrite also occur throughout the salt-deposits, and are known to the miners as 'year-rings.' In contact with water anhydrite becomes altered into gypsum with an increase in volume of 60 p.c. On this account galleries in the salt-mines when driven through beds of anhydrite gradually become closed up. Extensive beds of the mineral occur in the gypsum deposits of Nova Scotia. In the red rocks of Permian and Triassic age of the North of England anhydrite is not uncommon. For example, it forms a bed 7 feet in thickness in the Cocklakes gypsum mine at Cumwhinton in Cumberland; and it is recorded from Durham, Westmoreland, Yorkshire, Staffordshire, Leicestershire, Nottinghamshire, Derbyshire, and Cheshire. For details of British occurrences, *see* Special Reports on the Mineral Resources of Great Britain, vol. iii, Gypsum and Anhydrite, Mem. Geol. Survey, London, 1915; 2nd edit., 1918.

Anhydrite has as yet been put to few practical uses. It has been employed in agriculture as a 'land plaster.' By exposure to the weather it becomes converted into gypsum, and can then be used for the manufacture of plasters. A bluish-violet, compact variety known as 'vulpinite,' from Vulpino in Lombardy, has been used as an ornamental stone. The suggestion to use gypsum as a source of sulphur would apply also to anhydrite. L. J. S.

ANIL. The name of the American species of the indigo plant, *Indigofera anil* (Linn.).

ANILINE.

History.—First observed by Unverdorben in 1826 among the products of the destructive distillation of indigo. Detected by Runge in coal tar in 1834, and by Fritzsche in 1840, among the products obtained by distilling indigo with alkali hydroxides. Prepared by Zinin in 1840, by the reduction of Mitscherlich's nitrobenzene with hydrogen sulphide. Unverdorben called his product *krystallin*; Runge, *kyanol*; Fritzsche, *anilin*; Zinin, *benzidam*.

In 1843 Hofmann showed that nitrobenzene could be reduced by a metal such as zinc in the presence of a dilute acid, and also that krystallin, kyanol, anilin, and benzidam were identical with each other. Shortly afterwards Bechamp stated that nitrobenzene could be reduced by ferrous acetate in the presence of water, but that the oxalate, sulphate, &c., had no effect.

In the year 1856 Perkin's discovery of mauve gave rise to a commercial demand for aniline, and the manufacture was commenced by Messrs. Simpson & Maule.

Preparation.—Benzene, then only obtained in small quantities and with much difficulty, as the treatment of tar scarcely existed, was introduced into glass balloons (known as 'bolt heads') of 1 gallon capacity, and the calculated quantity of nitric acid, mixed with about an equal volume of sulphuric acid, was gradually added, the mixture swung round and well agitated, and then allowed to stand. It was usual to have about twenty balloons in a row, and to add acid in turn until the reaction was complete.

The nitrobenzene was separated, washed, and reduced with iron borings and acetic acid, at first in a copper still, later in an iron cylinder. The aniline was freed from water, rectified, and was then ready for use. The selling price was about a guinea a pound.

Somewhat later cast-iron cylinders of considerable size were used for the reduction, acetic acid being still used and neutralised with soda or lime at the end of the reaction, and the aniline was in some factories distilled off over a naked fire, in others steam was blown into the mixture, and the aniline and water condensed and separated. Acetic acid continued to be used until about 1866. Since that time the apparatus has undergone little change, the treatment consisting in reduction mainly by the use of iron and water, hydrochloric acid being employed to start the reaction.

U, Air pressure egg.

The aniline machine shown in Fig. 1 is the type that gives the best results.[1] A careful comparison between this design and the horizontal machine has proved unmistakably that the vertical machine is more economical and better in every respect. This is particularly the case with regard to repairs and maintenance. The machine is of cast-iron, 1⅜ inches thick, with driving gear, agitating shaft, and blades, as shown in the sketch. An important feature is the renewable cast-iron lining plates at the sides and bottom, which protect the machine from the friction caused by the revolving mass of iron borings. It is 6 feet 6 inches deep, and 4 feet 6 inches in diameter, having a total capacity of 650 gallons. Steam is admitted through the vertical shaft, which is hollow, and passes through the extremities of the horizontal agitating blades. Twenty-one of these machines are required to produce 150 tons of aniline oil per month.[2] A charge of 1000 lbs. of nitrobenzene is run into the receiving pan above the machine.

---

[1] See Chem. Trade J. 1906, 38, 59. The writer is indebted to Messrs Davis Bros. for permission to reproduce the two figures.

[2] Larger machines, on the same principle, in which several tons of nitrobenzene can be reduced, are used by some manufacturers.

To start the reaction, 1 cwt. of clean cast-iron borings, 10 gallons of hydrochloric acid, and 6 gallons of water are run in through the funnel-shaped hopper, and simultaneously steam is turned on and the nitrobenzene run in a thin stream into the dish on the top of the machine. The wooden plug in the hopper is driven in tight, and the space between it and the hopper is kept full of iron borings. By dexterously manipulating the wood plug, the borings can be added without allowing any vapour to escape. This simple method of 'feeding' the iron borings has proved better than many of the mechanical feeding devices that have been tried. Distillation proceeds, and the distillate passes through the condenser and runs back into the dish, together with the nitrobenzene which is carried over. The iron borings and nitrobenzene are added only in sufficient quantities to maintain a constant level in the dish. If the reaction proceeds too violently, loss is caused by the formation of benzene. When the level of the liquid in the dish begins to lower, the supply of nitrobenzene and iron borings is increased. This process is continued until the whole charge of nitrobenzene is run in, which takes about 10 hours. The total weight of iron borings required is 9 cwt. A sample caught as it runs from the condenser should then be quite free from nitrobenzene, and the machine will contain only aniline oil, water, and oxide of iron. The supply of steam is then increased, so as to distil over the aniline oil and water,[1] and the distillate is diverted into the tank beneath the condenser. The steam used for this distillation is not pure steam, but is generated from the aniline water mentioned below, in a separate boiler. The aniline water is that which separates from the oil in the separating tubes, and contains about 2 p.c. of aniline oil in solution. The aniline and water in the tank below the condenser are pumped into the settling tubes, and allowed to settle for 48 hours. The distillation of the oil and water from the machine takes about 7 hours, and during the last hour pure steam is again used, so that when the operation is finished, the condensed water left in the machine will be free from aniline, and can be used for flushing out the oxide of iron into the gutter which runs to the settling tanks outside. The oxide, after the water is drained off, is dried and ground, and disposed of for the purification of coal gas from sulphur. Large quantities are also now being used in the manufacture of cheap black paints, and the consumption in this direction is increasing. The aniline oil which has settled to the bottom of the settling tubes is run off into the air-pressure

---

[1] In some works this distillation is not done, but the contents of the reduction apparatus are passed immediately through a filter press, the filtrate then running directly or being pumped into the settling tanks.

egg below, and blown into the crude aniline oil store tanks, ready for the final purification by distillation in the vacuum still. The upper layer of water left in the settling tubes, and which contains about 2 p.c. of aniline in solution, is, as already explained, used for feeding the aniline steam boiler. The average yield of crude aniline oil from each machine, with a charge of 1000 lbs. of nitrobenzene, is 765 lbs. The yield of pure aniline oil from nitrobenzene is given further on.

The final purification of the crude aniline oil is done in a vacuum still. The sketch (Fig. 2) shows one of these stills of recent design. The body of the still is wrought-iron, 15 feet long, and 7 feet 6 inches in diameter, having a total capacity of 4000 gallons, and capable of distilling 35,000 lbs. in one charge. The steam is supplied from a boiler having a working pressure of 100 lbs. per sq. inch, at which pressure the steam possesses a temperature of 170°. The internal steam tubes are wrought-iron, 2 inches in diameter. In place of the usual straight tubes which used to be expanded into both end plates, bent tubes are employed, which enter and return to the same end of the still. This prevents the 'tearing' of the tubes owing to expansion and contraction, and the 'breathing' of the end plates. The 'column' is of cast iron, 18 feet high and 9 inches in diameter. The condensing coils consist of three vertical flat copper coils, 2 inches in diameter, arranged side by side in a wrought-iron tank, the distillate entering all the three coils simultaneously from the still head by means of branch pipes. The total length of copper pipe in the condenser is 432 feet. The two receivers permit continuous working, so that when the first is full, as indicated by the gauge-glass tube, it is shut off, and the second brought into use. The contents of the first can then be drawn off while the second is being filled, and the vacuum is thus maintained throughout.

The still is charged with 35,000 lbs. of crude aniline oil from the store tank, and steam is turned on. The first fraction, about 7 p.c. of the distillate, consists of aniline oil and water, which is added to the crude oil and water in the separating tubes. The next fraction is 'light aniline,' and consists of aniline oil with a small quantity of benzene. If the reduction of the nitrobenzene has been carefully performed, this fraction is only about 4 p.c. of the distillate. It is collected and redistilled, giving pure aniline and benzene, the latter being returned to the nitrobenzene department, to be renitrified. The next fraction is pure aniline oil of marketable quality, clear and water-white. The tail end, called 'last runnings,' forms about 5 p.c. of the distillate, and, on redistillation, yields 80 p.c. of pure marketable aniline oil. The total yield of pure aniline oil obtained from nitrobenzene is 71¾ p.c. As the pure benzene yields 154½ p.c. of nitrobenzene, and the latter 71¾ p.c. of pure aniline oil, the total yield of pure aniline oil from pure benzene is 110·85 p.c. Compared with theory, there is little room for improvement.
